In women with macroadenomas, pituitary function tests are indicated to exclude other pituitary hormone deficiencies that may have important health implications. Although the required additional evaluation generally is not difficult to perform or interpret and only a few with abnormal results may require more complicated dynamic tests, the generalist reasonably may want to consult with or refer such patients to a reproductive or medical endocrinologist more familiar with the indicated tests. **The recommended endocrine evaluation of women with amenorrhea includes the measurement of serum hCG (to rule out pregnancy as a cause for amenorrhea), TSH (to assess for hypothyroidism or hyperthyroidism as a mechanism for amenorrhea), prolactin (to assess for hyperprolactinemia), and both FSH and estradiol (elevated FSH and low estradiol levels in the setting of amenorrhea are consistent with a picture of POI). Women with pituitary macroadenomas require additional evaluation, including a serum free T4 (reflecting adequacy of thyroid function), IGF-1 (reflecting GH axis), and morning cortisol level (reflecting adequacy of adrenal cortical function, to be drawn between 06:00 and 9:00 A.M.).**

When the serum TSH level is low or normal, a low serum free T4 demonstrates secondary hypothyroidism. **It is important to understand that measurement of serum TSH alone is not sufficient in patients who may have hypothalamic or pituitary disease.** A normal TSH level excludes hypothyroidism only when there is every reason to believe that the hypothalamo-pituitary-thyroid axis is intact and functioning normally. In women with a sellar mass and hypogonadotropic hypogonadism (low FSH and low

estradiol), indicating a dysfunctional HPO axis, normal function of the thyroid axis cannot be assumed. High levels of both TSH and free T4 suggest a rare functional thyrotroph adenoma (causing hyperthyroidism).<sup>284</sup>

Screening for GH deficiency or excess is best accomplished by measuring the serum IGF-1 level, because the basal serum GH concentration is not reliable in adults. IGF-1 is produced in the liver, in response to GH stimulation, and a concentration below the age-specific normal lower limit has greater than 95% specificity for diagnosis of GH deficiency.<sup>285</sup> Provocative tests of GH secretion such as the insulin-induced hypoglycemia test or the combined administration of arginine and GH-releasing hormone are more sensitive,<sup>285</sup> but seldom are necessary. An elevated serum IGF-1 concentration suggests a GH-secreting somatotroph adenoma (causing acromegaly).<sup>286</sup>

A very low morning cortisol level (<3–5 mg/dL) indicates adrenal insufficiency and implies ACTH deficiency; a value  $\geq$ 15–18 mg/dL demonstrates normal cortisol secretion. Intermediate values require additional evaluation to determine whether ACTH reserve is sufficient to meet demand during times of stress. ACTH reserve can be evaluated most easily by performing an ACTH stimulation test, based on the premise that chronic ACTH deficiency results in adrenal cortical atrophy and the inability to increase cortisol secretion normally in response to an acute ACTH stimulus. The test is performed by measuring the serum cortisol concentration before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 0.25 mg) intramuscularly or intravenously; a stimulated cortisol concentration  $\geq$ 15–18 mg/dL is a normal response. A grossly elevated basal serum cortisol concentration may suggest the possibility of hypercortisolism (Cushing syndrome), which, if resulting from an ACTH-secreting corticotroph adenoma, is then identified as Cushing disease. However, additional more specific evaluation is required for diagnosis of Cushing syndrome and to determine its cause,<sup>287</sup> as described below (see Corticotroph Adenomas).

Testing for prolactin deficiency is unnecessary because the only clinical consequence relates to nursing and there is no effective treatment for failed lactation due to prolactin deficiency. Whereas hyperprolactinemia obviously suggests a functional lactotroph adenoma, prolactin levels also are commonly elevated in women with nonfunctional pituitary adenomas and other sellar masses.

## Gonadotroph Adenomas

**The large majority of gonadotroph adenomas are nonfunctional, do not secrete significant amounts of FSH or LH, and do not cause clinical symptoms; 80–90% of all nonfunctional pituitary adenomas derive from gonadotrophs.** Moreover, even moderately elevated gonadotropin levels do not cause specific symptoms. Consequently, gonadotroph adenomas most often present with symptoms resulting from their sheer size,

such as headaches and visual disturbances, rather than with amenorrhea.<sup>288,289,290</sup> Rare FSH-secreting adenomas however may cause spontaneous ovarian hyperstimulation, resulting in amenorrhea, multiple large ovarian cysts, and high serum FSH and estradiol levels<sup>291,292,293</sup>; in prepubertal girls, they may cause breast development and vaginal bleeding.<sup>294</sup> However, most patients with gonadotroph adenomas have normal or low serum gonadotropin concentrations because these tumors are nonfunctional and disrupt menstrual function only indirectly, via compression of the pituitary stalk or the surrounding cells. They may inhibit gonadotropin secretion by interrupting the delivery of hypothalamic GnRH or by compressing normal gonadotrophs. Alternatively, they may cause hyperprolactinemia by interfering with the inhibitory actions of dopamine on the lactotrophs, resulting in a secondary suppression of hypothalamic GnRH secretion mediated via excess prolactin, with consequent amenorrhea. Although such “null cell” tumors rarely produce clinically significant amounts of gonadotropins, they do exhibit gonadotropin production in vitro or gene expression at the mRNA level.<sup>295,296</sup> Gonadotroph adenomas also may secrete large amounts of the  $\alpha$  (alpha)-subunit common to all of the pituitary glycoprotein hormones (having no intrinsic biologic activity and therefore causing no symptoms).

A nonfunctioning gonadotroph adenoma can be the cause for persistent mild elevations in prolactin levels and should be considered in patients having a serum prolactin level under 100 ng/mL with no signs of hyperthyroidism, acromegaly, or Cushing syndrome. In the presence of low or normal gonadotropin levels, an elevated level of free  $\alpha$ -subunit also suggests a nonfunctioning gonadotroph adenoma.<sup>295</sup> In rare cases of functioning gonadotroph adenomas, the serum FSH may be elevated when the LH level is low. In premenopausal women, persistent elevated levels of both FSH and estradiol, associated with multicystic ovaries and endometrial hyperplasia, strongly suggest a functional FSH-secreting gonadotroph adenoma causing ovarian hyperstimulation.<sup>291,297,298,299</sup> Treatment with a GnRH agonist fails to down-regulate gonadotropin secretion in women with such tumors and may even cause or exacerbate ovarian hyperstimulation.<sup>292</sup>

In patients with neurologic symptoms or clinically bothersome picture resulting from excess gonadotropin secretion (as in cases of multicystic ovaries with symptoms of ovarian hyperstimulation), transsphenoidal surgical resection of a gonadotroph or other nonfunctioning adenoma can provide rapid relief. If surgery succeeds in removing the adenoma but not the adjoining normal pituitary, gonadotropin secretion and ovarian function should return to normal. However, surgery also may result in damage to the normal pituitary tissue, thereby causing additional pituitary hormone deficiencies or a more global panhypopituitarism.<sup>300</sup> Serious complications of transsphenoidal surgery are uncommon, occurring in less than 5% of patients, but include worsening vision,

hemorrhage, and cerebrospinal fluid rhinorrhea leading to meningitis. Variations in the secretion of ADH, causing diabetes insipidus or the opposite problem, the syndrome of inappropriate antidiuretic hormone (SIADH), are more common but are usually only transient. Conventional or stereotactic radiation therapy is useful when postoperative imaging reveals significant residual tumor or progressive regrowth following surgery. In patients having no neurologic symptoms or clinically important gonadotropin secretion, nonfunctioning microadenomas and macroadenomas can be monitored carefully by serial imaging at annual intervals (beginning 6 months after diagnosis for macroadenomas) to detect progressive growth and with decreasing frequency in the absence of any change. Any associated pituitary hormone deficiencies should be replaced.

## **Thyrotroph Adenomas**

Functional thyrotroph adenomas are a rare cause of hyperthyroidism, accounting for less than 1% of all functional pituitary tumors. Most patients present with the typical signs and symptoms of hyperthyroidism; other clinical manifestations can include a diffuse goiter, visual impairment, menstrual disturbances, and even galactorrhea. Because the TSH secreted by thyrotroph adenomas can vary greatly in biologic activity and in immunoactivity, serum TSH concentrations also can vary widely, ranging from normal (but still inappropriately high in the presence of hyperthyroidism) to markedly elevated.<sup>301</sup> The majority of patients with functional thyrotroph adenomas also have elevated serum concentrations of the free  $\alpha$ -glycoprotein hormone subunit.

Transsphenoidal surgery is the standard treatment for patients with functional thyrotroph adenomas, but has yielded mixed results, primarily because most such tumors are macroadenomas and surgery often is not curative. For those with persistent tumor, treatment with the somatostatin analog octreotide is effective in most,<sup>301</sup> so much so that 6–12 months of preoperative treatment with octreotide may be considered for patients with large functioning thyrotroph adenomas. Antithyroid therapy is not indicated, because the decrease in thyroid hormone may be expected to further stimulate TSH secretion and accelerate tumor growth.

## **Somatotroph Adenomas**

Functional GH-secreting somatotroph adenomas are the cause of more than 95% of cases of acromegaly.<sup>286</sup> GH stimulates excess hepatic IGF-1 secretion, which, in turn, causes most of the clinical features of the disorder. The characteristic signs of acromegaly are an enlarged jaw; enlarged and swollen hands and feet, resulting in increasing shoe and ring size; thickening and enlargement of the tongue; and joint symptoms relating to hypertrophic arthropathy. However, the onset and progression of

acromegaly are extremely slow, and it typically evolves over a period of several years. At the time of diagnosis, most patients have macroadenomas, many with extension outside of the sella.

Serum IGF-1 levels do not vary with meals, the time of day, or exercise, but do vary with age, being highest during puberty and decreasing gradually thereafter. The IGF-1 level therefore must be interpreted according to established age-specific norms. Most patients with acromegaly also have elevated serum GH levels, but concentrations fluctuate widely in response to a variety of stimuli, including fasting, exercise, stress, and sleep; levels also may be elevated in those with poorly controlled diabetes, liver disease, and malnutrition. Because random serum GH measurements can be difficult to interpret confidently, the most specific test for diagnosis of acromegaly is an oral glucose tolerance test. In normal individuals, GH levels fall to very low levels within 2 hours after ingesting 75 g of glucose ( $<0.3$  ng/mL when measured with a modern highly sensitive immunoradiometric or immunochemiluminescent assay); a GH level greater than 0.3 ng/mL is abnormally high.<sup>302</sup>

Transsphenoidal surgery is the treatment of choice for patients with somatotroph adenomas. The outcomes achieved with surgery generally are very good; in 80–90% of patients with microadenomas, GH secretion declines to normal and other pituitary functions are preserved; results are more variable in those with macroadenomas.<sup>303,304</sup> Clinical symptoms rapidly improve after successful surgery. Effective medical treatments are available for treatment of persistent or recurrent tumor and symptoms, including somatostatin analogs (e.g., octreotide, lanreotide), which inhibit GH secretion, and GH receptor antagonists (e.g., pegvisomant), which lower IGF-1 concentrations.

## **Corticotroph Adenomas**

Functional ACTH-secreting corticotroph adenomas are the specific cause of Cushing disease and one cause of the more general disorder, Cushing syndrome, which results from an excess of circulating glucocorticoids. The most common cause of Cushing syndrome is the ingestion of prescribed glucocorticoids (e.g., prednisone), although oral, injected, topical, and inhaled glucocorticoids also may cause the disorder.<sup>305,306,307</sup> Other causes include cortisol-secreting adrenal adenomas and carcinomas and ectopic production of ACTH or corticotropin-releasing hormone (CRH) by bronchial carcinoids and other rare tumors.

The classical clinical manifestations of Cushing disease result primarily from hypercortisolism, caused by increased ACTH stimulation of the adrenals, and vary with the duration and extent of excess cortisol secretion. The most common features are progressive central obesity, features resulting from excess fat accumulation in the buccal

(“moon face”) and nuchal (“buffalo hump”) fat pads, those caused by atrophy of the skin and subcutaneous tissue (such as easy bruising and purple striae on the abdomen and flanks), and hyperpigmentation (caused by excess ACTH), which is most noticeable in areas exposed to light (the face, neck, and back of the hands) or at skin sites exposed to chronic mild trauma, friction, or pressure (the elbows, knees, knuckles, and shoulders); hyperpigmentation of Cushing disease may additionally involve mucosal surfaces such as the inner lip. Menstrual abnormalities are common, affecting up to 80% of women, with one-third developing amenorrhea.<sup>308</sup> Other common signs and symptoms result from mild androgen excess (hirsutism, acne) and the effects of excess cortisol on skeletal muscle (proximal muscle wasting and weakness), bone (osteoporosis), and glucose metabolism (insulin resistance, glucose intolerance, diabetes). Functional corticotroph adenomas are usually quite small and may be difficult to image.

The diagnostic evaluation for suspected Cushing syndrome begins by measuring 24-hour urinary free cortisol excretion (twice) and the late-night (11:00 P.M.) salivary cortisol level (twice) or by performing an overnight or low-dose dexamethasone suppression test; the three screening tests have similar diagnostic accuracy.<sup>309</sup> Urinary creatinine excretion should be measured in the same specimen to judge compliance with instructions because a reliable 24-hour urine collection can be difficult to obtain. The urinary cortisol excretion and the late-night salivary cortisol level are interpreted by comparison to established normal laboratory ranges. The overnight dexamethasone suppression test is performed by administering 1.0 mg of dexamethasone by mouth between 11:00 P.M. and midnight and measuring the serum cortisol at 8:00 A.M. the following morning; a value less than 1.8 mg/dL is a normal result.<sup>287</sup> The low-dose dexamethasone suppression test is performed by administering 0.5 mg of dexamethasone by mouth every 6 hours over 2 days for a total of 8 doses (e.g., 8:00 A.M., 2 P.M., 8:00 P.M., and 2:00 A.M.) and measuring serum cortisol 2 or 6 hours after the last dose; as with the overnight test, a value less than 1.8 mg/dL is a normal result.<sup>287</sup> If the first screening test is abnormal, a second, different, test should be performed. Those with concordant abnormal results require additional evaluation to determine the cause of Cushing syndrome, as discussed in detail in [Chapter 13](#). Those with discordant results also merit further testing. Those with normal results require no further evaluation, except when the clinical suspicion is high, based on the clinical presentation.

The treatment of choice for Cushing disease is transsphenoidal surgery; among experienced surgeons, the permanent cure rate is approximately 70%. Radiation therapy is an option for those not cured by surgery and is effective in approximately 45% of adult patients. Bilateral total adrenalectomy, requiring lifelong daily glucocorticoid and mineralocorticoid treatment, is the final and definitive cure.<sup>310</sup>

## **Lactotroph Adenomas (Prolactinomas)**

Functional lactotroph adenomas are common, accounting for approximately 40% of all clinically recognized pituitary adenomas. Most arise from clonal expansion of a single cell, presumably due to a somatic mutation. They also may occur as part of the MEN1 syndrome, a possibility that can be effectively excluded by measuring the serum calcium level since primary hyperparathyroidism (hypercalcemia associated with an inappropriately high parathyroid hormone level) is the most common clinical manifestation of the disorder. Approximately 10% of adenomas that secrete prolactin also secrete GH, leading some to recommend measuring the serum IGF-1 concentration, even in women with microadenomas.<sup>311</sup> In women with lactotroph adenomas, serum prolactin concentrations generally correlate with the size of the adenoma. Microadenomas usually are associated with serum prolactin concentrations less than 200 ng/mL and macroadenomas with higher levels, but exceptions in either case are not uncommon. In some women with large lactotroph macroadenomas, prolactin levels are only modestly elevated because the tumor is largely cystic, or due to an assay artifact that may occur when a test sample contains a massive excess of antigen that saturates both the capture and signal antibodies, preventing them from forming a “sandwich” in immunoradiometric and chemiluminescent assays (known as the “hook effect”).<sup>312</sup>

Hyperprolactinemia commonly results in menstrual disturbances and is the cause of secondary amenorrhea in up to 30% of women.<sup>313</sup> The mechanism relates to inhibition of hypothalamic GnRH secretion, which, in turn, results in decreased pituitary gonadotropin secretion and in anovulation or a more severe hypogonadotropic hypogonadism, depending on the level of hyperprolactinemia and the extent to which gonadotropin secretion is suppressed. Chronic hypogonadism in a reproductive-age woman may result in progressive bone loss that improves after prolactin levels get normalized and functioning of the HPO axis is restored, but bone mineral density does not always return to normal.<sup>314</sup> Hyperprolactinemia also may result in galactorrhea, but most hyperprolactinemic women do not have galactorrhea, primarily because their estrogen levels are abnormally low. Although prolactinomas are much more common in adults, they can cause growth failure and primary amenorrhea in children.<sup>315</sup> Postmenopausal women with prolactinomas do not exhibit the classical symptoms and often are recognized only when a large tumor causes neurologic symptoms.

## Medical Treatment

Dopamine agonists are the first-line treatment of choice for women with functional prolactin-secreting lactotroph adenomas of all sizes because they effectively lower prolactin levels and decrease the size of more than 90% of such tumors.<sup>316</sup> Bromocriptine and cabergoline both are highly effective. Cabergoline, a selective dopamine receptor type 2 agonist, has fewer side effects, has greater potency, and is

also more effective than bromocriptine in restoring normal prolactin levels in women with lactotroph adenomas.<sup>26,27</sup> Consequently, most consider it the better choice. However, even at relatively low doses, long-term use of cabergoline may increase the risk of hypertrophic valvular heart disease.<sup>30,31</sup> Bromocriptine poses no such risk and some therefore consider it a somewhat safer choice, reserving cabergoline for those patients who prove intolerant or resistant to bromocriptine. To minimize side effects, treatment with either drug should begin with a low dose (e.g., bromocriptine 1.25 mg at bedtime; cabergoline 0.25 mg twice weekly) and increase gradually, guided by serial prolactin levels obtained at approximately monthly intervals. In general, the higher the prolactin level, the greater the dose of dopamine agonist required to restore normal prolactin levels. In women with large macroadenomas and very high prolactin levels, doses of bromocriptine up to 5 mg twice daily and of cabergoline up to 1.5 mg twice weekly may be required. Either drug also may be administered vaginally in women who cannot tolerate oral treatment.<sup>33,34</sup>

Prolactin levels typically decrease within 2–3 weeks after treatment begins and can be normalized in virtually all patients with microadenomas and in nearly all of those with macroadenomas.<sup>317</sup> In women with macroadenomas causing visual impairment, significant improvement can be observed within days after treatment begins and increases gradually over a period of months.<sup>318,319</sup> Significant shrinkage of adenomas may begin in as little as 6 weeks but can be assessed more confidently by repeating the MRI after 3–6 months of treatment. Longer durations of treatment often achieve further shrinkage in the size of the adenoma.<sup>317,320,321</sup> In women with macroadenomas, size generally decreases in parallel with the prolactin level. However, the overall response does not always correlate with the basal prolactin level, the absolute or relative decrease in concentrations, or even the normalization prolactin levels. **The failure of a tumor to shrink significantly in size despite a normalization of prolactin levels strongly suggests it is a nonfunctioning adenoma, rather than a functional lactotroph adenoma.** Menses, ovulation, and fertility typically return when normal prolactin levels are restored.<sup>26</sup> For women seeking pregnancy, the safety of both drugs is now established.<sup>35,36</sup> In those who cannot tolerate dopamine agonist treatment and therefore remain hyperprolactinemic and anovulatory, ovulation induction can be induced with exogenous gonadotropins.

In women with microadenomas, the dose of dopamine agonist often can be reduced after approximately 1 year of treatment, and a trial discontinuation can be attempted if prolactin levels have been normal for 2 years or more and MRI reveals no evidence of the adenoma. In those with macroadenomas, an MRI should be repeated after 6 and 12 months of treatment to determine the extent to which the adenoma has decreased in size. If the prolactin level has been normal for a year or more and the adenoma has decreased

significantly in size, the dose of treatment can be reduced gradually as long as the prolactin level remains normal.<sup>322</sup> As with microadenomas, a trial discontinuation of treatment can be attempted after prolactin levels have been normal for 2 years if MRI reveals no persistent tumor. Frequently, but not always, prolactin levels rise again after discontinuation of treatment. In a large retrospective study, recurrent hyperprolactinemia was observed in 75% of patients with microadenomas and in 84% of those with macroadenomas treated with bromocriptine.<sup>323</sup> However, in a prospective study involving 105 patients with microadenomas and 70 with macroadenomas, treatment was discontinued when prolactin levels were normal and MRI demonstrated no residual tumor, or more than a 50% decrease in size with no cavernous sinus invasion and more than 5 mm separation from the optic chiasm; hyperprolactinemia returned in only 31% of patients with microadenomas and in 36% of those with macroadenomas and no tumor regrowth was observed in any patient after 2–5 years of observation.<sup>324</sup> The best candidates for discontinuation of treatment are those with normal serum prolactin levels and very little or no visible residual tumor on MRI.

A dopamine agonist is the best initial treatment for women with prolactin-secreting macroadenomas and is certainly a suitable choice, but not the only treatment option, for women with microadenomas. As in hyperprolactinemic women having no adenoma, treatment can be tailored to the patient's needs and goals. Treatment with a dopamine agonist is the clear choice for women ready to attempt pregnancy (for ovulation induction) and those with troublesome galactorrhea. Others may be treated with physiologic cyclic estrogen/progestin therapy or with combined hormonal contraception (orally or vaginally administered), according to their contraceptive needs; such treatments pose little or no risk for stimulating tumor growth.<sup>37,38</sup> However, it is prudent to monitor serum prolactin levels approximately every 6 months and to repeat the MRI 1 and 2 years after diagnosis to reassess the size of the adenoma.

## Surgical Treatment

In patients with lactotroph adenomas who cannot tolerate or prove resistant to dopamine agonist treatment, transsphenoidal surgery is an appropriate alternative. Surgery might also be considered for women with very large macroadenomas (e.g., >3 cm) who want to attempt pregnancy, even when their tumor responds to medical treatment. Although surgery offers the possibility of a permanent cure, it also has important limitations and potential consequences. Incomplete resection of the tumor and persistent hyperprolactinemia are unfortunately common, more so in patients with macroadenomas (up to 90%) than in those with microadenomas (approximately 30%), as might be expected, and depending upon the skill and experience of the neurosurgeon. Recurrent hyperprolactinemia and tumor also may be observed within 5 years after surgery.<sup>325,326</sup> In general, the higher the initial prolactin level, the lower the permanent cure rate. Not

surprisingly, better outcomes can be expected when the adenoma lies entirely within the sella, emphasizing the importance of preoperative medical treatment for patients with extrasellar lesions.<sup>327</sup> The best predictor of a long-term cure is the prolactin level on the day following surgery. In the largest series with long-term follow-up on more than 400 women, the recurrence rate was 26% when postoperative prolactin levels were 20 ng/mL or less.<sup>328</sup> The risks and potential consequences of transsphenoidal surgery otherwise are the same as for other types of pituitary adenomas (see Gonadotroph Adenomas, above). For those with persistent hyperprolactinemia and tumor, management options include dopamine agonist treatment and radiation therapy.

## Radiation Therapy

Radiation therapy can decrease the size of lactotroph adenomas, but prolactin levels and tumor size decrease only very slowly, over a period of several years.<sup>329,330</sup> Therefore, radiation therapy is used primarily in the management of women with large macroadenomas having significant residual tumor after surgery. Approximately half of patients treated with radiation slowly develop panhypopituitarism over the 10 years following treatment.<sup>331</sup> Consequently, patients treated with radiation must be followed carefully over time, alert to the signs and symptoms of pituitary hormone deficiencies.

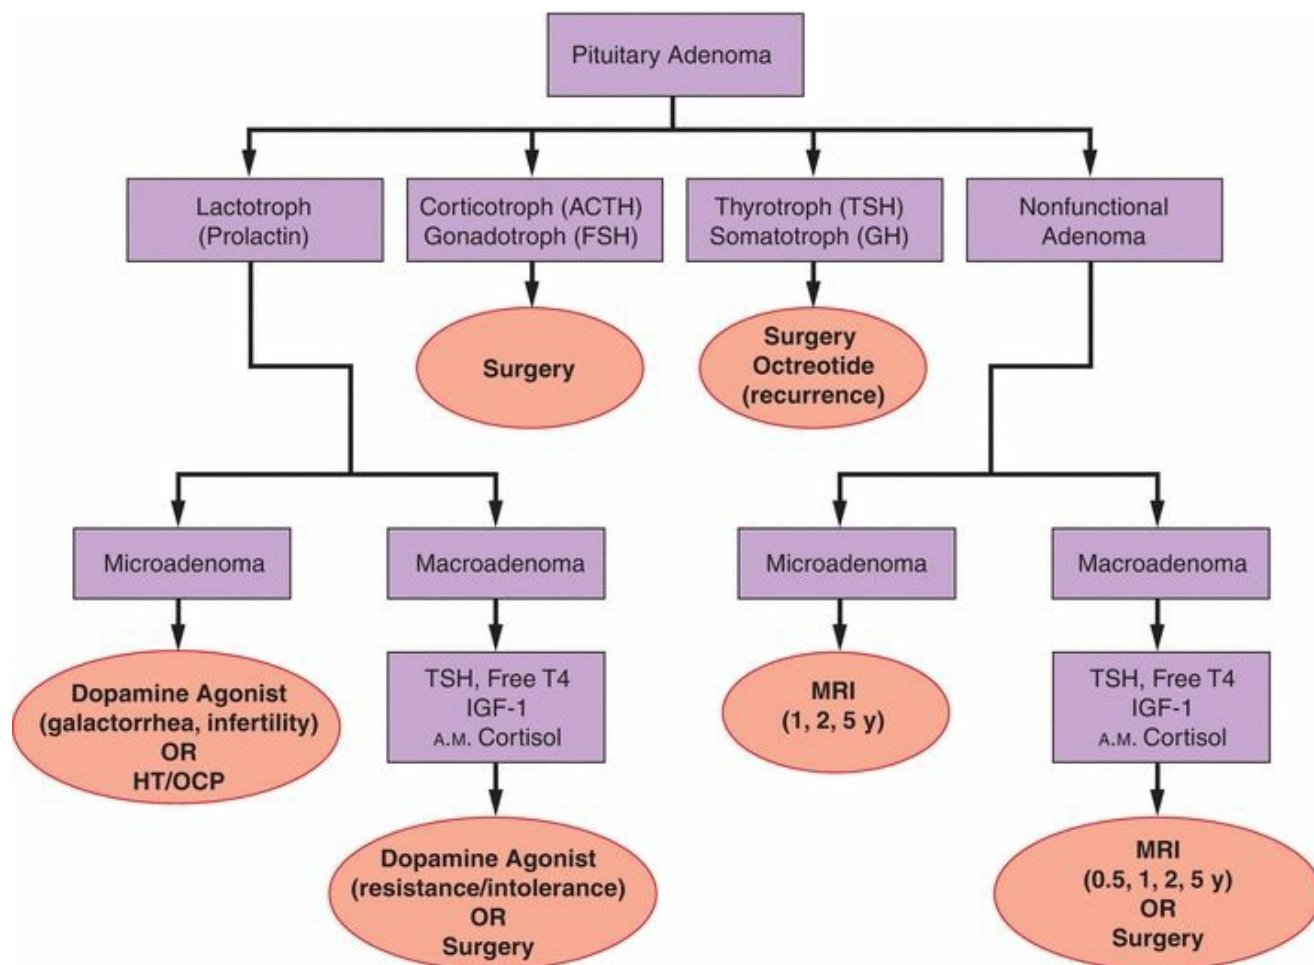

## Management During Pregnancy

Not surprisingly, given the effectiveness of dopamine agonist treatment in restoring ovulation and fertility in women with hyperprolactinemia, many women with functional lactotroph adenomas become pregnant. Overall, approximately 80% of hyperprolactinemic women, with or without adenomas, achieve pregnancy with dopamine agonist treatment.<sup>332,333,334</sup> Understandably, because the normal pituitary gland approximately doubles in size by the third trimester of pregnancy<sup>335</sup> and estrogen levels are quite elevated throughout, there is some increase in the risk for tumor growth during pregnancy. The risk for clinically significant growth in women with microadenomas is extremely low—only approximately 1–2%.<sup>336</sup> About 5% will develop asymptomatic tumor enlargement (as determined by imaging), and essentially none will ever require surgical intervention. The risk is significantly higher (approximately 15–20%) in those with macroadenomas.<sup>333,336</sup> Nevertheless, serial prolactin measurements during pregnancy are unnecessary.

**Regardless of the size of the adenoma, there is no indication for treatment with dopamine agonists or for imaging during pregnancy in the absence of symptoms; treatment may be safely discontinued when pregnancy is established.** In women with microadenomas, the serum prolactin should be measured approximately 2 months after delivery or the cessation of nursing, and, if still elevated, treatment with a

dopamine agonist, hormone therapy, or hormonal contraception can resume, according to the patient's needs. In women with macroadenomas, an interval of treatment with a dopamine agonist before pregnancy is advisable, to shrink the tumor and reduce the associated risk. In those with macroadenomas that fail to shrink with treatment, pregnancy should be avoided until after surgical debulking since medical treatment is not likely to be effective if symptoms develop.

In the few women with macroadenomas who experience significant tumor growth during pregnancy, headaches usually precede visual disturbances, and both may occur in any trimester. The headaches have no specific characteristics and vary in intensity, location, and character. Bitemporal hemianopsia (tunnel vision) is the classic visual impairment, but other defects can occur. The symptoms typically regress promptly with resumption of dopamine agonist treatment. Although seldom necessary, such treatment poses no risk to the fetus.<sup>35,332,337,338,339</sup> Amniotic fluid prolactin, with its presumed actions on the regulation of amniotic fluid water and electrolyte balance, derives from the decidua, and its secretion is controlled by estrogen and progesterone, not by dopamine, which has no effect on amniotic fluid prolactin levels. **Breastfeeding poses no significant risk for tumor growth in women with microadenomas or macroadenomas that remain asymptomatic during pregnancy, but is contraindicated for those with neurologic symptoms at the time of delivery.**<sup>340</sup> Dopamine agonist treatment should not resume until after cessation of nursing (**Figure 10.6**).

**FIGURE 10.6**

Pituitary Incidentaloma MRI has a high sensitivity for detecting small lesions and may reveal a pituitary tumor when the head is imaged for reasons other than suspected pituitary disease. In sum, 13 autopsy studies involving the examination of more than 10,000 pituitary glands identified more than 1,000 unsuspected microadenomas and 3 macroadenomas, yielding an overall prevalence of pituitary “incidentaloma” of approximately 10%.<sup>341</sup>

Relatively little is known about the fate of such common asymptomatic sellar masses. However, in one series involving 506 patients, all having serum prolactin levels less than 100 ng/mL and no evidence of other pituitary hormone hypersecretion or deficiency, 258 (almost 51%) had immediate surgery and 248 received expectant management for an average of 27 months. In those receiving surgery, 209 (81%) of the lesions were nonfunctional adenomas. Among those followed expectantly with serial imaging, the lesions grew in 30 (12%), shrunk in 29 (12%), and remained unchanged in all others. Among the lesions that grew in size over the course of surveillance, 20 were initially  $\geq 10$  mm, 10 were less than 10 mm, and only 3 grew to more than 10 mm over

65–84 months of observation.<sup>342</sup> In 2 smaller studies involving a total of 98 patients with pituitary incidentalomas, 10/41 (24%) tumors  $\geq 10$  mm and only 1 of 57 smaller tumors ( $< 2\%$ ) grew over 2–11 years of observation.<sup>343,344</sup>

Based on the available data, it generally is recommended that patients with pituitary incidentalomas  $\geq 10$  mm in size be evaluated in the same way as those with symptomatic macroadenomas, with periodic pituitary function tests and visual field examination, because such tumors are more likely to be associated with abnormalities in pituitary hormone secretion and to enlarge over time. Those with functional macroadenomas should be treated accordingly, and those with nonfunctional tumors can be followed with serial testing and imaging at 6 months, 1 and 2 years, and less frequently thereafter; any associated hormone deficiencies should be treated appropriately. In patients with smaller incidentalomas ( $< 10$  mm), a serum prolactin should be obtained, but other endocrine evaluation is unnecessary when there are no clinical signs or symptoms to suggest a functional tumor.<sup>345</sup> In the absence of any clinical or endocrine abnormalities, MRI can be repeated once after 1–2 years to identify the very few that may exhibit significant growth.

## Empty Sella Syndrome

The “empty sella syndrome” is a misnomer because the sella turcica is not, in fact, empty. The sella is enlarged and appears empty on imaging because it contains cerebrospinal fluid (CSF), still within the subarachnoid space but extending downward into the pituitary fossa. The disorder is included here, in our discussion of pituitary adenomas, because it is most commonly iatrogenic, consequent to previous removal or destruction of a pituitary adenoma by surgery or radiation. A less common mechanism for an empty sella is of pituitary infarction. Alternatively, an empty sella may result from a congenital defect in the sellar diaphragm (“primary empty sella”) allowing encroachment of the subarachnoid space into the pituitary fossa; long-term compression of otherwise normal pituitary tissue against the sellar floor results in flattening of the tissue, and the sella itself may become demineralized due to the increased pressure within the pituitary fossa.

In autopsy studies, the prevalence of an empty sella is approximately 5%, with the prevalence being disproportionately higher in women (nearly 85% of affected individuals are women).<sup>346</sup> In women presenting with amenorrhea and galactorrhea, the prevalence of empty sella is between 4% and 15%.<sup>313,347</sup> Not surprisingly, the syndrome may coexist with an adenoma and, less commonly, with deficiencies in pituitary hormone secretion that can be severe.<sup>348</sup> However, the condition usually is quite benign and does not progress to pituitary failure. There is no convincing evidence to indicate that a primary empty sella causes pituitary insufficiency.

Because of the possibility of a coexisting adenoma, patients with hyperprolactinemia and an empty sella should undergo annual surveillance (prolactin assay and imaging) for a few years to detect any evidence of tumor growth. Treatment for the condition is dictated by the associated symptoms and disturbances in pituitary hormone secretion.

## **Sheehan Syndrome**

Acute infarction and ischemic necrosis of the pituitary gland resulting from postpartum hemorrhage and consequent hypovolemic hypotension are known as Sheehan syndrome, which remains one of the most common causes of hypopituitarism in the underdeveloped or developing countries.<sup>349,350</sup> Failed lactation after delivery is the classical and earliest presenting symptom. The rest of the clinical picture varies with the severity of the pituitary insult, ranging from severe hypopituitarism soon after delivery, manifesting as lethargy, anorexia, and weight loss, to secondary amenorrhea, loss of sexual hair, and less severe symptoms of fatigue that emerge weeks and months later.<sup>351,352,353</sup> Deficiencies in GH, prolactin, and gonadotropins are most common, although the majority also exhibit ACTH and TSH deficiencies. Approximately one-third of patients may have hyponatremia, but diabetes insipidus is almost never observed.<sup>352,353</sup> A partially or completely empty sella is a common later finding.

The evaluation and treatment of Sheehan syndrome are no different from that for other causes of hypopituitarism, with one caveat. Any ACTH stimulation test that may be performed to detect a secondary adrenal insufficiency should be postponed until approximately 6 weeks after delivery. Adrenal atrophy due to chronic ACTH deficiency, resulting in the inability to increase cortisol secretion normally in response to an acute ACTH stimulus, requires time to develop. Earlier testing therefore may yield inaccurate (false negative) results.

## **Infiltrative Pituitary Lesions**

Infiltrative pituitary lesions that by damaging the gonadotrophs may cause hypogonadotropic hypogonadism and thereby amenorrhea include hemochromatosis and lymphocytic hypophysitis.

### **Hemochromatosis**

Hereditary hemochromatosis is an inherited autosomal recessive disorder caused by mutations in the HFE gene (on chromosome 6). In individuals homozygous for the mutant gene, an alteration in the size or shape of the HFE (hemochromatosis) protein prevents its transport to the cell surface where it normally interacts with the transferrin receptor, thereby interfering with the regulation of transmembrane iron transport and entry into the

cells.<sup>354</sup> Excessive absorption of dietary iron is the consequence, leading to parenchymal iron overload and subsequent tissue damage. In the pituitary, gonadotrophs are the most common cell type affected, resulting in hypogonadotropic hypogonadism<sup>355</sup>; TSH and ACTH deficiencies are less common. An acquired form of hemochromatosis may result from frequent transfusions in individuals with transfusion-dependent severe anemias (such as sickle cell disease, beta thalassemia major, aplastic anemia).

The best screening test for hereditary hemochromatosis is a fasting transferrin saturation (a ratio of serum iron to total iron binding capacity, expressed as a percentage)<sup>356</sup>; values greater than 45% are an indication for proceeding with HFE genotyping to establish the diagnosis.<sup>357</sup> Early diagnosis and treatment (periodic phlebotomy, chelation therapy) help to prevent serious multisystem end-organ damage relating to excess iron deposition; organs particularly susceptible to iron toxicity are the liver, pancreas, anterior pituitary, and heart. Although hereditary hemochromatosis is an uncommon cause of hypogonadotropic hypogonadism, some have suggested that iron studies should be performed in all patients with hypopituitarism and normal imaging.<sup>358</sup>

## **Lymphocytic Hypophysitis**

Lymphocytic hypophysitis is a rare autoimmune disorder causing enlargement of the pituitary that mimics a pituitary tumor, most often occurring during pregnancy or in the first 6 months postpartum.<sup>359,360</sup> The chronic inflammatory process results in focal or diffuse adenohypophysial destruction of varying severity and subsequent fibrosis. In the initial phase of hypophysitis, hyperprolactinemia is common, followed by progressive hypopituitarism. The disorder should be considered in women with sellar enlargement soon after pregnancy and in those with hypogonadism and a coexisting autoimmune disorder. Patients with symptoms and signs of pituitary enlargement and suprasellar extension can be treated by transsphenoidal surgery, dopamine agonists, anti-inflammatory or immunosuppressive drugs, or pituitary radiotherapy.<sup>361</sup> Granulomatous infiltrative processes of sarcoidosis involving the hypothalamus and/or the pituitary gland and presenting as amenorrhea have been reported.<sup>362</sup> Similarly, cases of tuberculous meningitis and intrasellar tuberculoma resulting in amenorrhea have also been described.<sup>363,364</sup>

# Disorders of Hypothalamic Function

Hypothalamic dysfunction is one of the most common causes of secondary amenorrhea. In its most severe form, commonly known as **hypothalamic amenorrhea**, the HPO axis is profoundly suppressed—abnormally low levels of hypothalamic GnRH secretion stimulate only basal amounts of pituitary gonadotropin secretion, which, in turn, fail to stimulate ovarian follicular development, resulting in very low levels of estrogen production.<sup>365</sup> The clinical manifestations of dysfunctional hypothalamic GnRH secretion depend on the extent to which gonadotropin secretion is suppressed, much like in women with hyperprolactinemia and probably involving similar mechanisms. A minor disturbance in pulsatile hypothalamic GnRH secretion may result only in poor luteal function due to decreased LH stimulation of corpus luteum progesterone secretion, whereas a more significant dysfunction will result in disordered follicular development and chronic anovulation presenting as oligomenorrhea or amenorrhea, as discussed in an earlier section of this chapter devoted to the evaluation of ovarian function (see Chronic Anovulation). The primary focus here is on the more severe disorder, hypothalamic amenorrhea, characterized by overt hypogonadotropic hypogonadism. Other rare hypothalamic causes of amenorrhea include genetic mutations resulting in a congenital GnRH deficiency and infiltrative diseases involving the hypothalamus such as lymphoma, Langerhans cell histiocytosis, and sarcoidosis.

## Hypothalamic Amenorrhea

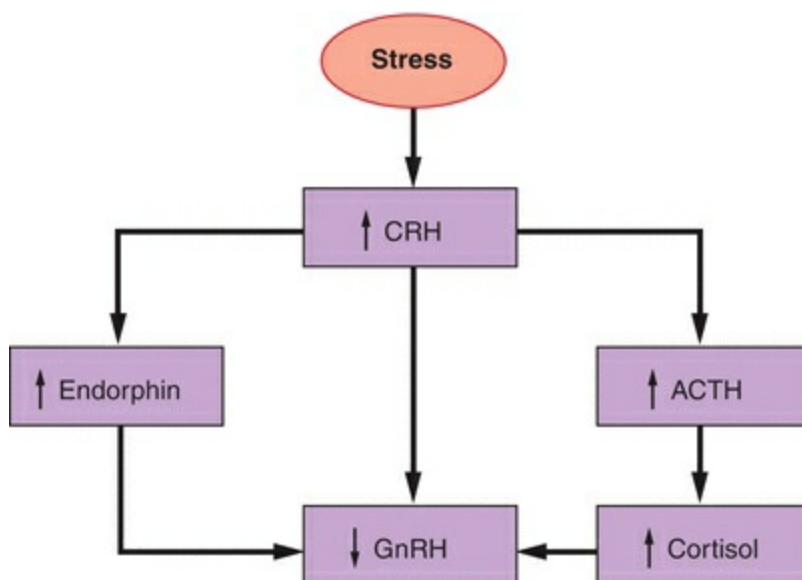

**Hypothalamic amenorrhea is a diagnosis of exclusion, based on findings of low or normal serum FSH concentration, despite low levels of estrogen production, in the absence of any sellar mass lesion or reason to suspect other rare pituitary causes of hypogonadotropic hypogonadism.**

Hypothalamic amenorrhea frequently is associated with extreme physical, nutritional, or emotional stress, suggesting it represents a functional suppression of reproduction as a psychobiologic response to life events.<sup>366</sup> Affected women frequently are underweight (e.g., <10% below ideal body weight), report recent weight loss, or engage in regular strenuous exercise; despite the recognized associations, it is important to appreciate that the critical threshold weight and the amount of weight loss or exercise required to induce amenorrhea vary significantly among individual women. Women with hypothalamic amenorrhea often exhibit abnormal eating patterns and generally expend more calories in aerobic activity and have a higher fiber intake and lower percent body fat than normally cycling women.<sup>367</sup> Many have endocrine, metabolic, and psychological characteristics that suggest a subclinical eating disorder.<sup>368,369</sup> However, in others with hypothalamic amenorrhea, no obvious mechanism or precipitating event

can be identified.

Regardless of the cause, the large majority of women with hypothalamic amenorrhea exhibit an abnormal pattern of hypothalamic GnRH secretion, as inferred from the pattern of pulsatile gonadotropin secretion. Some have no detectable gonadotropin secretory pulses (8%), and others exhibit low-frequency/low-amplitude (27%), low-amplitude/normal-frequency (8%), low-frequency/normal-amplitude (43%), or normal-frequency/normal-amplitude pulses (14%); different patterns may be observed over time.<sup>370</sup> Differences in the glycosylation of secreted gonadotropins, resulting in reduced bioactivity, also help to explain why those with normal immunoactive serum gonadotropin levels are nonetheless hypogonadal.<sup>62,371</sup> Almost half exhibit augmented LH secretion during sleep and higher serum levels of FSH than LH, as is observed in pubertal girls.

Observations of increased cortisol secretion in women with idiopathic hypothalamic amenorrhea suggest that stress may interrupt reproductive function indirectly by activating the hypothalamo-pituitary-adrenal axis.<sup>372,373,374</sup> Evidence suggesting the mechanism derives from experiments in nonhuman primates demonstrating that CRH inhibits gonadotropin secretion, probably by augmenting endogenous central opioid secretion (endorphins) (Figure 10.7).<sup>375</sup> Interestingly, cortisol levels return to normal months before the return of menses in women with hypothalamic amenorrhea, further suggesting the importance of stress, mediated via the adrenal axis.<sup>376</sup> Other studies indicate that increased hypothalamic dopaminergic inhibition of pulsatile GnRH secretion may be involved in at least some women with hypothalamic amenorrhea.<sup>377</sup>

**FIGURE 10.7**

The natural history of hypothalamic amenorrhea has been examined in a few studies that have followed women with the disorder over time. In those with hypothalamic amenorrhea associated with psychological stress or weight loss, spontaneous recovery with resumption of menses was observed in over 70% after 6–8 years of observation.<sup>378,379</sup> Women who recovered HPO function had higher BMI and lower cortisol levels than those who did not. Others have observed that women with an established cause or inciting event for their hypothalamic amenorrhea (such as stress, weight loss, or an eating disorder) were more likely to recover than those in whom no cause could be identified.<sup>380</sup> In patients with eating disorders, a return of menstrual function is associated with weight gain and recurrent amenorrhea with weight loss.<sup>381</sup>

## Eating Disorders

St. Wilgefortis was the seventh daughter of the King of Portugal, living around the year 1000. When confronted with an arranged marriage (despite her vow of virginity to join a convent), she turned to intense prayer, became ascetic and anorexic, and developed a diffuse growth of body hair, including a beard. Confronted with this new appearance, the King of Sicily withdrew his offer of marriage, and Wilgefortis's father had her crucified. Around 1200, the legend of Wilgefortis spread throughout Europe.<sup>382</sup>

St. Wilgefortis became a symbol, a woman who liberated herself from the burdens of womanhood, and became a protectress of women with sexual problems, including those associated with childbirth. Women who wished to free themselves from their husbands prayed to her, because she had successfully resisted both a father and an unwelcome suitor. In England, she was known as St. Uncumber because women believed she could uncumber them from their husbands. The medieval explanation (with ascendancy to sainthood) for a young girl's response (anorexia nervosa) to her fears of marriage and sexuality is still, to some extent, viable today, as anorexia can be the expression of the need to exert control over some facet of a rapidly changing and increasingly demanding and stressful life.

Our contemporary culture is obsessed with weight loss, clearly exhibited by the constant introduction and wide promotion of new fad diets, exercise regimens and apparatus, and the public adulation of models, actors, and athletes. Taken together, they send an unequivocal and unfortunate message to maturing adolescents, as reflected by the results of a national Youth Risk Behavior Survey taken in 2005: 38% of adolescent girls (in grades 9–12) considered themselves overweight, 62% were trying to lose weight, 17% had recently fasted for 24 hours or more, 8% had taken diet pills or similar products, and 6% had recently tried to induce vomiting or taken laxatives to lose weight or keep from gaining weight.<sup>383</sup> Although the estimated lifetime prevalence of eating disorders in women is relatively low, ranging between 0.3% and 2%,<sup>384,385,386,387</sup> these

disturbing statistics reveal the size of the population at risk.

In addition to cultural influences, other psychological, biologic, genetic, and social factors likely contribute to the development of eating disorders. Several have been associated with their development, including a history of dieting,<sup>388</sup> preoccupation with weight,<sup>389</sup> athletic and artistic pursuits that favor leanness or involve subjective judging, and, possibly, sexual abuse.<sup>389</sup> Young women having a first-degree relative with an eating or affective disorder or alcoholism are at increased risk for developing an eating disorder. Linkage analyses have identified possible susceptibility loci for anorexia nervosa on chromosome 1 and for bulimia nervosa on chromosome 10.<sup>390,391</sup> Affective, anxiety, and obsessive-compulsive disorders, personality disorders, and substance abuse are common in women with eating disorders.<sup>392</sup> Family stresses relating to high perceived parental expectations (for success, achievement, and appearance), poor communication, and marital tension also may play a role.

The clinical spectrum of eating disorders ranges from a limited period of amenorrhea associated with a crash diet in otherwise normal women to the grossly underweight anorexic having a distorted body image and the bulimic who cycles regularly between binge eating and purging behaviors. The specific diagnostic criteria for anorexia nervosa and bulimia nervosa are defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) and are briefly summarized here. The DSM-IV categorizes those with clearly abnormal eating patterns and weight control habits that do not meet the specific criteria for anorexia nervosa or bulimia nervosa as having an “eating disorder, not otherwise specified.”<sup>393</sup>

## **Anorexia Nervosa**

### **Key Points: Anorexia Nervosa**

- Refusal to maintain body weight within a normal range for height and age (<85% of ideal body weight)
- Fear of gaining weight or becoming fat, even though underweight
- Distorted body image, with undue importance on weight or shape
- In postmenarchal females, amenorrhea

Two subtypes of anorexia nervosa have been defined—restricting and binge/purging. In the first, a restriction of food intake is the primary method for achieving weight control. In the second, bingeing and purging, via self-induced vomiting or the use of laxatives or

diuretics, is the primary method for controlling weight. In both types, compulsive exercise may be an additional behavioral strategy for maintaining or losing weight.

The diagnostic criteria for bulimia nervosa are distinct from those for anorexia nervosa, primarily in that they do not include low body weight or amenorrhea.

## **Bulimia Nervosa**

### **Key Points: Bulimia Nervosa**

- Episodic binge eating, consuming abnormally large amounts of food, with a sense of lack of control.
- Recurrent compensatory behavior, including self-induced vomiting or misuse of laxatives, diuretics, or other medications, fasting, or excessive exercise.
- Binging and purging behaviors occurring at least twice per week, on average for an interval of 3 months or more.
- Dissatisfaction with body weight or shape.
- The behavior does not occur exclusively during episodes of anorexia nervosa.

Two subtypes are again described—purging and nonpurging. In the first, the purging behavior includes regular self-induced vomiting or the misuse of laxatives or diuretics. In the second, other compensatory behaviors predominate, such as exercise.

The clinical symptoms of restrictive anorexia nervosa include weight loss that frequently dates from a specific event like an illness, insensitive comment, rebuke, or loss. Amenorrhea typically precedes weight loss, which begins with dieting and specific restriction of fat intake. Affected women often admit fatigue, nausea, early satiety, or bloating after meals. They exhibit a distorted body image, denial, and disordered thinking and frequently use exercise as an additional weight control strategy. In women with anorexia nervosa, the physical examination may reveal hypotension, bradycardia, low body temperature, dry skin, and lanugo (fine, soft hair on the back, buttocks, and extremities). Those with bulimia nervosa exhibit impulsive and addictive qualities to their behaviors, an inability to control binge eating and purging, and frequently use cigarettes, alcohol, and other drugs. Many have irregular menses, but not amenorrhea, and in most, weight fluctuates but is not abnormally low. Those with bulimia nervosa may have parotid gland hypertrophy and erosion of their teeth enamel (from frequent vomiting).

The metabolic abnormalities associated with anorexia nervosa reflect dysfunctional hypothalamic regulation of appetite, thirst, temperature, sleep, autonomic balance, and

endocrine secretion.<sup>394</sup> The clinical consequences can be severe and even life-threatening. The associated endocrine abnormalities include low serum FSH, LH, estradiol, IGF-1, and leptin concentrations and increased cortisol levels; prolactin, TSH, and T4 levels are normal, but the T3 level is low, and reverse T3 (rT3) is high (rT3 is an isomer of T3, derived from T4, that binds but does not activate thyroid hormone receptors). With weight gain, all of the metabolic and endocrine abnormalities resolve. Even though normal gonadotropin secretion may be restored with weight gain, approximately one-third remains amenorrheic, likely reflecting persistent hypothalamic dysfunction.<sup>395</sup>

The treatment of anorexia nervosa and bulimia nervosa is complex, but generally requires nutrition, medical monitoring, and cognitive behavioral therapy in a multidisciplinary approach involving a physician, a dietitian, and a mental health professional. Antidepressant medications (primarily selective serotonin reuptake inhibitors) can be an important part of the management of bulimia nervosa, but have less value in anorexics. In those with anorexia nervosa, weight gain is the key to a successful outcome. Patients with severe medical or psychological symptoms may require hospitalization. Approximately half of patients with anorexia nervosa have good outcomes, as defined by weight gain and a return of menses, and about 25% improve but also have relapses; outcomes are poor in the remaining 25%.<sup>396</sup> Poor outcomes have been associated with older age at onset, longer duration of illness, lower nadir in weight, and lower body fat after weight gain.<sup>397</sup>

Low bone mass, osteopenia and osteoporosis, and an enhanced fracture risk are among the most serious complications of anorexia nervosa, the inevitable consequence of the combined adverse effects of severe malnutrition and estrogen deficiency. Although both contribute to bone loss, malnutrition clearly has the greater effect and importance.<sup>398,399</sup> In those who do not gain weight or resume menses, bone mineral density decreases approximately 2.5% annually in both the spine and the hip. Conversely, in those who gain weight and resume menses, bone density increases by approximately the same amount in both locations. In women who resume menses, spine bone density increases, independent of weight gain, and in women who gain weight, hip bone density increases, regardless whether they resume menses.<sup>400</sup> By itself, hormone therapy has little or no benefit. Treatment with oral contraceptives cannot prevent progressive bone loss in women with anorexia nervosa and generally has little value,<sup>401,402,403</sup> except perhaps in those with extremely severe illness (those below 70% of ideal body weight).<sup>404</sup> Undernourished women with eating disorders who do not achieve the rapid gain in bone density that normally occurs during adolescence may always have reduced bone density, even if they recover and resume normal menses.<sup>405</sup>

## Eating Disorders and Pregnancy

The caloric requirements of pregnancy, the changes in body shape, and the need to gain weight present particular challenges for women with eating disorders. For some, pregnancy may offer an opportunity or reason for recovery, but for others, it increases stress and risk. In general, women with restrictive behaviors tend to gain relatively little weight during pregnancy and those with bulimic behaviors often gain excessive weight.

Caloric restriction and compensatory behaviors such as purging pose risks for both mother and fetus. Anorexia nervosa increases the risk for maternal malnutrition, fetal growth restriction, and low birth weight. A low prepregnancy weight and inadequate weight gain during pregnancy each independently increase the risk of preterm birth.<sup>406</sup> The incidence of hyperemesis gravidarum, miscarriage, preterm birth, cesarean delivery, and postpartum depression is increased in pregnant women with eating disorders.<sup>407,408,409,410</sup> Women with anorexia nervosa in remission at the time of conception gain more weight and have higher birth weights than those with active illness.<sup>411</sup> In most women with bulimia nervosa, symptoms improve during pregnancy, but often recur or worsen postpartum.<sup>412</sup>

Overall, the best outcomes are achieved when illness is well-controlled before pregnancy. Consequently, treatment for anovulatory infertile women with eating disorders should focus first on management of their underlying illness before turning to ovulation induction.<sup>413</sup> The goal of pregnancy can be a strong motivational force and provides a unique opportunity for effective intervention.

During pregnancy, diet, weight gain, and fetal growth should be carefully monitored and nutritional counseling provided. Calcium supplementation is particularly important since most women with established eating disorders have low bone mass, which can further decline during pregnancy and lactation. As in nonpregnant women with eating disorders, a team management approach works best. Active management must continue into the postpartum period, when symptoms may resurface, and should involve the pediatrician because women with eating disorders are more likely to underfeed their babies.<sup>414</sup>

## Exercise and Amenorrhea

Soranus of Ephesus in the first century AD observed in his famous treatise, “On the Diseases of Women,” that amenorrhea is frequently observed in the youthful, the aged, the pregnant, in singers, and in those who take much exercise. In contemporary culture, a substantial proportion of reproductive-age women engage in some kind of regular exercise. Whereas exercise clearly offers significant health benefits, excessive exercise also may result in infertility or amenorrhea and, in adolescents, may even cause delayed

puberty.<sup>415</sup>

Women who are involved in strenuous recreational exercise or other forms of demanding physical activity, such as dancing, have a high prevalence of menstrual irregularity and amenorrhea. As much as two-thirds of runners who menstruate exhibit a short luteal phase or anovulatory cycles.<sup>416,417</sup> Typically, previously normal cycles become irregular after exercise begins and progress to amenorrhea as the intensity of exercise increases, particularly when accompanied by weight loss. Physical training that begins before menarche may delay its onset by as much as 3 years. **Exercise alone does not cause amenorrhea; the specific type and intensity of exercise are important.** Physical activities associated with a low body weight and high lean body mass (running, dance, gymnastics, figure skating) are associated with a higher incidence of amenorrhea than activities like swimming. Low body weight, by itself, unless extreme, also does not cause amenorrhea, because the effect of exercise on menstrual pattern varies significantly among women having a similar BMI. **The potential adverse effects of intense exercise and low body weight on menstrual function are synergistic.**

The critical weight hypothesis holds that the onset and regularity of menstrual function require that weight remains above a critical threshold level, with a corresponding critical level of body fat, which is estimated at 17% for menarche and at 22% for regular menstruation.<sup>418</sup> According to this hypothesis, excessive exercise or malnutrition may decrease the amount of body fat to below threshold values, resulting in delayed menarche in adolescents and in amenorrhea in postpubertal women. Logically, those at or near their critical thresholds of weight and body fat content would be at the greatest risk for loss of menstrual function.<sup>419</sup> Critics of the hypothesis acknowledge the correlation between body fat content and menstrual function, but deny any cause-effect relationship.<sup>420</sup> Indeed, normal and abnormal menstrual function may be observed at widely varying levels of body weight and fat content. However, the discovery of leptin (secreted by adipocytes in proportion to body fat stores) and of leptin receptors in the hypothalamus, revealing a feedback mechanism for the central regulation of body fat content, has stimulated renewed interest in the critical weight hypothesis (see [Chapter 19](#)).

In addition to the influence of weight and body fat on menstrual function, stress and energy expenditure exert important and independent effects, illustrated by the observation that menses often return in dancers during intervals of rest associated with injury, in the absence of any change in body weight or fat content.<sup>421</sup> Therefore, it is not surprising that women with low body weight and fat content who engage in strenuous physical activity are highly susceptible to anovulation and amenorrhea. **It appears that a negative energy balance, resulting when the level of energy expenditure exceeds**

**the available supply (derived both from intake and available stores), predisposes to a disruption in pulsatile gonadotropin secretion and a loss of menstrual function.**<sup>422</sup>

Other mechanisms that may help to explain the effects of exercise on menstrual function involve the actions of endogenous opioids, activation of the adrenal axis, and leptin. Substantial evidence suggests that secretion of endogenous hypothalamic opioids, which inhibit GnRH secretion, increases after exercise.<sup>423,424,425,426</sup> Cortisol levels are increased in hypothalamic amenorrhea (including that relating to exercise),<sup>373,427,428</sup> suggesting increased activity in the adrenal axis, mediated by CRH, which inhibits GnRH secretion.<sup>375</sup> Leptin levels are low in exercising amenorrheic women, lower than can be attributed to body fat content alone.<sup>429</sup> Exercising amenorrheic women do not exhibit a normal diurnal leptin rhythm.<sup>430</sup> Moreover, treatment with exogenous recombinant human leptin can restore gonadotropin pulsatility, follicular development, and ovulatory function in exercising amenorrheic women.<sup>431</sup> A decrease in leptin levels, resulting from low body fat stores and a negative energy balance, may thus suppress the HPO and thyroid axes and stimulate the adrenal axis, thereby producing many of the endocrine features observed in amenorrheic female athletes.

A unifying hypothesis focuses on the importance of energy balance.<sup>432,433</sup> When energy demands are high, as in exercise, or supplies are insufficient, as in eating disorders, reproduction is suspended in favor of more essential metabolic functions. Teleologically, the concept makes sense; adaptations to stress also inhibit menstrual function because conditions do not favor successful reproduction.

Regardless whether the critical factor is body weight, percent fat content, or energy balance, and whether endogenous opioids, CRH, and leptin mediate the effect, the mechanism by which exercise disturbs normal menstrual function relates directly to changes in the pattern of hypothalamic GnRH secretion, which may vary with body composition. In amenorrheic athletes with low body weight, both LH pulse frequency and amplitude are decreased; pituitary sensitivity to exogenous GnRH also is increased, further indicating that decreased gonadotropin levels result from decreased endogenous GnRH stimulation.<sup>368</sup> In contrast, when exercise is not weight-bearing and leanness is therefore less important, as in competitive swimmers, LH levels often are modestly elevated rather than suppressed, and estradiol concentrations are normal, suggesting a less severe disturbance in GnRH pulse rhythm that results in chronic anovulation and amenorrhea, but not in hypogonadotropic hypogonadism (hypothalamic amenorrhea) as more often occurs in runners and dancers.<sup>434</sup>

Because most women with exercise-induced amenorrhea are estrogen deficient, they are at risk for its natural clinical consequences, including genitourinary and breast atrophy and bone loss with consequent low bone mass. Unlike menopausal women,

vasomotor symptoms are not a feature of hypogonadism due to hypothalamic amenorrhea, a distinction that is attributable to the underlying hypothalamic dysfunction in the latter. **It is important to emphasize that the beneficial effects of weight-bearing exercise on the bone are not sufficient to prevent the adverse effects of estrogen deficiency, particularly in adolescents.** In general, hypogonadism has greater detrimental effects on trabecular bone than on cortical bone. However, because skeletal loading patterns differ with the type of exercise, exercising estrogen-deficient women exhibit site-specific differences in bone density. Gymnasts have a higher bone density in the spine than the runners, despite similar menstrual patterns and body fat.<sup>435</sup> In ballet dancers, cortical bone density may be normal or increased at weight-bearing sites, such as the proximal femur, but trabecular bone density is decreased in the lumbar spine.<sup>436</sup> Rowers may accrue greater bone density in the lumbar spine due to the mechanical loading produced in their exercise.<sup>437</sup> However, the normal stress-induced compensatory changes in bone density also may be impaired or prevented by estrogen deficiency.<sup>436</sup> Fractures, particularly stress fractures, are common in athletes, but more common in those with abnormal eating patterns,<sup>438,439</sup> possibly because a negative energy balance results in low rates of bone turnover and favors resorption.

For some women, an explanation of the need to maintain caloric intake at a level in balance with energy expenditure encourages behavioral modifications (increased caloric intake and/or a decrease in exercise) that may restore menses.<sup>440</sup> However, most women with exercise-induced hypothalamic amenorrhea understandably are resistant to the suggestion that they gain weight or reduce or stop exercising. For many, exercise also is an important stress management strategy. It is helpful to explain the effects of diet, exercise, and hormones and to emphasize the importance of building bone early in life; almost all of hip and vertebral bone mass accumulates by late adolescence (age 18), and the early postmenarchal years (age 11–14) are especially important.<sup>441,442</sup>

Bone loss is the most obvious, immediate, and demonstrable consequence of exercise-induced hypothalamic amenorrhea. **A baseline bone density measurement revealing significantly low bone mass compared to age- and gender-matched controls (BMD Z score of  $<-2.0$ ) is associated with an increased risk for debilitating stress fracture and can help to illustrate and to emphasize the need for a change in lifestyle and habits or for an intervention such as hormone therapy.** Subsequent periodic measurements of bone density are useful for assessing for interval change and effectiveness of therapy. The increase in bone mineral density that typically accompanies a return of normal menses is significantly greater than can be achieved by treatment with estrogen or combined hormonal contraceptives,<sup>443,444,445,446</sup> probably because normal bone metabolism requires both adequate nutrition (supporting bone formation) and estrogen (decreasing bone resorption). Nonetheless, in those unable or

unwilling to make the lifestyle changes that might restore gonadal function, exogenous estrogen (plus progestin to ensure endometrial protection, either as cyclic or continuous regimen) or a combination hormonal contraception (pill, vaginal ring, or patch) is indicated, particularly so if low BMD is diagnosed, according to the patient's needs and preferences. Those choosing physiologic hormone therapy must be cautioned that treatment will not prevent ovulation rendering the individual susceptible to possibility of an unplanned pregnancy if and when HPO function gets restored.<sup>447</sup> Resumption of spontaneous ovarian function remains the most effective strategy for improving skeletal mass in women with hypothalamic amenorrhea. Unscheduled and unanticipated menstrual bleeding is suggestive of resumption of ovarian function, and treatment may be discontinued for an interval of observation. For those who require reliable contraception, a low-dose oral contraceptive may be a preferred choice. Women should be informed that hormone therapy may cause modest increases in weight and fat mass, but also reassured that such minor changes in body composition likely will have little or no impact on physical performance.<sup>443</sup>

Supplemental calcium (1,000–5,000 mg daily) and vitamin D (1,000–2,000 IU daily) should be encouraged. Skeletal antiresorptive agents other than estrogen, such as bisphosphonates, are not a good choice for the prevention and treatment of low bone mass in premenopausal women with exercise-induced hypothalamic amenorrhea, for two reasons. First, they have low levels of bone formation and bone turnover and therefore respond poorly to antiresorptive therapy.<sup>445</sup> Second, bisphosphonates remain in the bone for 10 years or more and constantly leech into the circulation, most women with exercise-induced hypothalamic amenorrhea have not completed childbearing, and the effects of bisphosphonates on fetal skeletal development are unknown.<sup>448</sup>

Women with exercise-induced hypothalamic amenorrhea should be reassured that treatment aimed at inducing ovulation and restoring normal fertility is available. The ideal approach to ovulation induction in women with hypothalamic amenorrhea is to mimic the *in vivo* HPO axis through utilizing pulsatile GnRH (using a transdermal pump) in physiologic doses, which stimulates the release of pituitary gonadotropins, thereby achieving ovarian follicular development. While pulsatile GnRH may be considered as an optimal approach to achieve successful ovulation in women with hypothalamic amenorrhea,<sup>70</sup> due to restricted availability of GnRH for clinical use, treatment with exogenous gonadotropins is the most common treatment utilized to achieve ovarian stimulation because ovulation induction agents such as clomiphene citrate is typically ineffective in women with hypogonadotropic hypogonadism. Logically, if low endogenous estrogen levels have failed to stimulate the appropriate compensatory increase in gonadotropin secretion, there is little reason to believe that treatment with an estrogen antagonist such as clomiphene will do so. It may be useful to advise such women that whereas weight gain and a decrease in exercise may not restore

spontaneous ovulatory function and fertility, they may nonetheless result in sufficient improvement in hypothalamic function to allow them to respond to clomiphene and to avoid the rigors and risks of gonadotropin treatment.

## **Congenital GnRH Deficiency**

In rare individuals, hypothalamic amenorrhea results from a congenital GnRH deficiency relating to specific genetic mutations that prevent normal GnRH neuronal migration during embryogenesis or to mutations in the pituitary GnRH receptor. Although seldom necessary, the diagnosis of congenital GnRH deficiency can be inferred by demonstrating a complete lack of pulsatile LH secretion and little or no LH secretion in response to exogenous pulsatile GnRH treatment.<sup>449,450</sup> Congenital GnRH deficiency is more common in males than in females (5:1). In affected women, the gonads respond normally to exogenous gonadotropin stimulation, which can be used to induce pubertal changes as well as achieve ovulation and restore fertility, as in women with the more common causes of hypothalamic amenorrhea.

## **Kallmann Syndrome**

When congenital GnRH deficiency is associated with anosmia or hyposmia (an absent or grossly impaired sense of smell), the disorder is known as Kallmann syndrome.<sup>451</sup> The classical X-linked form of the disorder is caused by a variety of genetic mutations in the KAL gene (located on the short arm of the X chromosome, Xp22.3) encoding anosmin-1, a neural adhesion molecule that promotes migration of GnRH neurons, and olfactory neurons, from the olfactory placode into the hypothalamus during embryonic development.<sup>452</sup> Obligate female carriers in families with the X-linked form of the disorder have no recognizable specific phenotype. Kallmann syndrome also can be inherited in an autosomal dominant or recessive fashion. The autosomal dominant form has been linked to an inactivating mutation in the gene encoding the fibroblast growth factor-1 receptor (FGFR1). Mutations similar to but distinct from that in Kallmann syndrome, affecting only GnRH neuronal migration, offer a potential explanation for an isolated gonadotropin deficiency, unaccompanied by anosmia.

At puberty, both males and females with Kallmann syndrome usually present with delayed growth and sexual development. The presence of pubic hair, reflecting a normal adrenarche, helps to distinguish them from those with a constitutional delay of puberty in whom adrenarche typically also is delayed. However, the most distinguishing feature of Kallmann syndrome is the inability to perceive odors, such as coffee or perfume. Patients with the disorder also may have a family history of delayed puberty and other abnormalities, including cleft lip/palate, urogenital tract anomalies, or syndactyly.

## GnRH Receptor Mutations

More than 20 inactivating mutations in the GnRH receptor gene (GNRHR) have been described.<sup>453,454</sup> Some effectively prevent GnRH binding, some interfere with normal signal transduction, both resulting in resistance to GnRH stimulation, and others predispose to abnormal folding at the site of synthesis within the endoplasmic reticulum, leading to degradation before transport to the cell surface membrane.<sup>68</sup>

The phenotypic spectrum observed in individuals with GnRH receptor mutations ranges from a complete absence of sexual development to delayed puberty and generally correlates with the LH-secretory response to exogenous GnRH treatment. Standard treatments for hypogonadotropic hypogonadism, including hormone therapy and ovulation induction with exogenous gonadotropins, are effective. Specific evaluation aimed at identifying GnRH mutations might be considered when other family members are affected, for research purposes, but is not clinically necessary or indicated, at least not yet. Interestingly, a nonpeptide cell permeant GnRH receptor antagonist (IN3) has shown the ability to restore ligand binding and function for several naturally occurring mutant GnRH receptors in vitro, apparently by acting as a molecular chaperone, helping to properly arrange the mutant receptor and to usher it to the cell surface membrane. The discovery suggests that such “pharmacochaperones” may someday have therapeutic applications in patients with GnRH receptor mutations.<sup>68</sup>

# Chronic Anovulation and the Polycystic Ovary Syndrome

Anovulation is very common and has a number of different clinical manifestations, including amenorrhea, oligomenorrhea, and abnormal uterine bleeding. The condition, if long lasting, also has serious potential consequences, such as infertility and an increased risk for developing endometrial hyperplasia and neoplasia consequent to chronic estrogen dominance that remains unopposed by progesterone. In many anovulatory women, the pathophysiology for ovulatory dysfunction involves insulin resistance; these women are at an increased lifetime risk of developing type II diabetes mellitus and possibly also at risk for cardiovascular disease. In others, overt hypoestrogenism that results from disrupted ovarian folliculogenesis and chronic anovulation is associated with an increased risk for low bone mass and an enhanced lifetime fracture risk. All clinicians who care for women must therefore be thoroughly familiar with the evaluation and management of anovulatory women.

Normal ovulatory function requires coordination at all levels of the hypothalamic-pituitary-ovarian (HPO) axis (discussed in [Chapter 5](#)), and anovulation can result from disruption of functioning at any level of the HPO axis ([Figure 11.1](#)). This chapter considers the variety of mechanisms that can cause anovulation and the clinical consequences of chronic anovulation, focusing on the most common chronic anovulatory disorder, the polycystic ovary syndrome (PCOS), and its management.

**FIGURE 11.1**

# CAUSES OF ANOVULATION

---

The complex interaction of neuroendocrine, intraovarian, and endometrial mechanisms that regulate the normal ovulatory menstrual cycle is discussed in detail in other chapters in this text ([Chapters 4 and 5](#)). These mechanisms are summarized briefly here, to provide the foundation for subsequent discussion of the pathophysiology of anovulation.

As the corpus luteum regresses and the menstrual cycle draws to a close in the late luteal phase, serum concentrations of ovarian hormones estradiol, progesterone, and inhibin A decline to basal levels, releasing the hypothalamic-pituitary components of the HPO axis from their collective negative feedback effects. Accordingly, pulse frequency of the hypothalamic gonadotropin-releasing hormone (GnRH) secretion increases, which in turn stimulates pituitary secretion of follicle-stimulating hormone (FSH) secretion. Pituitary FSH in turn serves to “recruit” a new cohort of the ovarian small antral follicles or, more accurately, to rescue a group of follicles from an otherwise programmed demise via apoptosis. During the early follicular phase of the menstrual cycle, the serum concentration of inhibin B, which is secreted by the recruited pool of small growth and estrogen production ([Chapter 5](#)), rises progressively. This rise in circulating levels of inhibin B during the early follicular phase of the menstrual cycle in turn keeps the pituitary output of FSH in check through negative feedback, thus serving to control pituitary influence on ovarian follicular growth.

During the midfollicular phase of the menstrual cycle, ovarian autocrine and paracrine mechanisms involving activin and insulin-like growth factors enhance FSH-stimulated aromatase activity in ovarian follicular granulosa cells to help create and sustain the estrogenic microenvironment that is required for continued follicular growth and development. Whereas an estrogenic follicular milieu fosters further growth, an androgenic milieu promotes follicle atresia. As the serum inhibin B concentration reaches its peak, estradiol and inhibin A levels, derived from the granulosa cells of growing follicles in the cohort, begin increasing steadily. In response to their combined negative feedback effects, pituitary luteinizing hormone (LH) pulse amplitude decreases and pulse frequency increases (presumably reflecting the pattern of hypothalamic GnRH secretion), and serum concentrations of both FSH and LH fall gradually. Declining FSH levels remain sufficient to support continued growth of the selected dominant follicle, which has more granulosa cells and FSH receptors and a more advanced microvasculature compared to the remainder of smaller follicles in the recruited cohort, which are unable to continue to grow in the absence of FSH action and eventually are destined to apoptotic death.

During the late follicular phase, inhibin A and insulin-like growth factors combine to promote LH-stimulated androgen production in the ovarian theca cells, which

provides substrate for aromatization to estrogen in the proliferating mass of granulosa cells within the preovulatory follicle. FSH and estradiol then combine to induce expression of LH receptors on the granulosa cells that will mediate luteinization and ovulation when the follicle reaches full maturity. Ultimately, serum levels of estradiol derived from the preovulatory follicle exceed the threshold concentration required to exert positive feedback effects centrally, acting primarily on the pituitary to induce the midcycle LH surge. The LH surge completes follicular maturation and triggers a cascade of events resulting in extrusion of the oocyte and formation of the corpus luteum. The oocyte completes the first meiotic division, and local secretion of plasminogen activator and other cytokines mediates erosion of the follicular wall, allowing the oocyte to emerge with its surrounding investment of cumulus cells. The mural granulosa cells begin to luteinize and produce progesterone and, to lesser degree, estradiol.

After ovulation, serum estradiol concentrations fall precipitously, but only transiently, before rising again in parallel with progesterone and inhibin A produced by the corpus luteum. Progesterone transforms the endometrium from a proliferative to a secretory morphology and initiates a temporally restricted cascade of events that renders the endometrium receptive to embryo implantation. As the circulating progesterone level rises to its peak during the midluteal phase, LH pulse frequency decreases again and gonadotropin levels fall progressively to their nadir in the late luteal phase. Unless pregnancy intervenes and resulting rapidly rising levels of human chorionic gonadotropin (hCG) rescue the corpus luteum and stimulate continued high-level progesterone secretion, the corpus luteum has a finite life span and eventually regresses; progressive decline in estradiol and progesterone levels accompanies a failing corpus luteum, and this withdrawal of hormonal support for the endometrium results in a series of events that culminate in onset of menses ([Chapter 5](#)).

# Central Defects as a Cause of Anovulation

Although difficult to demonstrate, hypothalamic dysfunction offers both a logical and likely explanation for ovulatory dysfunction. A normal pituitary response to feedback signals from the follicle requires pulsatile GnRH secretion within a critical range for both pulse frequency and amplitude. The onset of puberty in girls results from decreasing central inhibition of GnRH neuronal activity and increasing pulsatile GnRH secretion, which stimulates a progressive increase in pituitary gonadotropin release and, in turn, ovarian follicular menstrual characteristics in adolescent girls typically vary until the HPO axis matures and the positive feedback relationship between estradiol and gonadotropin secretion and ovulation becomes established. **Factors that reactivate central inhibitory mechanisms, such as emotional, nutritional (weight loss, eating disorders), pharmacologic (opiates or dopaminergic agonists), or physical stress (excessive exercise), can suppress GnRH neuronal activity, leading to dysfunctional patterns of gonadotropin secretion that fail to promote progressive follicular development, resulting in anovulation.** Although such patients more commonly present with amenorrhea ([Chapter 10](#)), lesser degrees of GnRH neuronal suppression can result in homeostatic levels of pituitary-ovarian function and a euestrogenic chronic anovulatory state.

## Pituitary Tumors

Pituitary tumors can cause anovulation by inhibiting gonadotropin secretion. They may compress pituitary gonadotrophs directly or interrupt delivery of hypothalamic GnRH by compression of the pituitary stalk. Alternatively, they may cause hyperprolactinemia by interfering with the inhibitory actions of hypothalamic dopamine (the putative prolactin inhibitory hormone) on pituitary lactotrophs, resulting in a secondary suppression of pulsatile GnRH secretion ([Chapter 4](#)).

## Hyperprolactinemia

Hyperprolactinemia is another specific example of anovulation resulting from a central defect.<sup>1</sup> The mechanism involves disruption or inhibition of the normal GnRH pulse rhythm, resulting in ineffective or frankly low levels of pituitary gonadotropin secretion.<sup>2,3</sup>

Elevated prolactin levels can result in a spectrum of ovulatory dysfunction, ranging from a short luteal phase to anovulatory cycles to amenorrhea and hypogonadotropic hypogonadism, depending on the extent to which the gonadotropin secretion is disturbed or suppressed. Mild hyperprolactinemia may cause only a short luteal phase, resulting from inadequate preovulatory follicular development.<sup>1,4</sup> Moderate hyperprolactinemia

frequently causes oligomenorrhea or amenorrhea, and higher prolactin levels typically result in frank hypogonadism with low estrogen levels (Figure 11.2).<sup>5,6</sup> A breast examination with gentle compression looking for evidence of galactorrhea and measurement of the serum prolactin concentration are important parts of the evaluation of all anovulatory women.

**FIGURE 11.2**

## Abnormal Gonadotropin Secretory Dynamics

Abnormalities in GnRH pulsatility are principal drivers of abnormal gonadotropin secretion pattern and are commonly encountered in polycystic ovary syndrome (PCOS) as well as also seen with obesity-related ovulatory disturbances. Many, but not all, anovulatory women with polycystic ovaries (PCO) exhibit abnormal gonadotropin secretory dynamics.<sup>7,8</sup> The most common abnormality involving the gonadotropins is an increase in mean serum LH levels, due to an increase in both LH pulse frequency and amplitude.<sup>7,8</sup> Serum concentrations of FSH typically are normal or low. The pattern could result from a decrease in hypothalamic dopamine or opioid inhibition of pulsatile GnRH secretion,<sup>9</sup> or from abnormalities in steroid hormone feedback, including the lack of progesterone (due to anovulation)<sup>8</sup> or increased circulating androgen levels.<sup>9</sup> Other evidence from studies in nonhuman primates and women suggests strongly that prenatal exposure to increased androgen concentrations, induced by genetic and/or environmental factors, may program the GnRH pulse generator in the female fetus in such a way as to result in increased pituitary LH secretion, causing disordered follicular development and ovarian hyperandrogenism.<sup>10,11,12</sup> The increased prevalence of chronic anovulation and polycystic-appearing ovaries in women with epilepsy offers another example of how central nervous system dysfunction can disrupt the HPO axis and result in anovulation.<sup>13,14</sup>

# Abnormal Feedback Signals

Anovulation can result from abnormal estrogen feedback signals from the periphery, in two ways. Chronically elevated estrogen levels may not permit the increase in FSH secretion required to stimulate or sustain progressive follicular development (discussed in [Chapters 4 and 5](#)). Conversely, poor follicular development may not generate or sustain the estradiol level required to induce the ovulatory LH surge.

## Chronically Elevated Estrogen Concentrations

The fall in estradiol levels that normally occurs during the late luteal phase (as the corpus luteum regresses) is a prerequisite for the intercycle rise in FSH that drives the wave of new follicular development in the ensuing cycle. Sustained high levels of estrogen caused by increased production or decreased clearance and metabolism can, through negative feedback, prevent any significant increase in FSH levels, resulting in a chronic anovulatory state.

Pregnancy is the most common and obvious example of anovulation resulting from sustained high levels of estrogen production. Rare estrogen-producing ovarian tumors (e.g., granulosa cell tumors) can have the same effect. Although the adrenals do not normally secrete appreciable amounts of estrogen directly into the circulation, they contribute via their secretion of androgens (androstenedione, dehydroepiandrosterone, and its sulfate), which can be converted to estrogen in the periphery. Adipose tissue has significant aromatase activity, which converts androgens to estrogens,<sup>15</sup> thereby providing at least one mechanism for the well-known association between obesity and chronic anovulation (see below).

The clearance and metabolism of estrogen can be impaired in a variety of conditions, such as thyroid or hepatic disease. Both hyperthyroidism and hypothyroidism can cause chronic anovulation by altering the metabolic clearance and peripheral interconversion of steroid hormones.<sup>16,17,18</sup> **Hypothyroidism can be associated with elevated prolactin levels, providing the rationale for measuring serum thyroid-stimulating hormone (TSH), as well as prolactin, in the evaluation of anovulatory and amenorrheic women.** Hepatic disease also disturbs the normal clearance and metabolism of sex steroids.<sup>19</sup>

## Failure of the LH Surge

The rising estradiol levels arising from the preovulatory follicle in the late follicular phase induce the midcycle LH surge through a positive feedback effect primarily at the level of the pituitary, and this in turn stimulates ovulation (discussed in [Chapters 4 and](#)

5). Quite obviously, women with gonadal dysgenesis or ovarian failure are anovulatory because they have no remaining functional ovarian follicles and no significant estrogen production. More commonly, clinicians encounter patients with normal serum levels of gonadotropins and estradiol in whom the anovulation results from a failure to achieve complete follicular development and to generate and sustain the levels of estradiol required to induce the LH surge. Anovulatory cycles are common at extremes of reproductive ages such as in the months following menarche and in the perimenopausal period.

# Local Ovarian Conditions

Disturbance in one or more of the delicately balanced intraovarian regulatory mechanisms that serve to select the dominant follicle and allow it alone to grow and develop in the face of declining levels of FSH may lead to anovulation. Activins, inhibins, and insulin-like growth factors act via local autocrine and paracrine mechanisms to first enhance the action of FSH by increasing the concentration of FSH receptors within the dominant follicle and then act synergistically to induce the appearance of LH receptors that are required to mediate the actions of LH during the midcycle surge that drives the final stages of follicular maturation and stimulates ovulation. A follicle can thus fail to grow and ovulate due to a failure or interference with any of these local mechanisms (Chapter 5).

The “two-cell, two-gonadotropin” concept of ovarian follicular development (Chapters 4 and 5) emphasizes the critical importance of local androgen concentrations within the ovary. At low levels, ovarian androgens serve as substrate for FSH-induced aromatization and estrogen production. At higher concentrations however, intraovarian androgens are converted alternatively to more potent  $5\alpha$ -reduced androgens, which cannot be converted to estrogen and also inhibit aromatase activity and FSH induction of LH receptors on granulosa cells (Figure 11.3). Consequently, abnormally high local androgen concentrations, from any cause, impede follicular maturation, promote follicular atresia, and predispose to a chronic anovulatory state.

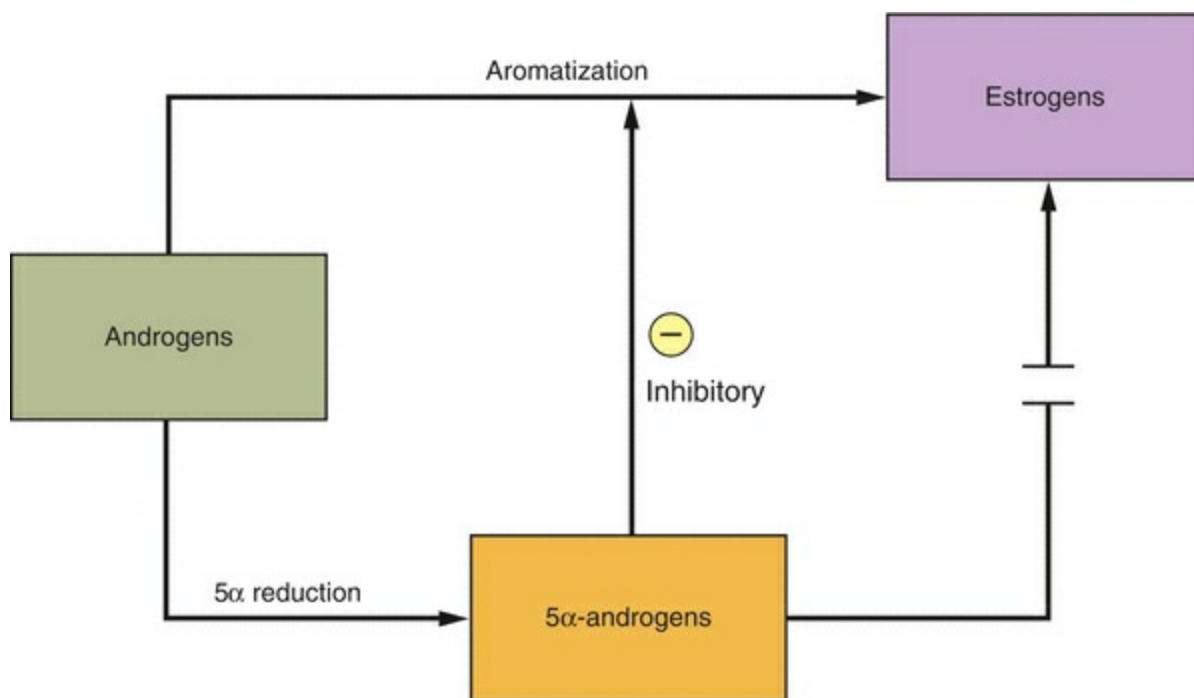

FIGURE 11.3

# Obesity

**Obesity predisposes to chronic anovulation in at least three distinct ways:**

1. Increased peripheral aromatization of androgens, resulting in chronically elevated estrogen concentrations.
2. Decreased levels of hepatic sex hormone binding globulin (SHBG) production, resulting in increased circulating concentrations of free estradiol and testosterone.
3. Insulin resistance, leading to a compensatory increase in insulin levels that stimulates androgen production in the ovarian stroma, resulting in high local androgen concentrations that impair ovarian follicular development. Importantly, mild insulin resistance as well as some degrees of hyperandrogenemia are often encountered as a physiologic phenomenon at puberty. However, both these states get exacerbated in the setting of childhood obesity.<sup>20</sup> These two features—persistent insulin resistance and elevated androgens—ultimately predispose to a PCOS phenotype in obese adolescents.<sup>19</sup>

Even modest weight loss, which results in decreased circulating insulin and androgen concentrations, frequently restores ovulatory function and normal menstrual cyclicity.<sup>21,22,23,24</sup> Therefore, in obese girls and women who are experiencing menstrual irregularity, weight reduction must be considered as a first-line management approach.

# Defining the Cause of Anovulation

Whereas the underlying cause of anovulation may be relatively clear, such as in women with ovarian failure (amenorrhea accompanied by menopausal symptoms, discussed in [Chapter 17](#)), more often than not, the exact cause for ovulatory dysfunction may not be obvious, but gets unmasked on further testing (such as hyperprolactinemia and hypothyroidism). Often however, it may not be possible to isolate the specific underlying mechanism. Goals of management are twofold: firstly, to establish or rule out identifiable causes of anovulation ([Table 11.1](#)) and, secondly, to identify the patient's prioritized goals and needs, so as to ensure that their concerns are targeted while also addressing the underlying etiology. **Women with absent or abnormal menstrual function who are otherwise healthy can be categorized as follows:**

## TABLE 11.1 Common Causes of Anovulation

Common Causes of Anovulation	Diagnosis	Reviewed Elsewhere in This Volume
Pregnancy	Elevated hCG	Chapter 7
Thyroid dysfunction	Elevated TSH—primary hypothyroidism Suppressed TSH—primary hyperthyroidism	Chapter 20
Hyperprolactinemia	Elevated prolactin Abnormal pituitary imaging	Chapter 5
Late-onset CAH	Elevated total testosterone, DHEA-S, 17-OH progesterone	Chapter 13
Obesity/insulin resistance	Elevated fasting and/or provoked insulin levels	Chapter 19
Ovarian failure	Elevated FSH Suppressed estradiol, undetectable inhibin B, AMH	Chapters 10 and 17
Iatrogenic Antianxiety/antidepressant Androgens	Elevated prolactin Elevated testosterone depending on the type of formulation	Chapter 4
Psychological stress	Prolactin may be elevated Normal or low-normal FSH/LH Low estradiol	Chapter 4
Eating disorders	Low to low-normal FSH/LH Low estradiol Low free T3 (anorexia)	Chapter 4

1. Ovarian failure. Hypergonadotropic hypogonadism, reflecting the inability of the ovary to respond to gonadotropin stimulation, due to follicular depletion ([Chapter 10](#))
2. Central defects. Hypogonadotropic hypogonadism, reflecting hypothalamic or pituitary failure or suppression ([Chapter 10](#))
3. HPO dysfunction, resulting in asynchronous gonadotropin and estrogen production, having a wide variety of causes and clinical manifestations that depend on the level of ovarian function, including amenorrhea ([Chapter 10](#)), hirsutism ([Chapter 12](#)), abnormal uterine bleeding ([Chapter 14](#)), endometrial hyperplasia and cancer ([Chapter 17](#)), and infertility ([Chapter 25](#))

PCOS is the most obvious and common condition associated with chronic anovulation, affecting 4–6% of reproductive-age women, although given changes in diagnostic criteria, the prevalence has doubled.<sup>25,26,27</sup> **It is inaccurate to state that PCOS is the most common “cause” of anovulation, because PCOS does not cause anovulation; rather, anovulation is commonly encountered in women with PCOS.** Several mechanisms are recognized to contribute to the pathophysiology of anovulation in PCOS, operating at every level of the reproductive system. **Although the term PCOS**

**is now firmly established in our scientific and clinical lexicon, it is important to emphasize that PCOS is not a discrete or specific endocrine disorder having a unique cause or pathophysiology; rather, PCOS is a heterogeneous disorder that is best approached as a diagnosis of exclusion. When diagnosed, approach to PCOS requires a systematic elimination of conditions that can masquerade as PCOS and a thought-out management to address both overt symptoms and covert risks that are recognized sequela of this syndrome.**

# POLYCYSTIC OVARY SYNDROME

---

Multicystic or “sclerocystic” ovaries were recognized as early as the mid-18th century but associated primarily with pelvic pain or menorrhagia. In the early 20th century, prevailing hypotheses viewed them as resulting from inflammation due to infection, from congestion due to pressure or partial torsion that disrupted normal blood flow to the ovary, or from dystrophy due to abnormalities in ovarian nutrition.<sup>28</sup>

In 1935, Irving F. Stein and Michael L. Leventhal first described a symptom complex associated with anovulation.<sup>29</sup> Both gynecologists were born in Chicago, both were graduates of Rush Medical College, and both spent their entire professional careers at the Michael Reese Hospital.<sup>30</sup> Stein and Leventhal described seven patients (four being obese) with amenorrhea, hirsutism, and enlarged, PCO. They reported that all seven resumed regular menses and that two became pregnant after bilateral ovarian wedge resection, involving the removal of one-half to three-fourths of each ovary. Stein and Leventhal developed the wedge resection procedure after observing a resumption of menses following ovarian biopsy in several patients with amenorrhea. They speculated that the thickened ovarian capsule prevented follicles from reaching and escaping from the surface of the ovary.

Careful histologic studies of the “Stein-Leventhal ovary” revealed that they had twice the cross-sectional area of normal ovaries, the same number of primordial follicles, double the number of developing and atretic follicles, a 50% thicker and more collagenized tunica, a fivefold thicker subcortical stroma, and a fourfold greater number of hilar cell “nests” than normal ovaries. These studies further suggested that “hyperthecosis,” characterized by an abundance of such nests and a markedly increased stroma, was likely just a later or more advanced stage of a progressive process.<sup>31</sup>

**Because there are many causes of anovulation, there are many causes of PCO.** Any of the causes of anovulation outlined earlier can yield the same or a similar clinical presentation. Furthermore, it is important to note that PCO (as discussed in the next section) can be found in up to a third of normal cycling/ovulating women.<sup>32</sup> **The polycystic-appearing ovaries result from a functional derangement and not from any one specific central or local defect.**

# Diagnostic Criteria for PCOS

It is generally accepted that PCOS is not a specific endocrine disease but a syndrome represented by a collection of signs and symptoms and that no one sign, symptom, or test is diagnostic. Not surprisingly, establishing criteria for diagnosis of PCOS has proven both challenging and controversial.

It has been argued that having a clear and specific definition for PCOS is important because affected women are at increased risk for a variety of problems (infertility, abnormal uterine bleeding, endometrial cancer, obesity, type 2 diabetes mellitus, dyslipidemia, hypertension, and cardiovascular disease), because this diagnosis can have health implications for other family members, and because the need for lifelong treatment may affect access to health care insurance in systems like that in the United States.<sup>33</sup> **One of the advantages to having specific diagnostic criteria for PCOS relates to research, because varying criteria cloud the conclusions and question the generalizability of results from studies involving women who are identified with “PCOS.” Responsibility of clinicians lies well beyond simply assigning a diagnostic label of PCOS; rather, emphasis should be on understanding the underpinnings to the clinical picture and to long-term health implications and consequences of chronic anovulation, so as to effectively address patient needs while minimizing lifetime risks.**

Diagnostic criteria of PCOS have evolved with time, concomitant with advances in our understanding of reproductive medicine and advances in medical technology. The earliest descriptions of the disorder were based on findings of enlarged ovaries, hirsutism, and menstrual dysfunction.<sup>29</sup> The advent and then refining of hormone assays moved the focus to serum gonadotropin and androgen concentrations.<sup>34</sup> More recent advances in ultrasonography and recognition of the importance of insulin resistance in the pathophysiology of PCOS have turned attention to ovarian morphology<sup>34</sup> and to the metabolic accompaniments and consequences of the disorder.

There have been three separate and distinct efforts to establish or refine the diagnostic criteria for PCOS (Table 11.2). The first was a conference sponsored by the National Institute of Child Health and Human Development (NICHD) in 1990, concluding that the major criteria for diagnosis of PCOS (in order of importance) were (1) hyperandrogenism and/or hyperandrogenemia, (2) menstrual dysfunction, and (3) exclusion of other endocrinopathies having a similar clinical presentation.<sup>35</sup> The second was a conference cosponsored by the European Society of Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM), convened in Rotterdam, the Netherlands, in 2003, concluding that diagnosis of PCOS should be based on at least two of the three major criteria: (1) oligoanovulation, (2)

clinical or biochemical signs of hyperandrogenism, and (3) polycystic-appearing ovary(ies) (assessed by ultrasonography, described as an ovarian volume of more than 10 mL<sup>3</sup> and/or more than 12 follicles measuring between 2 and 9 mm in size in at least one ovary; **Figure 11.4**), also excluding other endocrinopathies having a similar clinical presentation.<sup>36,37</sup> The third was a task force appointed by the Androgen Excess and PCOS Society (AE-PCOS) in 2006, concluding that diagnosis of PCOS requires (1) hyperandrogenism (hirsutism and/or hyperandrogenemia), (2) ovarian dysfunction (oligoanovulation or PCO), and (3) exclusion of other androgen excess or related disorders.<sup>38</sup>

## **TABLE 11.2 PCOS: Diagnostic Classification**

Criteria	National Institute of Health (NIH) Criteria 1990	Rotterdam Criteria 2003	Androgen Excess and PCOS Society Criteria 2006
1 Irregular periods <sup>b</sup>	1 and 2 <sup>a</sup>	Any 2 of 3 <sup>a</sup>	1 and 2 <sup>a</sup>
2 Elevated serum androgens or Hyperandrogenism Hirsutism Acne Androgenetic alopecia			or 2 and 3 <sup>a</sup>
3 Polycystic ovarian morphology (PCOM) or polycystic ovary (PCO) <sup>c</sup>			

<sup>a</sup>Differential diagnoses that can mimic clinical presentation must be excluded.

<sup>b</sup>Eight or less menses per year.

<sup>c</sup>Ovarian volume >10 mL<sup>3</sup> and/or >12 follicles between 2 and 9 mm in size in at least one ovary.

**FIGURE 11.4**

The original 1990 NICHD diagnostic criteria were based on traditional concepts of PCOS, requiring evidence of both hyperandrogenism (hyperandrogenemia and/or hirsutism) and menstrual dysfunction (oligo-/amenorrhea), with or without the presence of PCO. The 2003 ESHRE/ASRM (“Rotterdam”) criteria sought to recognize and accommodate a broader spectrum of the disorder. Given that women need only fulfill two of the three diagnostic criteria, it allows for inclusion of women with regular menstrual cycles and/or women having neither hyperandrogenemia nor hirsutism. The 2006 AE PCOS Society criteria allowed that either menstrual irregularity or polycystic

ovarian appearance be considered as a sign of ovarian dysfunction. However, unlike the Rotterdam criteria, AE-PCOS Society emphasizes the existence of signs or symptoms of hyperandrogenism as a requisite for diagnosing PCOS. Recently, the AE PCOS Society has recommended that threshold for number of small follicles needed for PCO diagnosis be increased from more than 12 to  $\geq 25$ .<sup>39</sup>

Women with the NIH-defined criteria have an increased risk of having reproductive and metabolic disorders (e.g., type 2 diabetes mellitus, obesity, dyslipidemia).<sup>40</sup> Ovulatory women with PCOS more often have a lower body mass index (BMI) and exhibit less severe degrees of hyperinsulinemia and hyperandrogenism than women with the NIH-defined criteria.<sup>41</sup> Oligo-/anovulatory women without clinical or biochemical signs of excess androgens tend to be least affected by the sequela of PCOS.<sup>25</sup>

Recently, antimüllerian hormone (AMH), a member of the transforming growth factor- $\beta$  (TGF- $\beta$ ) superfamily, has been implicated as another potential marker/contributor to PCOS.<sup>42</sup> AMH is produced by granulosa cells, and expression is greatest in the granulosa cells of follicles measuring less than 4 mm (preantral and antral follicles). In women with PCOS, there is an excessive amount of AMH, which is likely explained by increased follicles in the antral and preantral stages, which, as previously mentioned, produce the greatest amounts of AMH.<sup>42</sup> Further studies have also demonstrated that AMH production is increased severalfold in anovulatory PCOS and normo-ovulatory PCOS women when compared to “normal” ovaries, suggesting a dysregulation of the granulosa cells.<sup>42</sup> While the mechanism of increased production is not known, evidence supports a role for androgens, as there is a positive correlation between androgen and AMH levels. Interestingly, AMH also decreases FSH receptor and ovarian aromatase expression. In doing so, it prevents the continued follicular growth and development needed to reach maturity, resulting ultimately in follicular arrest, with no dominant follicle selected.<sup>42</sup> Given these recent findings, AMH has been proposed as an inclusion criterion for the diagnosis of PCOS, likely replacing (or serving as a surrogate for) PCO morphology, as studies have demonstrated that an AMH of 5 ng/mL (using the EIAMH/MIS kit) has a high specificity (97%) and greater sensitivity than the current criteria for PCO morphology.<sup>42</sup> Of note, given no standardization/validation across populations as of yet, exercising caution is recommended before replacing PCO-appearing ovaries on US with AMH level; rather, a threshold of AMH  $\geq 5$  ng/mL may be used as a further suggestion of PCOS, much like the utility of a reversed FSH/LH ratio in serving to suggest ovulatory dysfunction.

The diagnostic criterion most commonly utilized in clinical practice for diagnosing PCOS is the “Rotterdam” criterion.<sup>20</sup> However, the overall prevalence of PCOS among different populations (accounting for the three different diagnostic criteria) is relatively

similar (NIH 6%, Rotterdam and AE-PCOS 10%).<sup>43</sup> Regardless of the criteria utilized to diagnose PCOS, it is important to rule out common causes of anovulation ([Table 11.1](#)) and exclude other potential endocrinopathies and conditions that can mimic PCOS (discussed later in this chapter).

# Pathophysiology of Polycystic Ovary Syndrome

Whereas the morphologic characteristics of PCO were attributed at first to pathologic changes in the ovaries themselves that prevented ovulation,<sup>31</sup> they now are recognized as reflecting the disordered endocrine milieu that results from chronic anovulation. In contrast to the cyclic pattern of hormone concentrations that occurs during the normal cycle, the endocrine milieu in women with chronic anovulation is characterized by a “steady state” in which gonadotropin and sex steroid concentrations vary relatively little, by comparison.

The average daily production of both androgens and estrogens is increased in women with PCOS, as reflected by elevated serum concentrations of testosterone, androstenedione, dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), 17 $\alpha$ -hydroxyprogesterone (17-OHP), and estrone. The results of treatment with a long-acting GnRH agonist (aimed at suppressing gonadotropin-dependent ovarian steroid production) indicate that the increases in serum testosterone, androstenedione, and 17-OHP derive from the ovary and are LH-dependent, whereas those in DHEA and DHEA-S derive from the adrenal.<sup>44,45,46,47</sup> Serum estrone concentrations are modestly elevated, due to peripheral conversion of increased amounts of androstenedione. In contrast, serum estradiol levels in women with PCOS fluctuate but generally remain within the range typically observed in the early follicular phase,<sup>48</sup> reflecting continued low-level production from limited follicular development.<sup>49,50</sup> Unlike the cyclic fluctuations in the HPO hormone concentrations that occur during and are determinants of normal ovulatory menstrual cycles, an altered pattern of gonadotropin secretion, chronic hyperandrogenemia, and insulin resistance (usually, though not always, associated with obesity) all contribute, to varying degrees, to the ovarian dysfunction of PCOS.<sup>25</sup> An altered pattern of GnRH release that leads to an increased LH pulse frequency (as discussed earlier) offers a unifying mechanism for both ovarian androgen excess (due to LH-mediated stimulation of androgen production by ovarian stroma) and impaired follicle development that results in chronic anovulation (due to the relatively low FSH levels that occur secondary to altered GnRH release pattern). The state of hyperandrogenism resulting from ovarian androgen excess in turn contributes to as well as gets further perpetuated by insulin resistance and the resultant hyperinsulinemia. A vicious cascade of events is thus created with insulin excess worsening hyperandrogenism through further ovarian androgen production and also by lowering of hepatic SHBG production. The endocrine milieu in women with PCOS therefore reflects a chronic anovulatory state, which may result from a wide variety of causes (**Figure 11.5**). **Current perspectives view PCOS as a complex disorder, similar to cardiovascular disease and type 2 diabetes mellitus, wherein numerous genetic variants and environmental factors interact, combine, and contribute to the**

**pathophysiology.**<sup>38</sup> In recent years, attention has focused on identifying genetic variants including involved in the regulation of gonadotropin secretion and action, insulin secretion and action, weight and energy regulation, and androgen synthesis and action, which may shed light on causative mechanisms for PCOS.

**FIGURE 11.5**

**Beyond the clinical stigmata of androgen excess and anovulation of PCOS, the hormonal environment sets a stage for a number of metabolic sequelae commonly encountered in women with PCOS and that contribute to lifetime health risks in this population.**

The pathophysiology of PCOS is most likely multifactorial involving endocrine, metabolic, genetic, epigenetic, and environmental factors. The following sections describe how each of the aforementioned factors may be relevant to the pathogenesis of this complex disorder.

## Gonadotropin Secretion and Action

Stein and Leventhal suggested that PCO were likely to result from abnormal anterior pituitary hormonal stimulation,<sup>29</sup> based on earlier observations that treatment with a

urinary extract of anterior pituitary hormones could induce changes similar to those in PCO.<sup>51</sup> Subsequent studies employing an LH bioassay (based on the ovarian response of immature female rats or the prostatic response of hypophysectomized male rats to urinary extracts) demonstrated excessive LH activity in women with PCOS,<sup>52,53,54,55</sup> which later was confirmed by studies using a radioimmunoassay.<sup>56</sup>

**Compared to normally cycling women, those with PCOS generally exhibit increased serum LH concentrations, low-normal FSH levels, and increased LH to FSH ratios.<sup>8,57,58</sup> The increase in serum LH levels results from abnormal LH secretory dynamics, characterized by an increase in LH pulse frequency and, to a lesser extent, also in pulse amplitude.<sup>7,59–61</sup> The decrease in FSH levels results from the increase in GnRH pulse frequency, the negative feedback effects of chronically elevated estrone concentrations (derived from peripheral aromatization of increased androstenedione), and normal or modestly increased levels of inhibin B (derived from small follicles).<sup>62,63</sup>**

LH pulse frequency in women with PCOS does not exhibit the normal cyclic variation seen in ovulatory women (discussed in [Chapter 5](#)) and is relatively constant, at approximately one pulse per hour ([Figure 11.6](#)). This pattern presumably reflects a similar increase in hypothalamic GnRH pulse frequency, which favors secretion of LH more than FSH.<sup>64,65,66</sup> The LH response to an acute exogenous GnRH stimulus also is exaggerated in women with PCOS, but to a lesser extent in the obese than in lean PCOS women; accordingly, LH pulse amplitude and serum LH levels are generally somewhat lower in obese than in lean women with PCOS.<sup>8,67</sup> Elevated serum LH concentrations in women with PCOS also exhibit increased bioactivity in bioassay systems in vitro, reflecting a difference in glycosylation with a predominance of more basic (alkaline) LH isoforms, which have greater bioactivity.<sup>60,68,69,70</sup>

**FIGURE 11.6**

The approximate hourly LH pulse frequency in women with PCOS is within the range of frequencies usually observed in the late follicular phase of a normal ovulatory cycle which favor LH over FSH release ([Chapter 4](#)); these observations imply that the defective mechanism in PCOS appears to lie in the failure of processes that normally slow the GnRH pulse generator rather than resulting from an abnormal acceleration in the GnRH pulse frequency. The increased pulse frequency might reflect an intrinsic hypothalamic dysfunction, the effects of abnormal feedback signals from the periphery, or both.<sup>71</sup>

Since dopamine and opioids normally inhibit hypothalamic GnRH neuronal activity (discussed in [Chapter 4](#)), the higher GnRH pulse frequency observed in women with PCOS may be secondary to a decrease in dopaminergic or opioidergic neuronal signals to the GnRH neurons. However, experimental evidence from studies involving treatment with medications that stimulate or inhibit these pathways does not support either mechanism. Treatment with a dopamine agonist has no discernible effect on the pattern of gonadotropin secretion in women with PCOS.<sup>72,73</sup> Treatment with a progestin slows LH pulse frequency,<sup>74</sup> just as progesterone does during the normal luteal phase, indicating that the opioid-dependent process that normally mediates the effects of progesterone is operating.<sup>75,76,77</sup> While these observations suggest that any alterations in GnRH pulsatility and decrease in opioid tone result primarily from the lack of progesterone feedback, that itself is a consequence of anovulation. However, in a transgenic mouse model in which GnRH neurons were labeled with green fluorescent protein, dihydrotestosterone (DHT) exposure resulted in increased excitatory inputs to GnRH neurons while impairing progesterone inhibition of GnRH pulse firing suggesting a greater complexity to the mechanisms that underlie HPO dysfunction of PCOS.<sup>78</sup>

Infusion of exogenous insulin<sup>79,80,81</sup> and treatments that decrease insulin levels (metformin, thiazolidinediones) have no significant effect on the pattern of LH secretion in women with PCOS.<sup>81,82</sup> LH levels also are lower in obese than in lean women with PCOS, even though insulin levels are higher in the obese.<sup>8,67</sup> These observations suggest that hyperinsulinemia has no significant direct effect on LH secretion. While insulin may not be causative to the hypothalamic-pituitary dysfunction of PCOS, as discussed earlier, insulin however does act synergistically with LH to perpetuate ovarian androgen production; these effects of insulin are mediated via a distinct pathway specific to insulin binding to its own receptor.<sup>83</sup>

Treatment with exogenous estrone does not increase basal or GnRH-stimulated LH concentrations in women with PCOS,<sup>84</sup> and treatment with an aromatase inhibitor does not decrease LH pulse frequency,<sup>85</sup> indicating that increased circulating levels of estrone may exert negative feedback effects on FSH, but probably do not have any important direct influence on LH secretion in women with PCOS. Whereas the lack of progesterone feedback resulting from anovulation undoubtedly contributes to the higher LH pulse frequency,<sup>74</sup> evidence suggests that the GnRH pulse generator also is less sensitive to the feedback inhibition of sex steroids. Treatment with an estrogen-progestin contraceptive or with physiologic doses of exogenous estrogen and progesterone slows LH pulse frequency in women with PCOS, but to a lesser extent than in normal women.<sup>86,87,88</sup> However, after pretreatment with flutamide (an androgen receptor antagonist), the effects of estrogen and progesterone on LH pulse frequency in women with PCOS are the same as in normal women,<sup>89</sup> suggesting that increased circulating androgen levels help to sustain the higher LH pulse frequency observed in women with PCOS by decreasing sensitivity to estrogen and progestin feedback.

Androgens also may contribute more directly to the abnormal pattern of gonadotropin secretion in women with PCOS. Evidence from studies in rats, sheep, monkeys, and women indicates that prenatal exposure to increased androgen concentrations may affect GnRH pulse generator programming, predisposing to an increased pulse frequency and LH secretion.<sup>11,12,90,91,92,93</sup> At least in rodents, prenatal androgen treatment also decreases basal and estrogen-induced hypothalamic progesterone receptor concentrations,<sup>92</sup> offering a mechanistic explanation for how androgens might decrease hypothalamic sensitivity to progesterone feedback, and provides support for a neuroendocrine origin of PCOS. It may be that hyperandrogenemia from any cause, arising during fetal life (maternal hyperandrogenism, classical congenital adrenal hyperplasia [CAH]), adolescence (premature adrenarche, nonclassical CAH), or in adulthood (obesity, hyperinsulinemia), induces abnormalities in the feedback control of pulsatile GnRH secretion, resulting in increased LH secretion, which stimulates increased ovarian androgen production, in a

self-perpetuating cycle.

Studies in rhesus monkeys, which display the most similar HPO axis to humans, have furthered our understanding of the interplay between androgens and gonadotropins and PCOS phenotype. In utero exposure of rhesus fetuses to excess testosterone has resulted in hormonal, reproductive, and metabolic disorders that are reminiscent of PCOS.<sup>93</sup> Following puberty, those animals exposed to excess testosterone in utero displayed LH hypersecretion, ovulatory dysfunction, hyperandrogenism, insulin resistance, and PCO (in 50%). The endocrine and metabolic effects of in utero exposure to excess androgens were also notable in the second-generation female offspring suggesting in utero programming effects.<sup>93</sup> Studies in the nonhuman primate model in particular provide support for a causative role for androgens in altering gonadotropin secretion in PCOS.

The primary evidence indicating that excessive LH stimulation plays an important role in the pathophysiology of PCOS comes from studies examining the effects of treatment with GnRH antagonists and long-acting GnRH agonists. In women with PCOS, treatment with a GnRH antagonist induces an acute dose-dependent decrease in both LH and testosterone concentrations,<sup>61</sup> and long-term treatment with an agonist can suppress ovarian androgen production to postmenopausal levels.<sup>32,94</sup> **These observations suggest that excessive LH secretion or stimulation may be an important cause of disordered follicular development and anovulation, but is not the proximate cause of PCO or of increased ovarian androgen production in women with PCOS.** A reversed FSH/LH ratio (higher LH than FSH levels) is often encountered in women with PCOS (more so in the lean compared to obese populations), and LH/FSH ratios of more than 2–3 are often interpreted to suggest PCOS diagnosis; the reliability of this observation is questionable given that the gonadotropin levels can vary by the gonadotropin assays used and are noninformative in the setting of obesity. **Consequently, gonadotropin levels or ratios are not reliable in helping diagnose PCOS.**

## **Insulin Secretion and Action**

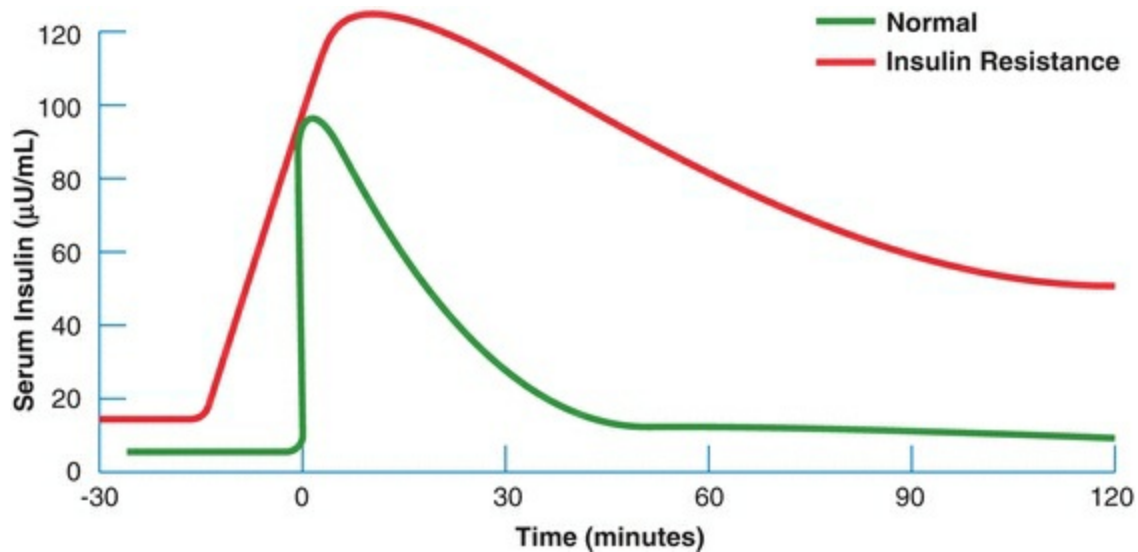

An association between glucose intolerance and hyperandrogenism was first recognized by Archard and Thiers in 1921, in a famous report describing a bearded diabetic woman.<sup>95</sup> Insulin resistance was first described in diabetic patients who required progressively higher doses of insulin to maintain effective glucose control, most often because they developed antibodies to preparations of insulin derived from animal sources.<sup>96</sup> Today, we recognize insulin resistance as a feature of a wide variety of disorders and conditions, ranging from extreme insulin resistance syndromes (autoantibodies to the insulin receptor, insulin receptor mutations, lipodystrophic

states)<sup>97,98,99</sup> to common problems such as type 2 diabetes, obesity, stress, infection, pregnancy, as well as PCOS. The importance of insulin resistance, hyperinsulinemia, and insulin action in the pathogenesis of PCOS was first suggested by a study conducted in 1980, demonstrating significant correlations between basal levels of plasma insulin, androstenedione, and testosterone and between insulin and testosterone levels after an oral glucose load.<sup>100</sup>

**Insulin resistance is a common feature in obese and, to a lesser extent, lean women with PCOS; the overall prevalence ranges between 50% and 75%.<sup>101,102,103</sup>** Insulin sensitivity is decreased by an average of 35–40% in women with PCOS, compared to normal women, similar to what is observed among women with non-insulin-dependent diabetes mellitus.<sup>104,105,106</sup> **Up to 35% of women with PCOS exhibit impaired glucose tolerance, and 7–10% meet the criteria for type 2 diabetes mellitus.<sup>107,108,109</sup>** Conversely, women with type 2 diabetes are sixfold more likely than nondiabetic women of similar age and weight to have PCOS.<sup>110</sup>

**In obese PCOS women, 70–80% are insulin-resistant, while 20–25% of lean women with PCOS are insulin-resistant.**

Insulin resistance is a condition in which endogenously or exogenously administered insulin has less than normal effects on fat, muscle, and the liver.<sup>111,112</sup> In adipose, insulin resistance results in increased hydrolysis of stored triglycerides and elevated circulating free fatty acid levels. Decreased glucose utilization (primarily in muscle) and increased hepatic gluconeogenesis (which insulin normally inhibits) result in increased blood glucose concentrations and a compensatory hyperinsulinemia (in those with adequate pancreatic reserve). Elevated fasting insulin levels are recognized as biochemical evidence of insulin resistance; however, fasting insulin levels may not be consistently elevated in all with insulin resistance. Insulin response to oral glucose load offers meaningful understanding of insulin response, sensitivity, and dynamics. In metabolically normal individuals, following ingestion of 75 g of oral glucose load as utilized for a 2-hour oral glucose tolerance test (OGTT), peak insulin levels are attained within 30 minutes of glucose ingestion and correspond to the first phase insulin release, and insulin levels subsequently decline over the duration of the 2-hour test. In contrast to regularly menstruating women, insulin response in women with PCOS is often exaggerated and prolonged (**Figure 11.7**). **Increased circulating insulin levels cause or contribute to hyperandrogenism in women with PCOS in at least two important ways—by stimulating increased ovarian androgen production and by inhibiting hepatic SHBG production.**

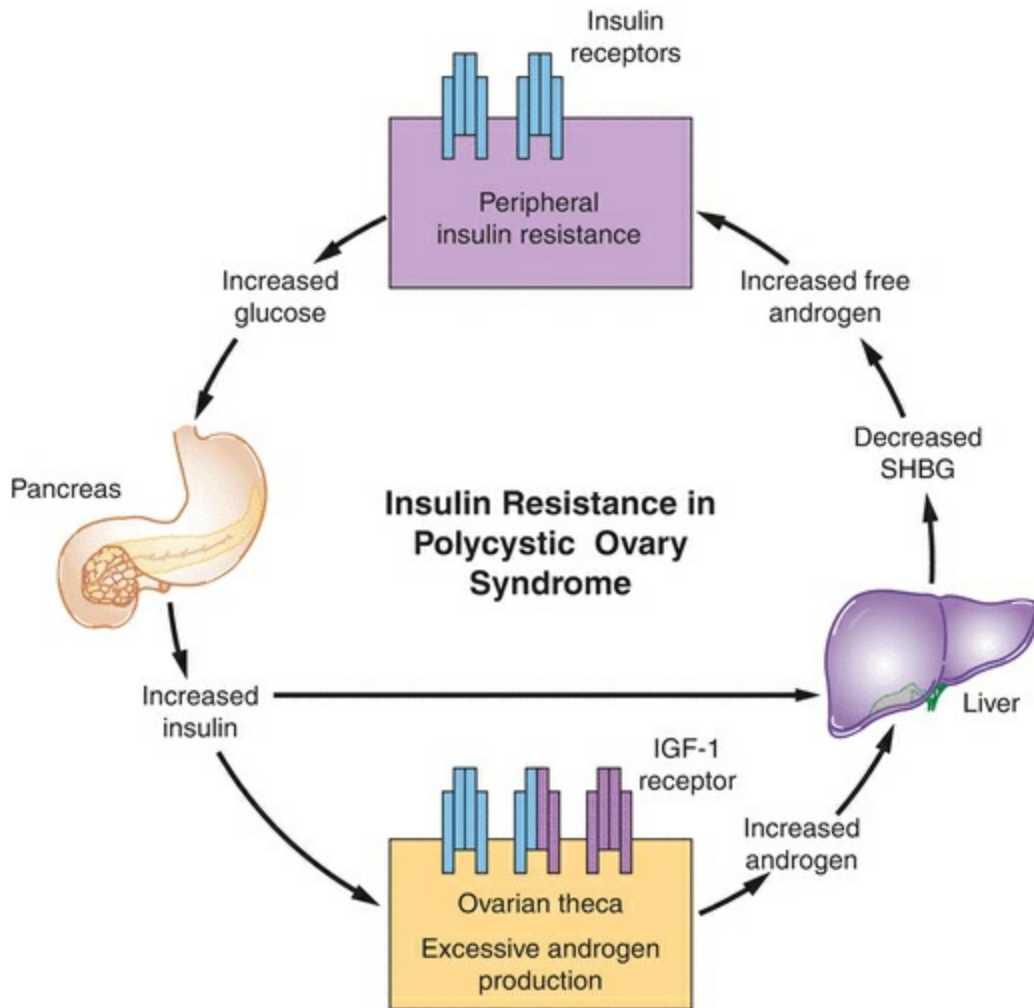

**FIGURE 11.7**

Numerous studies have demonstrated that insulin stimulates androgen production in ovarian theca cells in vitro.<sup>113</sup> Theca cells from women with PCOS also exhibit increased sensitivity to insulin, compared to those from normal women. Physiologic levels of insulin can stimulate androgen synthesis in theca cells of women with PCOS, whereas higher insulin concentrations are required in normal theca cells.<sup>114,115</sup> **Because insulin also potentiates the action of LH,<sup>116</sup> insulin and LH act synergistically to stimulate androgen production.<sup>114,117</sup>**

Clinical investigations in women with PCOS have demonstrated that insulin also stimulates ovarian androgen production in vivo. Notably, the cumulative sum insulin response during an OGTT correlates positively with the rise in serum androstenedione and testosterone above baseline concentrations.<sup>118</sup> Moreover, suppression of serum insulin levels by treatment with diazoxide or an insulin-sensitizing agent (troglitazone) decreases serum androstenedione and testosterone levels in women with PCOS.<sup>119</sup>

High insulin concentrations also inhibit hepatic SHBG production,<sup>120,121</sup> as do high androgen concentrations.

**The combined actions of insulin and androgens lower SHBG concentrations, yielding increased free androgen levels, which aggravate the underlying insulin resistance.<sup>122</sup> Ultimately, these conditions foster a self-propagating positive feedback loop that can increase in severity over time (Figure 11.8).**

**FIGURE 11.8**

Insulin stimulates ovarian androgen production acting via insulin receptors on theca/interstitial cells in the ovarian stroma.<sup>115,123</sup> At high concentrations, insulin also binds to IGF-1 receptors (and possibly hybrid receptors), which are structurally similar and use a similar signaling mechanism.<sup>104</sup> Insulin also acts primarily via its own receptor, by activating a signaling system separate from that involved in glucose transport.<sup>83</sup> Whereas an anti-insulin receptor antibody effectively inhibits insulin-stimulated steroidogenesis in cultured human granulosa cells, an anti-IGF receptor antibody has no effect.<sup>115,124,125</sup> In recent years, two stereoisomers of inositol, D-chiro-inositol and myoinositol, have received increasing attention as possible modulators of insulin signaling in PCOS. In vitro experiments utilizing D-chiro-inositol-containing glycan demonstrated increased theca cell testosterone production, and preincubation with an anti-inositolglycan antibody was shown to block insulin stimulation, but not that of hCG.<sup>115</sup> These observations suggest inositolphosphoglycan mediators act as second messengers in signal transduction for insulin stimulation of theca cell androgen synthesis

and that the mechanism differs from that mediating the actions of LH. Interestingly, treatment of women with PCOS with D-chiro-inositol, with myoinositol, and more recently with a combination of the two stereoisomers in the ratio of 1 (D-chiro-inositol) to 40 (myoinositol) has shown to result in improvements in clinical, endocrine, and metabolic parameters.<sup>126,127,128</sup>

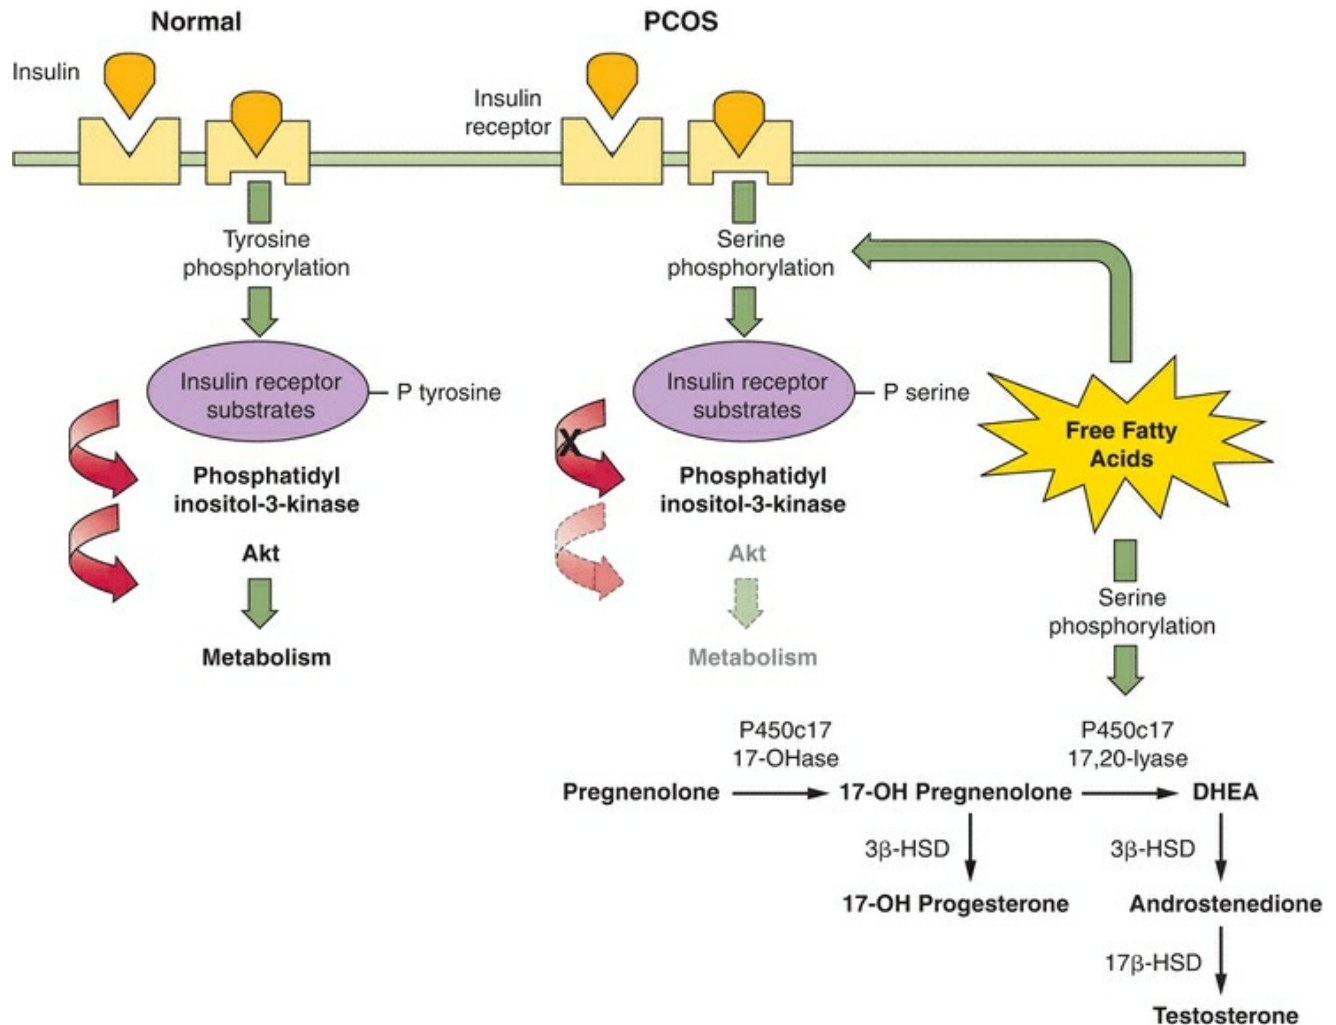

What causes insulin resistance in women with PCOS is not entirely clear. Not surprisingly, given the complexity and polygenic nature of the disorder, evidence suggests that more than one mechanism may be involved.

The classical actions of insulin are mediated via its receptor and two distinct intracellular pathways. The phosphatidyl-inositol 3-kinase (PI-3K) pathway mediates the metabolic effects of insulin, and the mitogen-activated protein kinase (MAPK) pathway mediates the proliferative actions of insulin. Normally, insulin binding to its receptor induces a conformational change, resulting in tyrosine phosphorylation of the receptor and protein substrates, which bind and serially activate PI-3K and Akt, an effector molecule that plays the major role in signal transduction for glucose regulation and metabolism.<sup>129,130</sup> Akt activation potentiates the translocation of glucose transporter 4 (GLUT4) from intracellular compartments to the plasma membrane, thereby increasing glucose uptake. Other effector molecules mediate insulin inhibition of gluconeogenesis and glycogenolysis,<sup>131,132</sup> stimulation of lipid synthesis, and inhibition of lipid catabolism.<sup>133,134</sup> Luteinized granulosa cells obtained from women with PCOS display both a selective increase in insulin activation of the mitogenic pathway, via MAPK, and resistance in the PI-3K-mediated metabolic pathway of insulin action.<sup>135,136</sup> **These and similar observations illustrate how insulin actions can be selectively inhibited and enhanced at the same time, via different signaling pathways,<sup>104,135</sup> explaining how insulin can stimulate hyperandrogenism in women who are “insulin-resistant.”**

Studies in cultured skin fibroblasts, muscles, and adipocytes from women with PCOS indicate that insulin resistance results from defects early in the postreceptor signaling pathway.<sup>106,136,137,138</sup> The number and affinity of insulin receptors in both obese and lean women with PCOS are not decreased,<sup>139,140</sup> but insulin receptors exhibit a constitutive increase in phosphorylation of serine residues and a decrease in insulin-stimulated phosphorylation of tyrosine residues.<sup>129</sup> Serine phosphorylation of insulin receptor substrates prevents their binding with PI-3K and thereby inhibits insulin signaling. Increased serine phosphorylation can be induced by intracellular metabolites of free fatty acids,<sup>138,141</sup> which are increased in most women with PCOS and have been demonstrated to cause insulin resistance in vivo.<sup>142,143</sup> High circulating free fatty acid levels also can increase androgen production in women,<sup>144</sup> by inducing serine phosphorylation of P450c17, which results in increased 17,20-lyase activity (**Figure**

11.9).<sup>145,146</sup> These observations offer a mechanism for insulin resistance that also further helps to explain the link between insulin and hyperandrogenism in women with PCOS.

**FIGURE 11.9**

Although hyperandrogenism can decrease insulin sensitivity, the effect is relatively modest.<sup>122</sup> **Insulin resistance and hyperinsulinemia are the cause, not the result, of hyperandrogenism in PCOS.** Treatment with a GnRH agonist can normalize elevated serum androstenedione and testosterone levels in women with PCOS, but has limited or no effect on insulin resistance.<sup>45,147,148,149</sup> Accumulating evidence suggests that deficiency or dysfunction in downstream signaling mediated by inositol phosphoglycans also may contribute to insulin resistance in women with PCOS.<sup>150,151,152,153</sup> Finally, obesity is a common feature of women with PCOS, representing yet another important mechanism contributing to the development of insulin resistance, as discussed below.

**Insulin resistance and hyperinsulinemia are undoubtedly an important part of**

**the pathophysiology of PCOS. However, it is important to emphasize that 25–50% of women with PCOS have no demonstrable insulin resistance. Moreover, among all women with insulin resistance, the prevalence of PCOS is relatively low (approximately 15%).<sup>154</sup> The prevalence of PCOS is similarly quite low in women with type 2 diabetes mellitus (2.5%).<sup>155</sup> Therefore, insulin resistance and hyperinsulinemia are not the primary cause or pathogenic factor in all women with PCOS.**

## **Obesity, Weight, and Energy Regulation**

The risk for developing PCOS-like picture rises with increasing obesity,<sup>154,156,157</sup> as does the severity of insulin resistance, hyperinsulinemia, and ovulatory dysfunction and the prevalence of metabolic syndrome, glucose intolerance, risk factors for cardiovascular disease, and sleep apnea.<sup>107,158,159,160,161</sup>

Obesity, by itself, is associated with insulin resistance and compensatory hyperinsulinemia. Insulin resistance is most highly correlated with intra-abdominal obesity, because visceral fat is more active metabolically than subcutaneous fat, is more sensitive to lipolysis, releases more free fatty acids, and produces a number of cytokines involved in insulin resistance, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-6, leptin, and resistin.<sup>162</sup> The accumulation of free fatty acids in tissues causes lipotoxicity and insulin resistance, in part via TNF- $\alpha$ , which increases serine phosphorylation and thereby inhibits insulin signaling.<sup>163</sup> Insulin resistance due to obesity also induces leptin resistance and decreases adiponectin levels, thereby decreasing fatty acid oxidation and promoting lipotoxicity.<sup>162,164</sup> Obesity in women with PCOS typically is distributed centrally, with a greater increase in visceral than in subcutaneous fat.<sup>165,166,167,168</sup> However, even lean women with PCOS have an increased percentage of body fat, a higher waist-hip ratio, and greater intra-abdominal, peritoneal, and visceral fat, compared to normal women matched for BMI.<sup>169</sup>

The overall prevalence of obesity, and in women with PCOS, varies among different patient populations<sup>170</sup>; in the United States, approximately 35% of all adult women and 60% of women with PCOS are obese.<sup>171,172</sup> However, the overall prevalence of PCOS among different populations is quite similar (approximately 7%).<sup>27,173,174,175</sup> Moreover, the prevalence of PCOS among unselected women varies relatively little with increasing BMI: 8.2% in underweight women (BMI < 18.5 kg/m<sup>2</sup>), 9.8% in normal-weight women (18.5–24.9 kg/m<sup>2</sup>), 9.9% in overweight women (BMI 25.0–29.9 kg/m<sup>2</sup>), 9.0% in obese class I women (BMI 30.0–34.9 kg/m<sup>2</sup>), 12.4% in obese class II (BMI 35.0 and 40.0 kg/m<sup>2</sup>), and 11.5% in obese class III or morbidly

obese women (BMI > 40.0 kg/m<sup>2</sup>).<sup>176</sup> **It is important to appreciate that obesity in itself can contribute to a PCOS-like picture given the HPO dysfunction resulting from obesity-related alterations in hypothalamo-pituitary function and hyperandrogenism resulting from an elevation in free testosterone levels due to suppressed hepatic production of SHBG.** The high androgen levels and chronically elevated estrogen levels (derived from aromatization of androgens in the adipose tissue) sustain or even perpetuate an abnormal pattern of gonadotropin secretion by increasing LH pulse frequency and amplitude and inhibiting FSH secretion. The prevalence of menstrual irregularity, dysfunctional bleeding, hirsutism, and infertility is higher in obese than in lean women with PCOS,<sup>177,178,179</sup> and obesity is an independent risk factor for developing glucose intolerance and diabetes.<sup>107,180</sup>

**Combined, these observations indicate that obesity relates primarily to genetic and environmental factors and is a common, but not essential, feature of PCOS. Obesity contributes modestly to the risk for developing PCOS and adds to the pathophysiology in already affected women by aggravating the degree of insulin resistance and hyperinsulinemia.**<sup>177,181</sup> While it is plausible that PCOS itself may, to some degree, predispose to weight gain and obesity, evidence-based support for such a directionality of association is presently lacking. **Obese women have a higher prevalence of miscarriage, gestational diabetes, and pre-eclampsia, regardless whether they also have PCOS.**<sup>182</sup>

## **Androgen Synthesis and Action**

**Hyperandrogenism is the key feature of PCOS, resulting primarily from excess androgen production in the ovaries and, to a lesser extent, in the adrenals as well as in excess body fat (Figure 11.10).**<sup>183</sup> In women with PCOS, approximately 60% of circulating androstenedione derives directly from the ovaries and the remainder from the adrenals; similarly, 60% of circulating testosterone is secreted directly by the ovaries, with most of the remainder deriving from peripheral conversion of androstenedione.<sup>184</sup>

**FIGURE 11.10**

The primary mechanisms driving increased ovarian androgen production in PCOS include increased LH stimulation resulting from abnormal LH secretory dynamics and increased LH bioactivity and hyperinsulinemia due to insulin resistance, which potentiates the action of LH and is worsened by obesity. Other evidence indicates that increased ovarian androgen synthesis in women with PCOS probably also relates to the increased volume of theca cells in an expanded ovarian stroma, which ultimately respond to the excess LH secretion, further perpetuating ovarian androgen production.<sup>25,185,186,187</sup> Androgen production remains elevated in long-term cultures of theca cells from women with PCOS,<sup>188</sup> even after suppression of LH levels by treatment with a GnRH agonist,<sup>189</sup> suggesting that increased androgen production in women with PCOS, to some extent, also reflects an intrinsic dysregulation of key steroidogenic enzymes, such as  $3\beta$ -hydroxysteroid dehydrogenase ( $3\beta$ -HSD) and 17,20-lyase,<sup>114,185,190,191,192</sup> which may have a genetic foundation.<sup>193</sup>

**Adrenal androgen production (androstenedione, DHEA, DHEA-S) also is increased in women with PCOS; over half exhibit moderately increased circulating DHEA-S levels.**<sup>194</sup> When ovarian synthesis is suppressed by treatment with a long-acting GnRH agonist, adrenal androgen levels remain higher in women with PCOS than in normal women.<sup>101,185,189,195</sup> Adrenal androgens have little or no intrinsic androgenic activity, but contribute to the pathophysiology of PCOS via conversion to testosterone in the periphery (discussed in [Chapters 12](#) and [13](#)).

A number of potential mechanisms for the increase in adrenal androgen production have been investigated, but the explanation remains uncertain. Chronic estrogen stimulation due to anovulation could decrease adrenal  $3\beta$ -HSD activity, as it does in the fetal adrenal cortex, but evidence for this mechanism is conflicting.<sup>196,197,198,199,200</sup> Increased pituitary ACTH secretion or increased sensitivity to ACTH could provide an explanation, as 30–50% of women with PCOS show increased 17-ketosteroid response to ACTH.<sup>201,202</sup> In some, but clearly not all, women with PCOS, adrenal androgen excess might result from intrinsic upregulation of P450c17 17,20-lyase activity<sup>47,146,203,204,205</sup> or from hyperinsulinemia.<sup>206,207,208,209,210</sup> **In sum, no one mechanism explains the moderate adrenal androgen excess commonly observed in women with PCOS.**

High local androgen concentrations contribute to the polycystic morphogenesis of the ovaries, via conversion to more potent  $5\alpha$ -reduced androgens, which cannot be aromatized to estrogen and inhibit both aromatase activity and FSH induction of LH receptors on granulosa cells, thereby impeding or preventing progressive follicular development. Granulosa cells obtained from PCO are not functionally impaired. They are sensitive to FSH and insulin-like growth factors and produce estrogen,<sup>211,212,213,214</sup> but cannot generate and maintain the estrogenic follicular milieu required to achieve more advanced stages of development. Consequently, new follicular growth continues but arrests long before full follicle maturation is achieved, resulting in multiple small follicular cysts (typically measuring 2–10 mm in diameter), surrounded by hyperplastic theca cells, which often become luteinized due to increased LH stimulation. Atretic follicles ultimately contribute to an expanding ovarian stroma that increases in volume over time, further increasing the cellular mass that contributes to producing androgens; the net result is a self-propagating cycle that predisposes to chronic anovulation.

Further evidence for a pathogenic role of androgens as causative to impaired follicular growth in PCOS comes from literature on ovarian surgical procedures, similar to concepts first proposed by Stein and Leventhal, which are aimed at reducing ovarian theca cell volume as a mechanism for restoring spontaneous ovulation. Ovarian wedge resection as first described by Stein and Leventhal, although no longer regularly performed, provided evidence of the important contributions of ovarian tissue to the pathophysiology of PCOS. The success of ovarian wedge resection correlated with the amount of androgen-producing stromal tissue that is removed, and wedge resection results in a sustained decrease in androgen levels that precedes the return of ovulatory cycles, indicating that high intraovarian androgen concentrations effectively inhibit follicular development and prevent ovulation.<sup>215,216,217,218</sup> Even a unilateral oophorectomy can restore menstrual cyclicality and ovulation in anovulatory women with PCO.<sup>219</sup> Although laparoscopic procedures such as ovarian “drilling” with an

electrosurgical needle or a laser have replaced the classical wedge resection, the results achieved are similar, albeit lesser lasting in longevity. PCO also have been observed in women with androgen-producing ovarian and adrenal tumors<sup>220,221,222</sup> and in female-to-male transsexuals treated with exogenous androgens.<sup>223,224</sup> **These observations again illustrate the important point that PCO are not a characteristic feature of a specific endocrine disorder. They result from a functional derangement in follicular development induced or sustained by increased intraovarian androgen levels and represent a consequence of chronic anovulation, whatever the cause (Figure 11.11).**

**FIGURE 11.11**

## Genetic Considerations

Familial clustering of hyperandrogenism, anovulation, and PCO suggests an underlying genetic basis or cause. At least one group of patients with a heritable X-linked form of PCOS has been described, albeit with a widely varying phenotype.<sup>213</sup> Studies in large families have suggested autosomal dominant inheritance, with premature balding as the male phenotype.<sup>225,226</sup> Other studies of siblings and parents of women with PCOS have

observed a high prevalence of hyperinsulinemia and hypertriglyceridemia, PCOS in females, and premature balding in males.<sup>227,228</sup> Nearly 50% of sisters of women with PCOS have elevated total or bioavailable testosterone concentrations,<sup>229</sup> and approximately 35% of mothers also are affected.<sup>230,231</sup> The first-degree relatives of women with PCOS also exhibit other metabolic abnormalities such as dyslipidemia, which may predispose to an increased risk for cardiovascular disease.<sup>35,157,232,233</sup> These observations further suggest a genetic predisposition or susceptibility.

Understandably, efforts to identify genes associated with a susceptibility to anovulation and PCO have focused on genes relating to the insulin receptor and substrates<sup>225,226,227</sup> and the genes encoding the P450 side-chain cleavage (CYP11) and P450c17 (CYP17) enzymes and SHBG and FSH receptors.<sup>234,235,236,237,238,239</sup> Ongoing genome-wide association studies (GWAS) have begun to identify several possible candidate genes, including the DENND1A (differentially expressed in normal and neoplastic cell domain-containing protein 1A) and THADA (thyroid adenoma-associated protein) genes.<sup>108</sup> Further support for DENND1A comes from studies demonstrating increased levels of the V2 isoform of DENND1A in theca cells obtained from women with PCOS.<sup>240</sup> Functional genomic studies are also underway, as are research aimed at understanding the role epigenetics/altered DNA methylation plays in PCOS.<sup>25</sup> **Currently, PCOS is best seen as a polygenic disorder involving the interaction of numerous genomic variants and the influence of environmental factors.**<sup>234,235,236,237,238,241</sup> Candidate genes include the long list of molecules that participate in any of the metabolic and reproductive pathways affected in the syndrome, emphasizing yet again that PCOS is not a specific endocrine disorder, but a result of chronic anovulation due to a wide variety of causes (Table 11.3).<sup>242</sup>

## TABLE 11.3 Genetics of PCOS

<b>Genes</b>	<b>Chromosome</b>	<b>Function</b>
LHCGR	Chromosome 9	Gonadotropin action
FSHR	Chromosome 2	Gonadotropin action
THADA	Chromosome 2	Apoptosis
DENND1A	Chromosome 2	Endocytosis, receptor-mediated turnover
YAP1	Chromosome 11	Cell proliferation
GATA4	Chromosome 8	Transcription factor
C9orf3	Chromosome 9	Aminopeptidase
HMGA2	Chromosome 12	Transcriptional regulating factor
TOX3	Chromosome 16	Chromatin remodeling
INSR	Chromosome 19	Insulin signaling
SUMO1P1	Chromosome 20	Cell proliferation
KCNA4/FSHB	Chromosome 11	Gonadotropin action
ERBB4	Chromosome 2	Mitogenesis and differentiation
RAD50	Chromosome 5	DNA repair
KRR1	Chromosome 12	Ribosome biogenesis
RAB5B, SUOX	Chromosome 12	Protein transport, breakdown

# Diagnosis of Polycystic Ovary Syndrome

It is generally accepted that PCOS is not a specific endocrine disease but a syndrome represented by a collection of signs and symptoms and that no one sign, symptom, or test is diagnostic. The individual biochemical, clinical, and radiologic components of the commonly utilized diagnostic criteria that were briefly presented earlier (Table 11.2) are discussed in some detail as under.

## Hyperandrogenemia

Testosterone is the most important androgen produced by the ovary, and evidence of circulating levels of total and/or free testosterone above the normal range specified for testing laboratory is the usual basis for diagnosis of hyperandrogenemia. Other androgens that may be elevated in women with PCOS include androstenedione, DHEA, and DHEA-S (further discussed in Chapters 12 and 13).

Testosterone levels are elevated in most, but not all, women with PCOS. The free testosterone level is more sensitive for diagnosis of hyperandrogenic disorders,<sup>38</sup> but measurements of free testosterone have several limitations. Direct radioimmunoassays (RIA) for free testosterone are highly inaccurate,<sup>243,244,245</sup> particularly in the lower range and in women with decreased SHBG levels.<sup>246</sup> More sophisticated and accurate methods (equilibrium dialysis, gas or liquid chromatography-mass spectrometry) are technically complex, costly, and not widely available.<sup>247</sup> Moreover, testosterone is converted in androgen-sensitive tissues by enzyme 5- $\alpha$  reductase to dihydro testosterone (DHT), which has a longer duration of action and greater potency than testosterone, so serum total testosterone concentrations do not necessarily reflect androgen bioactivity at the tissue level. Elevations in circulating total testosterone levels can accompany the LH surge, and thus if feasible, testing should be performed in the follicular phase of menstrual cycle.<sup>93,108</sup>

For purposes of clinical research, the free testosterone concentration can be calculated, using equations derived from the laws of mass action; the serum concentrations of total testosterone, SHBG, and albumin; and the association constants for the interactions of testosterone with SHBG and albumin.<sup>244,248</sup> Calculated values generally correlate well with those determined by equilibrium dialysis,<sup>243,244</sup> although accuracy varies with the specific assays used to measure total testosterone and SHBG. **For clinical purposes, measurement or calculation of the free testosterone level, or even measurement of the serum total testosterone concentration, usually is unnecessary.**<sup>249</sup> In most cases, clinical evidence of hirsutism (discussed in Chapter 12) provides ample evidence of hyperandrogenism, and if not severe, sudden in

**onset, rapidly progressive, or associated with symptoms or signs of virilization, there is little reason for concern about an androgen-producing tumor (Chapter 13).**

Measurement of the serum androstenedione concentration could yield evidence of hyperandrogenemia, but limited data suggest that levels are elevated in less than 20% of women with PCOS.<sup>26</sup> Measurement of serum DHEA also has little or no diagnostic value because levels are relatively low, exhibit a diurnal pattern and high between-subject variability, and are sensitive to stress.<sup>38,250</sup>

The serum DHEA-S concentration is the traditional marker for adrenal androgen excess,<sup>251,252,253</sup> because it derives almost exclusively from the adrenal,<sup>254,255,256</sup> and concentrations are relatively high and remain stable across the day and cycle.<sup>257,258</sup> Overall, the serum DHEA-S concentration is moderately elevated in over half of women with PCOS.<sup>194</sup> Some have an isolated increase in serum DHEA-S, suggesting a deficiency in 3 $\beta$ -HSD, but no genetic mutation in the enzyme has been found.<sup>259,260</sup> DHEA-S, similar to DHEA and androstenedione, has little or no intrinsic androgenic activity and requires conversion to testosterone to exert androgenic effects. **The AE-PCOS Society regards an elevated serum DHEA-S level as sufficient evidence of hyperandrogenism to support the diagnosis of PCOS<sup>44</sup>; serum DHEA-S levels are however not considered when diagnosing PCOS per the Rotterdam criteria. Clinical utility of routine testing of DHEA-S levels in settings of mild clinical hyperandrogenism is limited.** While, intuitively, information on DHEA-S can allow interpretation of adrenal contribution to hyperandrogenemia, this test is limited in both sensitivity and specificity for identifying women with adrenal causes of hyperandrogenism.<sup>256</sup> Although DHEA-S concentrations can be grossly elevated ( $\geq 700$  mg/dL) in women with rare androgen-secreting tumors, however, in almost all such patients, serum testosterone levels are also greatly elevated,<sup>261</sup> due to peripheral conversion of high circulating DHEA-S levels or because the tumor also secretes testosterone.

## Clinical Hyperandrogenism

Clinical manifestations of hyperandrogenism include hirsutism (discussed in detail in Chapter 12), acne, and androgenic alopecia, all of which relate to the effects of androgens on the pilosebaceous unit. Because the sensitivity of the pilosebaceous unit varies significantly among individuals, the correlation between these clinical features and biochemical measures of hyperandrogenism is relatively poor.<sup>262,263</sup>

**Hirsutism is the growth of terminal hairs on the face or body in a male pattern and a distressing symptom of PCOS.** As discussed in Chapter 12, the prevalence as well as severity of hirsutism can vary by race and ethnicity. Correlation of the severity

of hirsutism with hyperandrogenemia is, if at all, modest as circulating androgen levels do not capture the tissue activity of enzyme 5- $\alpha$  reductase that brings about the conversion of testosterone to the more potent androgen, DHT. **The modified Ferriman-Gallwey score is the accepted standard for assessing the severity of hirsutism in clinical investigations (discussed in Chapter 12), and this should be performed in conjunction with asking patients the method and frequency of hair removal (e.g., shaving, plucking, waxing), which also provides a clinically relevant measure for assessing the response to treatment.**

Acne is the second most common manifestation of hyperandrogenism in women with PCOS. Androgen-mediated stimulation of sebaceous secretions is recognized as a mechanism for acne, and in general, across all ages, males have a higher prevalence and severity of acne compared to women. Like hirsutism, the prevalence of acne among women with PCOS varies with ethnicity, ranging from 12% to 14% among White women with PCOS,<sup>171,173,264</sup> being higher in Asian Indians and women of Mediterranean descent (approximately 25%)<sup>264,265</sup> and lower among Pacific Islanders. Overall, among adult women with PCOS, the prevalence of acne ranges between 15% and 95%.<sup>266,267</sup> However, it is unclear whether acne is any more prevalent among women with PCOS than in the general population as approximately 6–55% of adult women acknowledge experiencing acne.<sup>266,268,269,270,271,272</sup> Although association between acne and hyperandrogenemia is described, existing data are equivocal. Excess local production of androgens within the skin due to overactivity of tissue-specific enzymes<sup>273</sup> may be a contributory mechanism, particularly in women with normal circulating androgen levels.<sup>274,275</sup> The extent to which PCOS may increase the risk for developing acne, if at all, is uncertain; however, the stress and psychological burden that acne can impose on the affected individual are real.<sup>276,277,278</sup> Counting of actual acne lesions was first described in 1966 as an approach to assessing efficacy of intervention,<sup>279</sup> and a number of nomenclatures have been examined with little consensus as regards superiority of any one tool in clinical practice.<sup>280</sup> Despite the prevalence as well as health care burden related to acne bother, there is no existing standardized methodology for quantifying severity of acne in women with PCOS. In the clinical setting, quantification of acne severity should take into consideration the number, distribution, and severity of the active lesions as well as residual scars. Pictorial records of the affected areas can allow comparative assessment of response to treatment (**Figure 11.12**).

**FIGURE 11.12**

**Androgenic alopecia** (also called androgenetic alopecia and female pattern hair loss), describing scalp hair loss in women (discussed in [Chapter 12](#)) is a recognized albeit relatively uncommon feature of PCOS.<sup>171,281,282,283,284</sup> In the normal hair cycle, the growth (anagen) phase lasts 2–3 years, accounting for up to 90% of the scalp hair. In situations of chronic androgen excess, hair follicles shrink in the anagen phase, leading to less scalp coverage and alopecia.<sup>285</sup> In a cross-sectional study of 254 women meeting Rotterdam criteria for PCOS, androgenetic alopecia was noted in 22% based on evidence of miniaturization of scalp hair.<sup>286</sup> Although the prevalence of androgenetic alopecia was higher in women with clinical or biochemical evidence of hyperandrogenism (24% vs. 5%,  $p = 0.05$ ), on adjusted analyses, neither androgens nor metabolic parameters are related to the presence of androgenic alopecia. In another cross-sectional study of 263 women diagnosed with PCOS by the Rotterdam criteria (of these, 74% also met the NIH diagnostic PCOS criteria), 27% of the population acknowledged symptom of scalp hair thinning; while no relationship was observed between hair thinning with hyperandrogenism or hyperandrogenemia, lifestyle and biochemical predictors of hair thinning were apparent as those acknowledging scalp hair thinning were significantly more likely to manifest abnormalities in glucose homeostasis.<sup>287</sup> Given that 25% or more of scalp hair must be lost before thinning becomes apparent, the actual prevalence of alopecia may be higher.<sup>171,288</sup> The pattern of hair loss in women with PCOS follows the well-recognized “female hair loss” phenotype wherein hair thinning is most apparent at the caput while the frontal hairline remains well preserved; when more severe, the frontal and bitemporal hair line can be involved<sup>285</sup> ([Figure 11.13](#)).

**FIGURE 11.13**

Overall, the mechanisms of scalp hair loss in women with PCOS remain poorly understood, and there appears to be no relevance of hyperandrogenemia to alopecia of PCOS.

## **Ovulatory and Menstrual Dysfunction**

Normal cyclic menses result from normal ovulatory function (discussed in [Chapter 5](#)). The normal intermenstrual interval ranges between 21 and 35 days. Menses that occur less or more often are an indication of ovulatory dysfunction.<sup>108</sup> Oligomenorrhea is defined as less than eight menstrual cycles per year. Cyclic menses occurring at normal intervals strongly suggest, but cannot be regarded, as proof of ovulation.

The majority of women with PCOS, approximately 60–85%, exhibit obvious menstrual dysfunction.<sup>25,38,170,173</sup> The most common menstrual abnormalities in women with PCOS are oligomenorrhea and amenorrhea. Polymenorrhea (regular cycles occurring at intervals <21 days) is quite uncommon, observed in less than 2% of the PCOS population.<sup>171</sup> Classically, menstrual dysfunction of PCOS can be dated back to onset of menarche in many, although it is not uncommon for the cycles to be regular for varying intervals preceding the onset of oligo-/amenorrhea.

In general, anovulation is accompanied by menstrual irregularity and anovulatory women seldom report regular menses.<sup>289</sup> However, regular cycles are somewhat more common in anovulatory hyperandrogenic women.<sup>38,290</sup> In studies of menstrual function in women with hyperandrogenism, 15–20% are eumenorrheic, despite evidence of oligoanovulation.<sup>108,291,292,293,294</sup> The prevalence of eumenorrhea among women with PCOS is significantly increased if the data in Rotterdam diagnostic criteria are applied,

because hirsute eumenorrheic women with PCO are included. The absence of any recognizable pattern of premenstrual molimina suggests anovulation in eumenorrheic women; confirmation of this impression requires objective some form of assessment, such as laboratory data and/or ultrasound imaging.

## Polycystic Ovaries

The syndrome takes its name from the enlarged polycystic-appearing ovaries that are so commonly observed in women with hyperandrogenic chronic anovulation.<sup>29</sup> Observations of mild hyperandrogenemia and insulin resistance in some asymptomatic women with PCO provided the rationale for including PCO among the Rotterdam diagnostic criteria for PCOS, as a sign of ovarian dysfunction.<sup>295,296,297,298,299</sup>

When defining PCO in PCOS, it is not sufficient to simply note the multiple follicles. Rather, in addition to the multiple small follicles, the ovaries of women with PCOS also exhibit increased size and stromal volume as well as a classic topographic relationship between the follicles and the stroma. The many small follicles are displaced peripherally and surround the dense central stroma of a polycystic ovary (**Figure 11.5**). The Rotterdam consensus criterion for an ovary to be considered polycystic weighs equally on the ovarian volume ( $>10 \text{ mL}^3$ ) and the total number of small follicles measuring between 2 and 9 mm in size ( $\geq 12$ ); presence of any one of these two morphologic ultrasonographic findings in a single ovary serves as meeting the Rotterdam criteria for polycystic ovary.<sup>36,300,301,302</sup> The prevalence of PCO is quite high among women with androgen excess ( $>80\%$ ).<sup>291,303,304,305,306,307,308,309</sup> **However, as mentioned earlier, up to a third of regularly menstruating normal women without PCOS, and even 14% of women using oral contraceptives, also meet the ultrasonographic criteria for PCO.**<sup>32,296,301,310,311,312,313</sup> Moreover, PCO are commonly observed during normal pubertal development and even in women with hypothalamic amenorrhea and hyperprolactinemia.<sup>314,315</sup> Thus, while the finding of polycystic-appearing ovaries alone is of little clinical significance, the inclusion of this ovarian appearance as one of the diagnostic features of PCOS per Rotterdam criteria has expanded the population of women that might be assigned a diagnosis of PCOS by approximately 50%, compared to the criteria earlier recommended by the NICHD, due entirely to the inclusion of PCO.<sup>316</sup> **Otherwise normal women with PCO generally have regular menstrual cycles, exhibit normal serum gonadotropin and ovarian steroid hormone levels, and are not infertile.**<sup>295,311,317,318,319</sup> As mentioned earlier, the AE-PCOS Society has recommended that in order to characterize ovarian appearance as PCO, the minimal number of small follicles should be increased from a threshold of 12, as is specified by Rotterdam criteria, to a minimum of 25.<sup>39</sup>

**Again, the important point is that PCOS is a functional disorder in which PCO result from chronic anovulation. Although present in most women with chronic hyperandrogenic anovulation, PCO do not establish and are not required for diagnosis of PCOS.** [175,195,310](#)

# Common Accompaniments to Polycystic Ovary Syndrome

In addition to the chronic anovulation, hyperandrogenism, hyperandrogenemia, and PCO, which are recognized as hallmarks of PCOS, certain perturbations in physiology are often encountered in women with PCOS but are not included in any diagnostic criteria; these include a reversed circulating FSH/LH ratio that is reflective of abnormal patterns of gonadotropin secretion, clinical and/or biochemical evidence of insulin resistance, and related metabolic abnormalities, such as abnormalities in glucose homeostasis, dyslipidemias, and a generalized proinflammatory state, which collectively reflect an exaggerated cardiometabolic risk profile ([Table 11.4](#)).

## TABLE 11.4 Common Metabolic Abnormalities in PCOS

Metabolic Abnormality	Health Implications	Screening	Management Considerations
Abnormalities in glucose homeostasis	Type II diabetes Risk for CVD Risk for endometrial hyperplasia	OGTT HbA1c Fasting or OGTT provoked insulin levels	Weight reduction Exercise and dietary modifications Insulin sensitizers Incretins Insulin
Lipid abnormalities	Risk for CVD Stroke risk	Fasting lipid profile	Weight reduction Dietary modifications Exercise Lipid-lowering agents Low-dose aspirin
Inflammation	Risk for CVD	Cardio CRP	Weight reduction Dietary modifications Exercise Lipid-lowering agents Low-dose aspirin
Metabolic syndrome	Exaggerated risk for CVD, all-cause mortality, and cancer risk	Fasting lipids HbA1c Fasting glucose Blood Pressure monitoring Waist circumference	Aggressive approach to risk reduction through combination of lifestyle modifications aimed at weight reduction, plus the use of antihypertensive, lipid-lowering and glucose-lowering agents

## Abnormal Gonadotropin Secretion

Abnormal patterns of gonadotropin secretion have long been recognized as a common characteristic of women with PCOS. As discussed earlier in the section of this chapter devoted to the pathophysiology of the disorder, increased serum LH concentrations, low-normal FSH levels, and increased LH/FSH ratios are typical, but not universal. Altered LH/FSH ratios are more often encountered in the lean than in obese women with PCOS. In the past, an increased LH/FSH ratio (e.g., >2:1) has been regarded as a marker of PCOS, but the dependence of results on assay sensitivities and the now recognized inherent differences in circulating gonadotropin levels by degree of adiposity limit the reliability of LH/FSH ratios for establishing PCOS diagnosis.<sup>8, 67, 320, 321, 322</sup> **Consequently, gonadotropin levels or ratios are not a reliable diagnostic criterion; they neither make, nor exclude, the diagnosis of PCOS.**

## Insulin Resistance

Insulin resistance and hyperinsulinemia are common but not universal features of women with PCOS, no matter what method is used to assess insulin sensitivity.<sup>101, 103</sup> **The overall prevalence of insulin resistance among women with PCOS is between**

**30% and 35% and is greater in the obese than in lean PCOS population.**

Most women with PCOS and insulin resistance are young and have ample pancreatic B-cell reserve. Consequently, they are able to generate a compensatory hyperinsulinemia, allowing them to maintain normal glucose homeostasis, at least in the fasting state.<sup>107</sup> Although most therefore display an exaggerated insulin response to a glucose challenge, some also exhibit evidence of B-cell dysfunction,<sup>323, 324, 325</sup> particularly those having a family history of type 2 diabetes mellitus.<sup>326</sup>

There is no debate that insulin resistance and hyperinsulinemia play an important role in the pathophysiology of PCOS. However, there is no universal testing modality, which can make diagnosis of insulin resistance difficult. Acanthosis nigricans (further discussed under the section on severe insulin resistance syndromes) serves as a clinical hallmark of insulin resistance (**Figure 11.14**).

**FIGURE 11.14**

The gold standard method for measuring insulin sensitivity (a concept that reflects the opposite of insulin resistance) is the **hyperinsulinemic-euglycemic clamp** to which all other methods are compared.<sup>25, 327</sup> The technique involves a fixed-rate intravenous infusion of insulin and a simultaneous intravenous glucose infusion, varying the rate as needed to establish a steady-state plasma glucose level within the normal fasting range. The glucose infusion rate at steady state estimates the rate of glucose uptake in tissues at the defined plasma insulin concentration and is inversely proportional to the degree of insulin resistance; the lower the glucose infusion rate at steady state, the greater the degree of insulin resistance. Insulin sensitivity is defined as the ratio of the glucose disposal rate to the steady-state insulin concentration (glucose disposal rate [mmol/kg]  $\times$  min per mU/L  $\times$  100). The clamp technique and other methods involving intravenous

infusions of glucose and/or insulin (e.g., the frequently sampled intravenous glucose tolerance test, the insulin sensitivity test, the insulin tolerance test, and the continuous infusion of glucose with model assessment) have been used extensively in clinical investigations of glucose and insulin dynamics. However, they have no real practical clinical application because they are time-consuming, invasive, and costly and require experienced personnel.

The complexities of clamp techniques and other methods requiring intravenous infusions and multiple blood samplings spurred efforts to find an uncomplicated and inexpensive quantitative method for evaluating insulin sensitivity. A number of fasting state (homeostatic) measures have been described, all based on the fasting glucose and insulin concentrations and using straightforward calculations.<sup>328</sup> One common weakness that all such methods have is that they assume a linear relationship between glucose and insulin that is, in fact, parabolic.

The **fasting serum insulin concentration** is easy to obtain and requires no calculations<sup>329</sup>; in euglycemic white women with PCOS, values greater than 20–30 mU/mL suggest insulin resistance. The **fasting glucose/insulin ratio** has been used widely as an index of insulin sensitivity across populations including in women with PCOS; a ratio less than 4.5 has reasonable sensitivity and specificity for insulin resistance.<sup>103</sup> The **homeostatic model assessment of insulin resistance (HOMA-IR)** is another measure of insulin sensitivity commonly used in larger epidemiologic studies. The HOMA-IR is calculated by dividing the product of the fasting glucose (mg/dL) and insulin (mU/mL) concentrations by a constant: (glucose [mg/dL]) (insulin [mU/mL])/405 or (glucose [mmol/L]) (insulin [mU/mL])/22.5.<sup>330, 331</sup> The HOMA-IR value correlates relatively well with results from clamp studies<sup>332, 333</sup> and, unlike the fasting insulin concentration and the glucose/insulin ratio, compensates for fasting hyperglycemia; values greater than 3.2–3.9 generally indicate insulin resistance.<sup>38, 334, 335</sup> The **quantitative insulin sensitivity check index (QUICKI)** is yet another method for assessing insulin sensitivity in clinical investigations. Like the HOMA-IR, QUICKI can be applied in both euglycemic and hyperglycemic patients.<sup>336</sup> The QUICKI value is the inverse of the sum of the fasting glucose and insulin concentrations, expressed logarithmically:  $(1/[\log(\text{glucose}) + \log(\text{insulin})])$ ; values greater than 0.33 indicate insulin resistance.<sup>38, 337</sup> Still other methods use a weighted combination of the fasting insulin and triglyceride concentrations and BMI to estimate insulin sensitivity.<sup>327</sup> All of the calculated indices have limitations, primarily the lack of a standardized insulin assay. **As the sheer number of different measures of insulin resistance demonstrates, there is no uniformly accepted test for measuring insulin resistance in a clinical setting. However, a combination of routinely undertaken evaluations (such as estimates of fasting glucose and insulin levels and results of OGTT) and**

**evidence of acanthosis nigricans and central obesity on clinical examination can provide meaningful insights into existence of insulin resistance in a clinical setting.**

The standard **OGTT** is the mainstay of methods for diagnosis of abnormalities of glucose homeostasis such as impaired glucose tolerance and diabetes mellitus and also can be used to assess insulin sensitivity and magnitude of insulin resistance (discussed below). Although the techniques may vary, all involve measures of plasma glucose (and insulin) at intervals over 2–4 hours after a 75- or 100-g oral glucose load. Inclusion of timed insulin estimates during the course of an OGTT allows a meaningful quantification of insulin resistance as it will identify patients who require larger amounts of insulin in order to remain euglycemic as in the absence of insulin response, estimates of glucose levels alone do not allow an insight into the magnitude of transient hyperinsulinemia that follows ingestion of a finite glucose load. **A baseline 2-hour OGTT is recommended for all women with PCOS, as up to 35% exhibit impaired glucose tolerance and up to 10% have diabetes mellitus.**<sup>36, 109, 338, 339, 340</sup> **Screening for glucose intolerance also is recommended for girls with premature adrenarche or menstrual irregularity that persists for more than 2 years after menarche because hyperinsulinemia often is a contributor to dysfunction of the HPO axis and they are at high risk for developing diabetes and severe hyperandrogenism.**<sup>341, 342, 343, 344</sup> In this population, specific screening for insulin resistance also is warranted because evidence indicates that early intervention in those affected can prevent progressive debilitating disease.<sup>343, 345, 346</sup> Specific screening for insulin resistance also is recommended for women with markedly elevated serum androgen levels ( $\geq 150$  ng/dL), to differentiate the severe insulin resistance syndromes (discussed below) from androgen-secreting tumors ([Table 11.5](#)).

## **TABLE 11.5 Interpreting Glucose and Insulin Response During 2-Hour Oral Glucose Tolerance Test (75 grams glucose load)**

Timing	Glucose (mg/dL)	Insulin (mU/mL)	Interpretation
Fasting (0 min)	<100	<20	<b>Impaired fasting glucose (IFG)</b> is between 100 and 125.99 mg/dL <b>Diabetes mellitus</b> if fasting glucose level is $\geq 126$ <b>Insulin-resistant</b> if fasting insulin level is $>20$
30–90 min	<200	<80–100 Level peaks at 30 min and should decline over time and remain <80–100	<b>Insulin-resistant</b> if insulin level is $\geq 80$ –100 at any time <b>Severe insulin resistance</b> if insulin level is $>300$
120 min	<140	Level should be less than at 90-min interval $<80$	<b>Impaired glucose tolerance (IGT)</b> if glucose level is between 140 and 199.9 mg/dL <b>Diabetes mellitus (DM)</b> if glucose level is $\geq 200$ mg/dL <b>Insulin-resistant</b> if insulin level is $>55$ <b>Severe insulin resistance</b> if insulin level is $>100$

## Dyslipidemia

Dyslipidemia is perhaps the most common metabolic abnormality observed in women with PCOS. Applying the National Cholesterol Education Program guidelines, nearly 70% have at least one borderline or elevated lipid level,<sup>347</sup> although many women with PCOS have entirely normal lipid profiles.<sup>348,349,350,351,352,353</sup> Insulin resistance and hyperinsulinemia are associated with decreased high-density lipoprotein (HDL) cholesterol and elevated triglyceride levels, and numerous studies have observed such abnormalities in women with PCOS.<sup>350,354,355</sup> Some also have observed elevated low-density lipoprotein (LDL) concentrations,<sup>158,351,352,353</sup> which are not usually associated with insulin-resistant states and may result from hyperandrogenism or reflect a genetic or dietary influence, and although this can be seen in both lean and obese women with PCOS, this metabolic abnormality is more prevalent in the setting of excess adiposity.<sup>35,349,356,357</sup>

## Inflammation

PCOS is a proinflammatory state.<sup>358</sup> Several studies have demonstrated that glucose can elicit an inflammatory response in mononuclear cells of women with PCOS, regardless of body weight.<sup>359</sup> In addition, hyperandrogenism, a common feature of PCOS, leads to maturation of adipocytes, which favors central obesity.<sup>359</sup> The adipocyte maturation results in adipocyte hypertrophy and ultimate hypoxia from inadequate perfusion. As increased central adiposity is present in PCOS patients regardless of BMI, this may explain the inflammatory state of PCOS.<sup>359</sup> The end result is recruitment of macrophages, which produce inflammatory cytokines, perpetuating a systemic inflammatory response and negatively impacting glucose metabolism.<sup>359</sup> In a systematic

review and meta-analysis studying the status of inflammatory markers in women with PCOS compared to non-PCOS women, it was found that C-reactive protein (CRP) was elevated in PCOS.<sup>358</sup> CRP is a marker of chronic inflammation and is correlated with insulin resistance, body weight, and adipose mass.<sup>359</sup> Treatment with metformin lowers CRP levels.<sup>359</sup>

## **Cancer Risk**

Chronic anovulation, obesity, and hyperinsulinemia provide an environment that is conducive to risk for proliferative endometrial pathologies such as endometrial hyperplasia and even endometrial cancer in women with PCOS.<sup>360,361,362,363,364</sup> The constant, unrelenting estrogen stimulation of the endometrium as well as the growth-promoting effects of insulin predisposes women with PCOS to abnormalities of the endometrium<sup>365</sup>; endometrial hyperplasia and even endometrial cancer can be encountered in young anovulatory women.<sup>366,367,368</sup> The risk for endometrial cancer may be as high as threefold greater in anovulatory women with PCOS compared to women with normal reproductive physiology.<sup>369</sup>

## **Exclusion of Other Disorders**

PCOS is a diagnosis of exclusion, after considering and eliminating other causes of chronic anovulation (primarily thyroid disorders and hyperprolactinemia) and of androgen excess. Together, CAH, androgen-secreting tumors, severe insulin resistance syndromes, Cushing syndrome, and idiopathic hirsutism account for about 10–30% of hyperandrogenism in women.<sup>171,288,293,370</sup> **All should be considered and excluded and are discussed in detail in other chapters, but briefly reviewed here (Table 11.6).**

### **TABLE 11.6 Conditions that Can Masquerade as PCOS**

Condition	Features Shared with PCOS	Unique Features and Methods for Exclusion
Late-onset congenital adrenal hyperplasia (Chapter 13)	Oligoanovulation Hyperandrogenism Hyperandrogenemia	Autosomal recessive disorder Elevated 17-OHP levels in the commonest variant due to 21-hydroxylase deficiency
Androgen secreting tumor Ovarian (Chapter 12) Adrenal (Chapter 13)	Oligoanovulation Hyperandrogenism Hyperandrogenemia	Rapid progression of clinical symptoms of hyperandrogenism Signs of virilization Markedly elevated total testosterone levels Elevated DHEA-S levels
Cushing syndrome (Chapter 13)	Oligoanovulation Hyperandrogenism Hyperandrogenemia	Clinical stigmata including hypertension, moon facies, buffalo hump, skin plethora, hypertension Elevated 24-hour urine-free cortisol (Chapter 13)
Hyperprolactinemia (Chapters 4 and 5)	Oligoanovulation	Elevated prolactin levels
Hypothyroidism (Chapter 20)	Oligoanovulation Coarsening of hair Hair loss	Elevated TSH levels (primary hypothyroidism) Positive antithyroid antibodies (Hashimoto thyroiditis)
Iatrogenic Androgenic agents Antidepressants Antiseizure	Oligoanovulation Hyperandrogenism	Androgen exposure Suppressed FSH/LH levels Elevated total testosterone Antidepressants and antiseizure Hyperprolactinemia
Severe insulin resistance syndrome	Oligoanovulation Hyperandrogenism Hyperandrogenemia	Elevated fasting insulin levels Markedly elevated provoked insulin levels during OGTT Acanthosis nigricans

## Thyroid Disorders

Thyroid disorders are associated with menstrual dysfunction (detail discussion in [Chapter 20](#)). In addition to being causative for ovulatory dysfunction, thyroid disorders can have serious adverse impact on pregnancy outcomes and on child development.<sup>371,372,373,374,375,376</sup> **The overall high prevalence of thyroid dysfunction in women warrants specific testing to exclude the diagnosis in all anovulatory women, including those with evidence of hyperandrogenism. Serum TSH is considered as the gold standard first-line test for assessing primary thyroid disorders.**

## Hyperprolactinemia

Hyperprolactinemia is highly associated with menstrual dysfunction and is one of the most common causes of secondary amenorrhea. The many causes of hyperprolactinemia are considered at length elsewhere in this text ([Chapters 4, 5, and 10](#)). Hyperprolactinemia is associated with increased adrenal androgen production in vivo and in vitro,<sup>377,378</sup> but its prevalence among women who present with hyperandrogenism

is quite low and generally less than 3%.<sup>288,370,379,380,381,382,383,384</sup> **The high prevalence of hyperprolactinemia among women with menstrual dysfunction justifies specific testing to exclude the diagnosis in all women with menstrual abnormalities and ovulatory dysfunction.**

## **Nonclassical Congenital Adrenal Hyperplasia**

CAH is caused by adrenal steroidogenic enzyme defects that result in excessive adrenal androgen production. The most common cause is 21-hydroxylase deficiency; other enzyme defects (11 $\beta$ -hydroxylase, 3 $\beta$ -hydroxysteroid dehydrogenase) are relatively rare. In all, the pathophysiology stems from decreased cortisol production, which stimulates a compensatory increase in pituitary ACTH secretion, causing adrenal hyperplasia; increased levels of steroid hormones proximal to the enzyme block seek an alternative metabolic pathway, resulting in increased production of androgens. The disorder is inherited in an autosomal recessive fashion and is discussed in detail in [Chapter 13](#).

Females with classical CAH (both salt-wasting and simple virilizing forms) typically present at birth with ambiguous genitalia<sup>385,386,387</sup> and thus would rarely be confused with PCOS, but those with the nonclassical or “late-onset” form of CAH present later, during childhood or early adolescence with precocious puberty, or as young adults with signs of hyperandrogenism, very much like those with PCOS.<sup>388</sup> **Whereas it is logical to recommend that nonclassical CAH be excluded specifically in all women with hyperandrogenism,<sup>38</sup> we believe that specific testing can be safely reserved for those having an early onset of hirsutism (pre- or perimenarcheal, including girls with premature adrenarche), women with a family history of the disorder, and those in high-risk ethnic groups (Hispanic, Mediterranean, Slavic, Ashkenazi Jewish, or Yupik Eskimo heritage).** The yield from routine screening is very low, because the disorder is uncommon.<sup>170,171,389</sup> While it is important to identify women at risk for conceiving a child with the more severe classical form of the disorder, the risk among women with hyperandrogenism is limited to those who carry one classic mutation and a variant allele associated with mild enzyme deficiency (compound heterozygotes), also having a male partner who carries an occult classic mutation. In the United States, the prevalence of classical CAH is 1 in 15,500 White and 1 in 42,000 African Americans.<sup>390</sup>

In chronically anovulatory women with evidence of hyperandrogenism, a follicular phase morning serum 17-OHP concentration less than 200 ng/dL excludes, and a level greater than 800 ng/dL all but establishes the diagnosis of late-onset CAH due to 21-hydroxylase deficiency.<sup>391,392,393</sup> Concentrations between the two threshold values

suggest the possibility, which can be confirmed by performing an ACTH stimulation test, obtaining blood samples before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 0.25 mg intramuscularly or intravenously); in most women with nonclassical CAH, the 17-OHP concentration will rise above 1,500 ng/dL.<sup>389,394,395</sup>

## Androgen-Secreting Ovarian and Adrenal Tumors

Androgen-secreting ovarian and adrenal tumors are rare. A short history and rapidity in progression of symptoms of androgen excess should alert one of this possibility, and diagnosis can be arrived at through further testing (discussed in [Chapters 12](#) and [13](#)). The prevalence of ovarian androgen-producing tumors is between 1 in 300 and 1 in 1,000 among women with hyperandrogenism.<sup>171,370,381,396</sup> Androgen-secreting adrenal tumors are even less common.<sup>380</sup> Androgen-secreting tumors almost always are accompanied by severe or rapidly progressive hirsutism or symptoms or signs of virilization (deepening of the voice, temporal or male pattern balding, breast atrophy, increased muscle mass, and clitoromegaly). **The possibility of a tumor is excluded primarily by the clinical history and physical examination. A serum total testosterone concentration** greater than 150 ng/dL identifies almost all women with a potential androgen-producing tumor. However, a tumor still should be suspected and excluded in women with rapidly progressive hirsutism or signs or symptoms of virilization, even when the serum testosterone concentration is below the threshold value. Transvaginal ultrasonography will identify almost all solid ovarian mass lesions, although very small tumors located in the hilar region can escape detection. Adrenal computed tomography (CT) is extremely sensitive for detecting rare androgen-secreting adrenal tumors, most of which are malignant. Selective ovarian venous catheterization can be considered for the rare patient having no demonstrable ovarian or adrenal mass lesion, but should be reserved only for those in whom a tumor is strongly suspected.

## Cushing Syndrome

Cushing syndrome results from excess adrenal cortisol secretion and can be ACTH-dependent (pituitary- and ectopic ACTH-secreting tumors) or ACTH-independent (adrenal adenomas, exogenous glucocorticoid treatment). **The disorder has features commonly observed in women with PCOS, including menstrual dysfunction and central obesity. However, the prevalence of Cushing syndrome in women presenting with hyperandrogenism is extremely low, well below 1%.<sup>40,170,171,288,370</sup>** Consequently, routine screening is not justified and should be limited to the very few patients who also have distinct signs and symptoms of hypercortisolism (discussed in detail in [Chapter 13](#)). Symptoms of severe fatigue and muscle weakness and signs suggesting atrophy of the skin and subcutaneous tissue (easy bruising and

purple striae on the abdomen and flanks); hyperpigmentation in areas most exposed to light or chronic mild trauma, friction, or pressure (the elbows, knees, knuckles, and shoulders); hypertension; diabetes; and features of cognitive impairment in an anovulatory woman should raise concerns for Cushing syndrome.

Methods of screening for Cushing syndrome, specific tests for those who screen positive, and evaluation to differentiate among the causes of Cushing syndrome are discussed in detail in [Chapter 13](#). **The overnight dexamethasone suppression test is the best single screening test because of its simplicity and ability to discriminate.** The test is performed by administering 1.0 mg of dexamethasone between 11:00 P.M. and midnight and measuring the serum cortisol at 8:00 A.M. the next morning; values less than 1.8 mg/dL are normal.<sup>385</sup>

## Idiopathic Hirsutism

Idiopathic hirsutism is defined classically as hirsutism (discussed in detail in [Chapter 12](#)) accompanied by normal ovulatory and menstrual function and with normal circulating androgen levels. Using that definition, the prevalence of idiopathic hirsutism among hirsute women is approximately 5–7%.<sup>170,171,293,294,397</sup> If the 2003 Rotterdam criteria for diagnosis of PCOS are used, the definition would also include the absence of PCO, further decreasing the prevalence of idiopathic hirsutism.

By definition, a diagnosis of idiopathic hirsutism requires measurement of serum androgen levels, which otherwise is not necessary for those with mild hirsutism. It is generally assumed that idiopathic hirsutism results from increased peripheral 5 $\alpha$ -reductase activity, which amplifies the action of normal circulating testosterone concentrations via increased intracellular conversion to the more potent androgen, DHT.

## Severe Insulin Resistance Syndromes

Severe insulin resistance is a specific characteristic of a variety of uncommon clinical disorders. The type A insulin resistance syndrome results from defects in the insulin receptor and affects primarily lean women. The type B syndrome is an autoimmune disorder affecting the insulin receptor. The type C syndrome is a variant of type A and is characterized by marked acanthosis nigricans, hyperandrogenism, obesity, and the absence of insulin receptor defects and is also known as the hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) syndrome. Other rare disorders involving severe insulin resistance include leprechaunism, the Rabson-Mendenhall syndrome, and a variety of lipodystrophic syndromes.<sup>38,112</sup>

Although the HAIR-AN syndrome might reasonably be viewed as a severe form or phenotype of PCOS, the more profound insulin resistance and related metabolic

abnormalities in the syndrome distinguish the two.<sup>398,399,400</sup> Ovarian hyperthecosis, characterized by distinct clusters of luteinized theca cells scattered throughout the ovarian stroma and associated with severe hyperandrogenism,<sup>401,402</sup> frequently is observed in women with severe insulin resistance syndromes. Skin tags and acanthosis nigricans (a gray-brown, velvety, sometimes verrucous, discoloration of the skin, usually involving the neck, groin, axillae, and the area beneath the breasts) are other common features of the severe insulin resistance syndromes. The mechanism responsible for their development is uncertain.

Although specific diagnostic criteria for the severe insulin resistance syndromes have not been established, the diagnosis can be substantiated by findings of markedly elevated levels of insulin, typically greater than 80 mU/mL fasting or greater than 300 mU/mL 2 hours after an oral glucose load.<sup>399,400</sup> As might be expected, most patients will have normal glucose levels in the early stages of the disorder, but are at high risk to develop pancreatic  $\beta$ -cell failure and consequent diabetes mellitus, as well as dyslipidemia. Accordingly, such individuals require early institution of primary prevention and secondary intervention strategies aimed at reduction of cardiovascular disease burden as well as require careful long-term follow-up.

## Key Points: Severe Insulin Resistance Syndromes

- Polycystic ovary syndrome is not a specific endocrine disease but is a syndrome represented by a collection of signs and symptoms, and no one sign, symptom, or test is diagnostic.
- Diagnosis of polycystic ovary syndrome is based primarily on the clinical history and physical examination. The major clinical features of polycystic ovary syndrome are chronicity of hyperandrogenism and menstrual dysfunction.
- Although present in most women with chronic hyperandrogenic anovulation, polycystic-appearing ovaries alone do not establish and are not required for diagnosis of polycystic ovary syndrome.
- Gonadotropin levels or ratios are not a reliable criterion for diagnosis of polycystic ovary syndrome.
- Knowing and understanding the health implications and consequences of chronic anovulation and timely initiation of appropriate management strategies are far more important than simply assigning a diagnostic label of PCOS.
- Laboratory evaluation of women with suspected polycystic ovary syndrome should include:
  - **Tests for ruling out common conditions that can mimic PCOS:**
    - Serum thyroid-stimulating hormone (TSH)

- Serum prolactin
- Serum 17-hydroxyprogesterone (especially in women with a pre- or perimenarcheal onset of hirsutism, a family history of congenital adrenal hyperplasia, or high-risk ethnicity time blood draw in morning in follicular phase)
- 24-hour urine-free cortisol if suspecting Cushing syndrome in differential diagnosis
- **Tests that quantify presence, severity, and source of hyperandrogenemia:**
  - Serum total and free testosterone (in women with moderate to severe hirsutism and/or acne or alopecia)
  - Serum DHEA-S (to determine adrenal contribution to signs/symptoms of androgen excess)
- **Tests that allow risk assessment:**
  - Oral glucose tolerance test (2-hour, 75-g glucose load) with frequent sampling for glucose (can consider additionally testing insulin levels)
  - Fasting lipid profile
  - Comprehensive metabolic panel
  - Endometrial sampling to rule out endometrial hyperplasia/cancer (consider in obese women and in those with history of prolonged periods of oligomenorrhea/amenorrhea that indicate long-term endometrial exposure to unopposed estrogen)

# Clinical Management

The management approach for women with PCOS must be individualized to address the symptom burden while harnessing individual's risks and minimizing long-term clinical consequences through tailored management and timely intervention of preventative strategies.

**Women with PCOS may be seeking care for any one or more of the following:**

- Menstrual abnormalities
- Symptom(s) of androgen excess (hirsutism, acne, alopecia)
- Infertility

**Long-term health risks in women with PCOS include:**

- Increased risk for endometrial hyperplasia and neoplasia
- Increased risk for infertility
- Increased risk for type 2 diabetes
- Increased risk for cardiovascular disease

Lifestyle changes are an important part of the clinical management, requiring careful education, counseling, encouragement, and follow-up. For patients having no immediate desire to attempt pregnancy, estrogen-progestin contraceptives provide effective management for menstrual dysfunction and protect against the risk for development of endometrial hyperplasia and cancer. Estrogen-progestin contraceptives and antiandrogens help to prevent or decrease symptoms of hyperandrogenism. In those not interested in taking oral contraceptives, the levonorgestrel-based intrauterine devices serve the dual role of offering excellent endometrial protection and effective contraception. Those seeking to conceive are candidates for ovulation induction, in conjunction with lifestyle modification. Women with impaired glucose intolerance and concomitant risk for developing type 2 diabetes, or having features of the metabolic syndrome, indicating a high risk for developing cardiovascular disease, may warrant consideration for treatment with insulin-sensitizing agents or other medications aimed specifically at reducing those risks. The important point to emphasize is that women with chronic anovulation require comprehensive clinical management that addresses their immediate needs, but also considers their longer-term health and incorporates appropriate risk reduction strategies.

## **Lifestyle Modification: A First-Line Approach**

The strong association between obesity, hyperandrogenism, impaired glucose tolerance,

menstrual abnormalities, and infertility emphasizes the importance of addressing lifestyle issues in women with PCOS, focusing on nutrition and exercise. At least 50% of women with PCOS are obese. **It is important to stress that even a small reduction in weight (2–5%) can result in significant improvements in metabolic and reproductive function.**<sup>22,24,403,404,405,406,407</sup> The loss of abdominal fat may be the best predictor of the effects of weight loss.

**Weight reduction is the first-line management strategy for overweight and obese women.**<sup>408</sup> Weight loss increases SHBG concentrations, thereby reducing free androgen levels and decreasing androgen stimulation of the hair and skin. Weight loss also improves ovulatory function, thereby increasing conception rates and also possibly decreasing the risk for miscarriage. Despite much debate on superiority of low-carbohydrate versus low-fat diets for women with PCOS, **significant overall decrease in net caloric intake remains the most important dietary strategy for weight reduction. While treatment with metformin may facilitate weight loss,**<sup>405,409,410,411</sup> **primarily by suppressing appetite,**<sup>400</sup> **the overall effect is modest and inconsistent.**<sup>412,413,414,415,416,417,418,419,420,421</sup> **Consequently, metformin should not be used primarily for the purpose of weight reduction.** Appropriate designed clinical trials are needed to clearly establish a place of metformin in euglycemic women with PCOS for metabolic benefit.<sup>422</sup>

The benefits of exercise for improving diabetes and cardiovascular health have been demonstrated in the general population. Incorporation of moderate activity into daily activities appears as effective for reducing the risk of developing diabetes and cardiovascular disease as that achieved with vigorous physical activity, is more likely to be sustained, and is essential for maintaining weight loss over time.<sup>423,424</sup>

## **Managing Menstrual Abnormalities and Risk for Developing Endometrial Cancer**

Oligomenorrhea is the most common presentation of women with chronic anovulation, although many present with amenorrhea or abnormal uterine bleeding, and some even have regular menses. The typical patient presents with irregular or infrequent menses or with amenorrhea. While oligomenorrhea is defined as less than eight menstrual cycles per year, risk assessment for endometrial abnormalities and for abnormal bleeding episodes in women with PCOS should take into consideration not just the overall number of menstrual cycles but also the degree of obesity, insulin resistance, and hyperandrogenism, and also the concomitant morbidities. The evaluation and management of amenorrhea are discussed in depth in [Chapter 10](#), and abnormal uterine bleeding is the focus of [Chapter 14](#).

Chronic anovulation, obesity, and hyperinsulinemia all are associated with risk for developing endometrial cancer.<sup>360,361,362,363,364</sup> The mechanism relates to constant, unrelenting estrogen stimulation of the endometrium, predisposing to abnormal patterns of growth. Endometrial hyperplasia and even endometrial cancer can be encountered in young anovulatory women.<sup>366,367,368</sup> Consequently, for those with long-standing anovulation, endometrial sampling to exclude endometrial hyperplasia is a prudent precaution. **The decision on whether to perform an endometrial biopsy should not be based on the patient's age, but on the duration of potential exposure to unopposed estrogen stimulation, and the severity of obesity and insulin resistance must also be given consideration in this regard.** Whereas a grossly increased endometrial thickness (>12 mm) clearly suggests the possibility of endometrial hyperplasia,<sup>425</sup> a normal endometrial thickness does not exclude the diagnosis.<sup>426,427</sup>

Combined oral contraceptives (COCs) are the most commonly utilized treatment approach for the menstrual abnormalities associated with chronic anovulation, although transdermal and vaginal formulations of synthetic estrogen and progestins are relatively recent additions to the available combined hormone strategies (discussed in [Chapter 22](#)). The combined estrogen and progestin formulations (oral and non-oral) provide endometrial protection due to their progestin component, which attenuates the endometrial growth, thereby preventing abnormal uterine bleeding and also attenuating the risk for developing endometrial hyperplasia and neoplasia. Predictable and lighter withdrawal bleeding is seen with cyclic use of combination hormone regimens, thus offering both physical and psychological benefits. In those who are unable to use combination hormonal regimens (this may be due to bothersome side effects or because of factors that contraindicate the use of such regimens, as discussed in [Chapter 22](#)), effective endometrial protection and cycle regulation can be achieved with progestin-alone continuous or cyclic regimens. A number of effective formulations are available for use that offer various routes of administration (oral, subcutaneous, intramuscular, intravaginal, and intrauterine). While offering effective endometrial protection and contraceptive benefits, the progestin regimens however are lacking in some important actions that the combined estrogen-progestin contraceptives offer in the treatment of hyperandrogenism, as discussed in [Chapter 12](#) and briefly reviewed below.

## Hirsutism

Nearly two-thirds of anovulatory women complain of cosmetically disturbing hirsutism. The severity of hair excess in women with PCOS relates to the level of hyperandrogenemia, degree of adiposity, and genetic sensitivity of the individual's hair follicles to androgens. Hirsutism is more common in obese anovulatory women; free androgen levels increase with increasing BMI the combined inhibitory effects of insulin

and androgens on hepatic SHBG production. Skin and hair disorders can be both physically and psychologically very damaging. The spectrum of treatments for hirsutism is discussed in [Chapter 12](#) and briefly summarized here.

Mild focal hirsutism can be managed effectively with cosmetic measures (shaving, plucking, waxing, electrolysis, or laser hair removal), but most who present with a complaint of hirsutism are already using one or more such methods and may require additional treatment. Medical management options include primarily combination estrogen-progestin contraceptives, topical agents, and antiandrogens.

COCs are an effective treatment for hirsutism primarily because they suppress LH-dependent ovarian androgen production and stimulate hepatic SHBG production.<sup>428,429,430,431,432,433</sup> Some have questioned the wisdom and safety of estrogen-progestin contraceptives in women with PCOS, primarily because they have been associated with modest decreases in insulin sensitivity in some studies.<sup>434,435,436,437,438</sup> However, the overall weight of available evidence supports their safety in women with PCOS, with and without insulin resistance.<sup>349,418,439,440,441,442,443,444,445,446,447,448,449</sup>

Antiandrogens are effective for the treatment of hirsutism, but must be used in combination with a highly reliable contraceptive method (e.g., an intrauterine device) because of their potential to adversely affect sexual development in a male fetus if the patient were to conceive unexpectedly. Options commonly utilized in clinical practice include spironolactone (50–100 mg twice daily)<sup>450,451</sup> and finasteride (5 mg daily).<sup>452</sup> Flutamide, while an effective antiandrogen, has a concerning safety profile and caution is advised against its use in PCOS management. It is important to review side effects/risks associated with each—spironolactone can cause orthostatic hypotension and/or hyperkalemia (caution in those with renal disease); finasteride is overall well tolerated, with minimal hepatorenal toxicity.<sup>453</sup>

Eflornithine is a reversible inhibitor of ornithine decarboxylase, an enzyme that is needed for cell division,<sup>454</sup> and eflornithine hydrochloride is available as a topical treatment that, if applied regularly, is effective in slowing the growth of unwanted facial hair; continued use is however required for maintaining effectiveness.

Although a number of strategies including treatments with insulin-sensitizing agents (metformin, thiazolidinediones), statins, vitamin D, and stereoisomers of inositol have demonstrated reduction in circulating androgens, effects of such interventions on hirsutism have ranged from lacking to minimal or inconsistent,<sup>111,455,456,457,458,459,460,461,462,463,464</sup> and guidelines issued by the Endocrine Society, the European Society of Human Reproduction, and the American Society for Reproductive Medicine (ASRM) are unified in suggesting against their use for the treatment of hirsutism.<sup>249,349</sup>

## Alopecia

Loss of scalp hair can cause significant psychosocial burden. Unfortunately, effective and reliable therapies are limited. As discussed in [Chapter 12](#), a trial of antiandrogens can be considered. In women with evidence of hyperandrogenemia, a combination of COCs and spironolactone can be tried, whereas when circulating androgen levels are normal, finasteride may be preferred given its effects at lowering tissue DHT levels. Notably, any reliable long-term data on the magnitude of benefit, if any, from use of antiandrogens in managing PCOS-related alopecia are lacking. Topical minoxidil in concentrations recommended for men (5%) has been shown to offer some benefit with minimal side effects and should be offered to women who are particularly bothered by hair loss/thinning. Hair transplant may be an expensive but effective option to consider.

## Infertility

Chronic anovulation is one of the most common causes of infertility. Infertility however is a couple's problem, and despite the female partner's diagnosis of PCOS, evaluation must rule out factors in addition to ovulatory disturbance as a cause for couple's infertility. Factors other than lack of ovulation may contribute to reproductive compromise in women with PCOS, such as factors relating to oocyte quality or endometrial receptivity, and metabolic abnormalities may also contribute.<sup>349,458</sup> When anovulation is determined as the mechanism for infertility, strategies to achieve ovulation should be considered as first-line approach. Methods for ovulation induction are the subject of [Chapter 27](#) and are outlined briefly here.

Until fairly recently, the first ovulation-inducing drug of choice for women with PCOS was clomiphene citrate. However, the Pregnancy in Polycystic Ovary Syndrome II (PPCOS II) randomized controlled trial established superiority of letrozole (an aromatase inhibitor) over clomiphene in achieving significantly higher live birth and ovulation rates among infertile women with PCOS.<sup>459,460</sup> PPCOS II was a double-blind, multicenter trial, where anovulatory women diagnosed with PCOS by Rotterdam criteria and seeking fertility were randomized to receive letrozole or clomiphene for up to five treatment cycles. The rationale for this trial was based on previous findings that demonstrated an overall success rate (defined as live birth rate) with clomiphene of only 22% (following six treatment cycles).<sup>460</sup> The incidence of clomiphene resistance (i.e., failure to ovulate) was as high as 25%, underscoring a need to explore alternative treatment options to achieve successful ovulation in women with PCOS. In PPCOS II trial, women with PCOS were randomized to treatment with starting doses of 50 mg of clomiphene or 2.5 mg of letrozole, with increased doses as needed for each group (not to exceed the maximum dose of 150 or 7.5 mg, respectively).<sup>459,460</sup> Significantly higher cumulative live birth rate of 27.5% was observed in subjects randomized to receive

letrozole compared to 19.1% in women receiving clomiphene in a rate ratio of 1.44 (95% CI 1.10–1.87).<sup>460</sup> Monthly ovulation rates as well as likelihood for singleton pregnancy were significantly higher in those treated with letrozole compared to clomiphene, whereas rates of pregnancy loss were similar between the two groups. It is important to note that the mechanisms of action for letrozole and clomiphene are distinct. Clomiphene, as a selective estrogen receptor modulator (SERM), competitively binds the estrogen receptors at the level of the hypothalamus, thereby releasing the higher centers from the negative feedback effects of estrogen, allowing an increased pituitary secretion of FSH, which then acts at the dormant ovarian follicles to initiate follicular growth. In contrast to the SERM-like effects of clomiphene, aromatase inhibitors (represented by letrozole in PPCOS II), by blocking the enzyme aromatase (which is responsible for conversion of androgens to estrogens, as discussed in [Chapters 12 and 13](#)), bring about a profound decrease in both the circulating and tissue levels of estrogens, with consequent withdrawal of the negative feedback effects of estrogen at the hypothalamo-pituitary axis, and rise in endogenous FSH secretion by the pituitary. Unlike clomiphene that has a long half-life (in weeks), the half-life of letrozole is fairly short (48 hours). Despite its availability and increasing utilization as first-line approach to managing ovulatory dysfunction of PCOS, the choice of aromatase inhibitors for ovulation induction represents an off-label use as this class of drugs has not gained approval of regulatory bodies such as the FDA (in the United States). The rates of maternal and neonatal complication and fetal anomalies in pregnancies resulting from exposure to clomiphene and letrozole were comparable and offer reassurance regarding safety of letrozole as an ovulation induction agent. **It is our opinion that based on existing evidence, letrozole should be considered as a first-line agent for ovulation induction in women with PCOS and in those with a history of resistance to clomiphene. For women with PCOS who fail to achieve successful pregnancy despite multiple successful ovulations with the use of either clomiphene or letrozole, consideration should be given to proceeding directly to in vitro fertilization with single embryo transfer as a strategy that maximizes likelihood of achieving pregnancy while minimizing risks of ovarian hyperstimulation syndrome (OHSS) and multiple pregnancy that women with PCOS are particularly susceptible to with the use of gonadotropins to achieve ovulation induction.**

Treatment with insulin-sensitizing agents (metformin, thiazolidinediones, D-chiro-inositol, and myoinositol) has been used in attempts to increase/improve ovulation rates.<sup>461</sup> Metformin has been widely used for this purpose, yet studies have not demonstrated superiority to other agents/ovulation induction regimens.<sup>349,462,463,464,465</sup> PPCOS I was the largest clinical trial that compared the efficacy of metformin alone with that of clomiphene alone, and with combination of metformin and clomiphene, in women with PCOS. This randomized controlled trial confirmed superiority of

clomiphene as an ovulation induction agent over metformin; clomiphene treatment yielded a significantly higher live birth rate compared to metformin alone (22.5% vs. 7.2%), and while higher live birth rates were seen in the combined treatment group (26.8%), this difference was not of statistical significance.<sup>464</sup> A 2008 meta-analysis including 17 randomized trials concluded that combined treatment with metformin and clomiphene achieves higher ovulation and pregnancy rates than treatment with clomiphene alone, but there was no improvement in live birth rate.<sup>462,466</sup> In a few small studies involving clomiphene-resistant anovulatory women with PCOS, combined treatment has increased ovulation and pregnancy rates over those achieved with clomiphene alone, yet these studies did not assess live birth rate.<sup>467,468,469,470</sup> Information on whether addition of metformin to letrozole regimens may offer any benefit is currently lacking. At this time, routine use of metformin is not recommended for improving fertility or live birth rates.<sup>349</sup> Limited evidence indicates that combined treatment with metformin and rosiglitazone,<sup>471</sup> or with clomiphene and rosiglitazone,<sup>472</sup> is no more effective than metformin alone. In a recent Cochrane review, given the lack of primary outcomes reported in available studies, no definitive conclusions can be drawn regarding clinical pregnancy rates or live birth rates when using rosiglitazone.<sup>461</sup>

There is no evidence that metformin treatment during pregnancy is associated with any increased risk for major fetal malformations.<sup>473</sup> Metformin use in pregnancy has been examined as a strategy to reduce risk of development of gestational diabetes as well as to mitigate risk of miscarriage, with inconsistent results. The risk for miscarriage may be higher in women with PCOS compared to those without PCOS, and underlying metabolic disturbances are suggested to play a role.<sup>161,474,475,476</sup> Miscarriage risk reduction has been demonstrated, although inconsistently, with the use of metformin in women with PCOS.<sup>463,464,465</sup> Others have shown that stopping metformin at the time of pregnancy diagnosis does not affect miscarriage risk.<sup>349</sup> Metformin treatment during pregnancy also has been advocated to reduce the risk for developing gestational diabetes and other pregnancy complications in women with PCOS.<sup>477</sup> Given its favorable effects on several metabolic parameters, potential for facilitating ovulatory response to clomiphene (such as in those who have demonstrated resistance to trial of ovulation induction), lack of adverse fetal effects, and even a potential for mitigating incidence of gestational diabetes, for women who are already on metformin regimen, it may be reasonable to consider continuing through the first trimester of pregnancy. However, currently metformin treatment during pregnancy is not routinely recommended for women with PCOS.<sup>478</sup>

Induction of ovulation with exogenous gonadotropins is highly effective, but requires careful monitoring to avoid the intrinsic risks of multiple pregnancy and OHSS. Many women are highly sensitive to low doses of medication and exhibit a relatively

narrow therapeutic range.<sup>479,480,481,482,483,484</sup> Interestingly, metformin use has emerged as a risk reduction strategy against OHSS in women with PCOS as evidence indicates the risk for OHSS is decreased with concomitant use of metformin.<sup>485,486,487</sup>

Two different stereoisomers of inositol (D-chiro-inositol and myoinositol) have been systematically examined for their effects on endocrine and metabolic profiles and in facilitating ovulatory response in women with PCOS. Inositol and its isomers are involved in glucose metabolism, specifically the transport of glucose and its conversion to glycogen.<sup>488</sup> Utilization of myoinositol specifically in PCOS patients has demonstrated improvement in both ovarian function and metabolism (i.e., reduced insulin resistance).<sup>488</sup> Although the bulk of data are mixed with some studies showing improvements in insulin sensitivity, lowering of androgens, and improved ovulatory responses, with others demonstrating null effects, a combination of the two stereoisomers in the ratio of 1 (D-chiro-inositol) to 40 (myoinositol) has shown promise with evidence of clinical, endocrine, and metabolic improvements.<sup>126,127,128</sup>

Laparoscopic ovarian drilling (LOD), with laser or diathermy (monopolar or bipolar), is effective in restoring ovulatory function in women with PCOS, albeit in the short term.<sup>489,490,491</sup> When deliberating on the choice of LOD as a strategy to improve chances of spontaneous ovulation, the choice of instrument (laser or electrocautery), number and depth of punctures, and laterality (bilateral or unilateral ovarian drilling) must be given due consideration. Given the risks of surgery including potential for pelvic adhesive disease and detriment to ovarian reserve, as well as availability of a widening range of medical strategies, surgical management is often relegated to near bottom of strategies currently available for the management of PCOS.<sup>492</sup>

Vitamin D deficiency (serum 25-hydroxy level <30 ng/mL, as per the Endocrine Society guidelines) has been associated with a reduced likelihood for live birth in populations undergoing various infertility treatments.<sup>493</sup> In a secondary analysis of PPCOS I clinical trial, serum 25-hydroxy D levels (a circulating metabolite that reflects the status of vitamin D) were tested in stored sera from 540 women with PCOS, and the relationship between vitamin D status and likelihood for ovulatory response and live birth following ovulation induction was examined.<sup>494</sup> Women with evidence of vitamin D deficiency were significantly less likely to achieve ovulation and live birth following ovulation induction with clomiphene (with and without metformin). Interestingly, the likelihood of treatment-related live birth was fourfold higher in those with serum 25-hydroxy D level in excess of 45 ng/mL. The existing data relating vitamin D deficiency with fertility are almost entirely observational, and intervention trials are needed to examine and establish if a cause and effect relationship exists to the observed associations. However, while awaiting confirmation of this impression, normalization of vitamin D status through judicious supplementation represents a simple, cost-

effective, and safe approach toward optimizing fertility treatment–related successes.

## **Metabolic Abnormalities and Associated Health Risks**

Women with PCOS commonly exhibit insulin resistance and other risk factors for the development of type 2 diabetes and cardiovascular disease. These observations have focused a great deal of attention on the importance of incorporating risk reduction strategies into the clinical management of women with PCOS.

Insulin resistance results in compensatory hyperinsulinemia, which predisposes to a progressive decline in pancreatic  $\beta$ -cell reserve, leading to glucose intolerance and ultimately type 2 diabetes mellitus. In women with PCOS, pancreatic  $\beta$ -cell dysfunction can be demonstrated even before glucose intolerance becomes apparent, and the rate of progression from glucose intolerance to frank diabetes is increased<sup>109,495,496</sup>; up to 10% of women with PCOS develop type 2 diabetes before the age of 40.<sup>107,109,497</sup> Obesity adds to the risk, by aggravating the underlying insulin resistance. Overall, the risk for developing impaired glucose tolerance or type 2 diabetes is increased four- to sevenfold in women with PCOS, compared to women of comparable age without PCOS.<sup>107,109,496,498</sup>

Although direct evidence for an increased incidence of cardiovascular disease in women with PCOS is lacking, the prevalence of known risk factors and surrogates of cardiovascular disease (such as hypertension, endothelial dysfunction, and increased carotid intimal-medial thickness) is substantially increased.<sup>499,500,501</sup> Insulin resistance and hyperinsulinemia are associated with chronic low-grade inflammation, as reflected by elevations in CRP, interleukin-6, leukocyte count, and other inflammatory markers.<sup>502,503,504,505,506,507</sup> Hyperinsulinemia also is associated with hypertension and increased production of plasminogen activator inhibitor-1 (PAI-1), thereby inhibiting fibrinolysis.<sup>508,509</sup> Hyperandrogenemia and obesity each contribute to dyslipidemia and aggravate the underlying insulin resistance in PCOS. Consequently, many women with PCOS have some degree of dyslipidemia, such as decreased HDL cholesterol and increased total and LDL cholesterol, and elevated triglycerides.<sup>354,510</sup> Many also have central obesity, and some even meet the criteria for the diagnosis of the metabolic syndrome, a condition that is predictive of a higher risk for developing cardiovascular disease.<sup>511,512,513</sup> Despite manifesting a plethora of cardiovascular risks, the incidence of cardiovascular events is not as high as estimates project as not all patients with PCOS experience adverse cardiovascular events, making a direct relationship between the two difficult.<sup>25</sup>

The **metabolic syndrome**, originally known as syndrome X,<sup>514</sup> represents a constellation of closely related cardiovascular risk factors, and several studies have

observed an increased prevalence of metabolic syndrome in women with PCOS.<sup>511,515</sup> A number of different definitions for the metabolic syndrome have been proposed, varying in emphasis on abnormalities in glucose metabolism (insulin resistance, hyperinsulinemia, glucose intolerance, diabetes mellitus), central obesity, and cardiovascular risk factors (hypertension, increased triglycerides, decreased HDL cholesterol).<sup>516,517,518,519</sup> Although all of the definitions yield comparable estimates of the overall prevalence of the metabolic syndrome, they identify different populations in different ethnic groups.<sup>520</sup> For example, the risk for type 2 diabetes increases at much lower levels of body fat in Asians than in Europeans (White people of European origin).<sup>521</sup> The definition proposed by the International Diabetes Federation (IDF) in 2005 attempted to reconcile the differences in definitions and to produce a consensus definition that would be useful for identifying those at risk for developing cardiovascular disease in all populations and also allowing comparative long-term studies.<sup>522</sup> The IDF definition views central obesity (as defined by waist circumference) as an essential component of the metabolic syndrome, because of the strength of the evidence linking waist circumference with cardiovascular disease and the other components of the syndrome and the strong likelihood that central obesity is an early step in the pathophysiologic cascade leading to full expression of the metabolic syndrome.<sup>519</sup> **As defined by the National Heart, Lung, and Blood Institute and the American Heart Association, a diagnosis of metabolic syndrome requires the presence of any three of the following five clinical characteristics<sup>522</sup>:**

- **Increased waist circumference (population specific, >88 cm in women in the United States)**
- **Increased blood pressure ( $\geq 130$  mm Hg systolic;  $\geq 85$  mm Hg diastolic) or receiving medication for hypertension**
- **Increased triglycerides ( $\geq 150$  mg/dL) or receiving medication for hypertriglyceridemia**
- **Decreased HDL cholesterol ( $< 50$  mg/dL) or receiving medication for reduced HDL**
- **Increased fasting glucose ( $\geq 100$  mg/dL) or receiving medication for hyperglycemia**

Our recognition of a central role of insulin resistance in the pathophysiology of PCOS and our knowledge of its potential longer-term health consequences have focused a great deal of attention on the benefits of insulin-sensitizing medications and other drugs aimed at reducing the risks for developing diabetes and cardiovascular disease.

Metformin is a biguanide oral insulin-sensitizing agent and currently is the most

widely used drug in the world for the treatment of type 2 diabetes mellitus. Metformin decreases hepatic glucose production, decreases intestinal glucose uptake, and increases peripheral insulin sensitivity; metformin also inhibits lipolysis, resulting in decreased circulating concentrations of free fatty acids, which further helps to reduce hepatic gluconeogenesis.<sup>478,523,524</sup> Mechanism of action of metformin is not entirely clear, but involves activation of the adenosine monophosphate–activated protein kinase pathway in the liver and skeletal muscle.<sup>525,526,527,528,529</sup>

A large number of trials have observed beneficial effects of metformin in women with PCOS; in most, the dose has ranged between 1,500 and 2,000 mg daily. **In general, metformin treatment increases insulin sensitivity,**<sup>413,421,471,530,531,532,533</sup> **decreases weight and BMI,**<sup>413,416,417,421,534</sup> **decreases blood pressure and LDL cholesterol,**<sup>535</sup> **and overall improves the chronic inflammatory state in women with PCOS.**<sup>536</sup> A meta-analysis of 31 trials concluded that metformin increases insulin sensitivity up to 20%, decreases weight and BMI by 3–5%, decreases fasting glucose by about 5%, and increases HDL cholesterol and decreases triglycerides by approximately 10% in patients at increased risk for developing diabetes.<sup>537</sup> Insulin resistance improves during metformin treatment, no matter how severe, and in lean and overweight women with PCOS as well as in those who are obese.<sup>421,530,531,533</sup> Weight loss enhances the effects of metformin.<sup>421</sup> Metformin appears to decrease levels of CRP and soluble vascular cellular adhesion molecules (sVCAM), which reflect the low level of chronic inflammation associated with insulin resistance.<sup>503,538,539</sup> Indirect evidence suggests metformin also may improve vascular endothelial function and coronary flow rate in women with PCOS.<sup>540,541,542,543</sup>

Metformin is available in both a regular and a sustained release form that may be associated with fewer gastrointestinal side effects (nausea, vomiting, diarrhea, constipation, bloating, flatulence, heartburn, indigestion, unpleasant metallic taste). To improve tolerance and decrease side effects, it is generally recommended that metformin treatment begin with a low dose (250–500 mg daily), with the dose increasing gradually over an interval of 4–6 weeks until the desired dose is attained. The drug also can interfere with intestinal absorption of vitamin B12, so patients should be alerted to symptoms of vitamin B12 deficiency, which include numbness, paresthesia, macroglossia, memory loss, behavioral changes, and pernicious anemia. Lactic acidosis is a rare complication of metformin treatment, but for that reason, the drug should not be administered to those with renal insufficiency, liver disease, or alcohol abuse.<sup>544</sup> In clinical practice, it may be prudent to establish normal renal function based on serum creatinine level, prior to initiation of therapy.

Thiazolidinediones are another type of insulin-sensitizing agent that has been used

to improve insulin resistance in women with PCOS. They include rosiglitazone, pioglitazone, and, formerly, troglitazone (withdrawn from the market due to concerns about liver toxicity). Thiazolidinediones are synthetic agonists for the peroxisome proliferator-activated receptor gamma (PPAR $\gamma$ ), which serves as a nuclear transcription factor in the regulation of genes involved in carbohydrate, lipid, and protein metabolism (free fatty acids and eicosanoids are the natural receptor ligands). In trials involving women with PCOS, treatment with troglitazone improved insulin sensitivity and glucose tolerance in a dose-dependent manner.<sup>545,546,547</sup> Similar observations have emerged from studies examining the effects of rosiglitazone and pioglitazone in women with PCOS.<sup>471,472,548,549,550,551</sup> However, overall experience with thiazolidinediones is quite limited and they have been associated with cardiac complications, and this class of medications is not recommended for use in reproductive-age women and especially those attempting to conceive.<sup>350,461,552,553</sup>

**Metformin improves insulin sensitivity as much or more than thiazolidinediones and currently remains the preferred insulin-sensitizing agent for women with PCOS.**

Incretins are the newest class of metabolic modulators that based on their mechanisms of action can be considered superior to metformin, at least in theory, although existing data on their use in women with PCOS are thus far limited.<sup>554</sup> Through a combination of effects that include delaying of gastric emptying, inhibition of pancreatic secretion of glucagon, increased insulin secretion, and improved insulin signaling and appetite suppression possibly through central effects, these agents achieve reduction in blood glucose levels while salvaging pancreatic  $\beta$ -cell function. There are two broad classes of incretins that are increasingly being utilized primarily in the management of type 2 diabetes. The first class of incretins is of glucagon-like peptide-1 (GLP-1) receptor analogs that mimic effects of GLP-1, a gut peptide that is secreted by the L cells residing in specified areas of the small intestine (distal jejunum and ileum) in response to dietary carbohydrate and lipid content. This class of incretins is susceptible to degradation by the gastric acid, requiring parenteral administration, and has demonstrated efficacy in improving not just glucose levels but also dyslipidemia as well as facilitating weight loss in diabetics. In a meta-analysis of 7 randomized controlled trials involving 172 women with PCOS, 3-month treatment with a synthetic GLP-1 receptor agonist liraglutide resulted in a significant reduction in BMI (a decrease of 1.65 [0.72–2.58] kg/m<sup>2</sup>,  $p < 0.01$ ).<sup>555</sup> Total testosterone levels were reported in five of the seven studies included in this meta-analysis, and significant reduction in serum testosterone levels (by 0.29 nmol/L,  $p < 0.01$ ) was similarly observed, and nonsignificant improvements in some indices of insulin sensitivity were also noted. The second class of incretins is that of DPP-4 (dipeptidyl peptidase-4) inhibitors.<sup>556</sup> The enzyme DPP-4 is a serine protease transmembrane glycoprotein that is expressed in the cell membrane of many cell types and mediates rapid inactivation of

GLP-1. This class of incretins is orally active, and formulations of a combination of DPP-4 with metformin have demonstrated additive metabolic benefit compared to either used as a single agent. As with the GLP-1 receptor agonists, data in PCOS population are limited, and future studies are needed to better appreciate the magnitude of metabolic benefit these agents can offer to women with PCOS.

Although the benefits of estrogen-progestin contraceptives in the treatment of women with PCOS are undisputed, they generally do not correct any of the metabolic abnormalities commonly observed in women with PCOS.<sup>418,557,558,559,560,561</sup> Although preparations containing drospirenone may have some limited impact,<sup>451</sup> other evidence suggests that even estrogen-progestin contraceptives containing antiandrogenic progestins may even aggravate an underlying chronic inflammatory state.<sup>503,505,560</sup> Not surprisingly, combination therapies aimed at more comprehensive treatment are now emerging, including estrogen-progestin contraceptives and metformin and low doses of metformin (850 mg daily) and an antiandrogen (flutamide, 62.5 mg daily), with or without an estrogen-progestin contraceptive.<sup>456</sup> In women receiving an estrogen-progestin contraceptive, the addition of metformin improves insulin resistance and further reduces hyperandrogenism.<sup>420,441,562</sup> The combination of low doses of metformin (850 mg daily) and an antiandrogen (flutamide, 62.5 mg daily) improves body composition (loss of fat and gain of lean mass) and lipid levels and increases levels of adiponectin, an anti-inflammatory protein secreted from adipose that modulates glucose regulation and fatty acid metabolism.<sup>559</sup> Combined treatment with an estrogen-progestin contraceptive and an antiandrogen has similar effects that are further enhanced if metformin also is added to the treatment regimen.<sup>346</sup> **Overall, these observations demonstrate that the spectrum of metabolic abnormalities that accompanies PCOS can be improved by treatment with low doses of metformin and antiandrogen in adolescents and by their addition to estrogen-progestin contraceptives in young women.**<sup>451</sup> At least in theory, alternative or adjunctive treatment with metformin and antiandrogens is attractive because it may improve or reverse “upstream” abnormalities and help to prevent their “downstream” consequences. **Experience with these combination treatment regimens is still limited, but is growing steadily, suggesting they may soon find their way into clinical practice.**

Dyslipidemia is common in women with PCOS, with many having decreased HDL cholesterol or increased total and LDL cholesterol or triglycerides.<sup>510</sup> As such, interest has turned to the potential benefits of treatment with statins. In the first clinical trial involving women with PCOS, lipid profiles improved more in women randomized to treatment with an oral estrogen-progestin contraceptive and simvastatin (20 mg daily) than in those receiving only the contraceptive.<sup>563</sup> In those receiving simvastatin, markers of systemic inflammation and endothelial function also improved, and serum

testosterone levels decreased to a significantly greater extent.<sup>563,564</sup> In a placebo-controlled trial, treatment with atorvastatin resulted in a significant decrease in serum testosterone, CRP, and insulin resistance and improved lipid profiles.<sup>565</sup> In a trial comparing the effects of simvastatin and metformin, the two drugs decreased testosterone and improved markers of systemic inflammation and endothelial function to a similar extent, but lipid profiles and insulin sensitivity improved only in those receiving simvastatin; results of combined treatment were not different from those of treatment with simvastatin alone.<sup>566</sup>

Statins exert their effects primarily by inhibiting 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting step in the mevalonate pathway leading to cholesterol synthesis.<sup>567</sup> The effects of statins on testosterone concentrations may relate to decreased availability of products of the mevalonate pathway (including cholesterol), to inhibition of the MAPK pathway that mediates the proliferative actions of insulin, or to other mechanisms regulating ovarian steroidogenesis.<sup>566,568</sup> **Statins may offer a promising new approach to the treatment of women with PCOS at risk for developing diabetes and cardiovascular disease. However, it is important to emphasize that statins may be teratogenic and are contraindicated in pregnancy.**<sup>569</sup>

A number of observational studies have examined relationship between serum 25-hydroxy D (a circulating metabolite that is recognized to reflect bodily stores of vitamin D) levels with metabolic parameters including lipid profile, serum levels of inflammatory markers, and indices of insulin sensitivity across populations.<sup>570</sup> In women with PCOS, vitamin D deficiency (serum 25-hydroxy level <30 ng/mL, as per the Endocrine Society guidelines) has been associated with insulin resistance, lipid abnormalities, and biomarkers of oxidative stress and inflammation. Improvements in insulin sensitivity and lipid profile and decrease in inflammatory markers such as TNF- $\alpha$  and CRP as well as reduction in circulating androgen levels hyperandrogenism have been described following vitamin D supplementation in women with PCOS.<sup>38,571</sup>

**Nonalcoholic hepatic steatosis or nonalcoholic fatty liver disease (NAFLD)** constitutes pathologic liver conditions that range from steatosis to nonalcoholic steatohepatitis (NASH). Steatosis is the result of lipid accumulation in parenchyma of the liver, while NASH includes chronic inflammation and fibrosis.<sup>572</sup> The prevalence is 70% of individuals with T2DM, 90% in those who are morbidly obese, and 27–60% of women with PCOS. Insulin resistance appears to be the primary driver, as even in the absence of obesity, women with insulin resistance have an independent risk of developing NAFLD.<sup>572</sup> Androgens also independently predict NAFLD, with a meta-analysis noting an OR of 2.54 (95% CI 2.19–2.95) in women with PCOS and hyperandrogenism, compared to those without hyperandrogenism.<sup>572</sup> Small studies have

demonstrated an improvement in NAFLD with diet and exercise, as well as with metformin.<sup>573</sup>

**Sleep disturbances** are prevalent in PCOS. The exact prevalence of **obstructive sleep apnea (OSA)** in women with PCOS is not known; this is apparent by the wide range in the estimated prevalence—0–69%.<sup>574</sup> What is more apparent, however, is the association of obesity with OSA risk. Obesity contributes to OSA through several mechanisms—increased parapharyngeal fat deposition, altered neural compensatory mechanism for maintaining airway, decreased residual capacity, reduced lung volume from abdominal fat, and increased chest wall thickness.<sup>574</sup> As obesity is also linked to PCOS, the above mechanisms likely apply to women with PCOS. Androgens and altered progesterone levels contribute to OSA in women with PCOS. Hyperandrogenism and low progesterone levels promote OSA by increasing upper airway collapsibility, with or without concomitant impaired sensitivity to ventilator chemoreceptors.<sup>574</sup> Furthermore, in a study of healthy premenopausal women receiving a transdermal testosterone patch (5 mg/day), testosterone increased the apneic threshold in women, which led to breathing instability during sleep.<sup>574,575</sup> OSA itself may also affect the hypothalamic-pituitary axis, as decreased sleep (i.e., as is seen in individuals with OSA) can lead to menstrual abnormalities by affecting GnRH, FSH, and LH pulsatility.<sup>574</sup> Similarly, OSA is associated with insulin resistance, and implementation of continuous positive airway pressure (CPAP) therapy reduces the homeostasis model assessment of insulin resistance. It is postulated that OSA may contribute to the severity of the PCOS phenotype through insulin resistance.<sup>576</sup> As OSA is considered a cardiovascular disease risk factor for women with PCOS, the Endocrine Society recommends screening overweight/obese women (including adolescents) with PCOS for OSA symptoms, with referral to the appropriate provider for definitive diagnosis and treatment.<sup>338</sup>

## Indications for Treatment with Metformin

The best overall approach to the treatment of chronic anovulation and PCOS currently is somewhat controversial. For decades, estrogen-progestin contraceptives have been the standard therapy for women who are not immediately interested in seeking pregnancy, for good reasons. However, the central role of insulin resistance in PCOS and limited evidence suggesting that estrogen-progestin contraceptives may aggravate insulin resistance have raised concerns that such treatment might increase long-term risks for diabetes and heart disease in women already predisposed.<sup>558</sup>

There is no question that the majority of both lean and obese women with PCOS are insulin-resistant<sup>577,578,579,580</sup> and that the prevalence of impaired glucose tolerance and

diabetes is increased in women with PCOS.<sup>107,109,495</sup> In the lean patient, insulin resistance is intrinsic, but poorly understood,<sup>105,138,581</sup> and the obese patient carries an additional metabolic burden.<sup>582</sup> There also is no debate that insulin resistance and PCOS are associated with increased risk for developing hypertension and<sup>168,583,584</sup> dyslipidemia<sup>351,585,586,587</sup> and with a number of other surrogate markers and risk factors for heart disease.<sup>347,502,514,518,546,588,589,590</sup> Understandably, some view PCOS as an early sign, or even as a component, of the metabolic syndrome in women.<sup>558</sup>

Some studies have observed that estrogen-progestin contraceptives decrease insulin sensitivity.<sup>415,437,439,441,591</sup> Overall, the evidence suggests that the effects of estrogen-progestin contraceptives on insulin resistance and glucose tolerance vary with the dose of ethinyl estradiol, with the dose and type of progestin, and with phenotype and, in general, are not clinically important.<sup>418,419,592</sup> No large studies have examined the risk for developing type 2 diabetes in women with PCOS specifically. Studies in healthy women have observed a modest increase in the relative risk for past and current users of estrogen-progestin contraceptives, compared with never users, although the differences were not significant.<sup>593,594</sup> **Estrogen-progestin contraceptives may decrease insulin sensitivity or glucose tolerance, to some extent, in some women, but concerns that the risk may be substantially higher in women with PCOS and underlying insulin resistance are unsubstantiated.**

Similarly, no large studies have examined the effect of estrogen-progestin contraceptives on the risk for developing cardiovascular disease in women with PCOS specifically. Alterations in vascular and endothelial function have been described, and increased death rates from cardiovascular disease have been observed in women with history of menstrual irregularity.<sup>584</sup> Case-control studies have observed that estrogen-progestin contraceptives are associated with an increased risk for myocardial infarction, but events are rare and risk is almost entirely limited to women with hypertension and those who smoke.<sup>595,596,597,598</sup> **Concerns that use of estrogen-progestin contraceptives might pose greater risk for women with PCOS are understandable, but there is no convincing evidence that they do.**

Treatment with metformin might indeed decrease the risk for developing diabetes and heart disease in women with PCOS, but evidence for those benefits is indirect, inferred primarily from studies in patients with impaired glucose tolerance<sup>408</sup> and from studies examining surrogate markers and risk factors for heart disease; conclusive evidence is lacking. The two most common and classical features of PCOS are anovulation and hyperandrogenism, and treatment with estrogen-progestin contraceptives and antiandrogens, or with clomiphene metformin, has little impact on either. Metformin improves menstrual cyclicality and ovulatory function in some women

with PCOS, but not in most, and standard treatments for anovulatory infertility are clearly more effective. Consequently, for the large majority of women with PCOS, metformin treatment alone will not suffice in allowing resumption of spontaneous ovulation, and use of an ovulation induction agent such as an aromatase inhibitor or clomiphene will be required. **The most clinically relevant question is who can benefit most from metformin treatment.**

The most logical candidates for treatment with metformin (aimed at preventing or slowing progression to type 2 diabetes and at reducing longer-term risks for cardiovascular disease) are women with indices of dysglycemia including impaired fasting glucose, impaired glucose tolerance, abnormally elevated hemoglobin A1c levels, or diabetes, those with obvious evidence of severe insulin resistance (acanthosis nigricans),<sup>590,599</sup> and women having other features of the metabolic syndrome, such as central obesity, hypertension, and dyslipidemia. **All women with PCOS should be screened with an OGTT at the time of presentation and at least every 2 years thereafter (or sooner if the clinical picture worsens); those with impaired glucose tolerance warrant annual screening.**<sup>340</sup> **Evaluation must include assessment of blood pressure and should include measuring waist circumference and assessing lipid profile, to help quantify their metabolic risk by identifying those with features of the metabolic syndrome.**

There is good evidence from the Diabetes Prevention Trial that metformin treatment can decrease the risk for progression to diabetes in those with impaired glucose intolerance, by approximately 30% (although better results were observed in those receiving intensive lifestyle interventions).<sup>408</sup> In a retrospective study of 50 women with PCOS treated with metformin (including 11 with impaired glucose tolerance at baseline), impaired glucose tolerance persisted in 5/11 (45%), and reverted to normal in the remainder (6/11, 55%), over an average of 43 months of follow-up.<sup>600</sup>

Overall, available data from small studies demonstrate that there is little if any exacerbation in cardiovascular disease parameters in women with PCOS using COCs.<sup>349</sup> Long-term data are needed to determine if long-term use of hormonal contraceptives may differentially impact on indices of insulin sensitivity, on pancreatic  $\beta$ -cell reserves, and on mechanisms predisposing to cardiovascular disease in women with PCOS compared to women without PCOS. Given the previously mentioned beneficial metabolic effects of metformin, usefulness of combination of metformin and hormonal contraceptives has been examined with reassuring results.<sup>601</sup> While it is plausible that metformin use may mitigate the risk for heart disease in women with PCOS using hormonal contraceptives, any conclusive evidence in this regard is lacking.<sup>602</sup> As mentioned earlier in the chapter, metformin does have a role in women with PCOS who also have NAFLD.

# Additional Considerations

## Adolescent with PCOS

The diagnosis of PCOS in adolescence presents a challenge to clinicians, as some of the features that are weighed among diagnostic criteria in adults are commonly encountered features of normal adolescent development, such as some degree of menstrual irregularity particularly within the first year postmenarche and acne.<sup>285</sup> Early pubarche or adrenarche have been associated with development of PCOS later in life, although the mechanisms are not clear.<sup>603</sup> Menstrual cycles are often longer during the first 3 years following menarche, becoming progressively more regular so that by the 3rd year following menarche, less than 50% of cycles remain irregular. Acne can also be a normal feature of puberty and polycystic appearance of ovaries may be normal for an adolescent female. However, menstrual irregularity persisting beyond 3 years postmenarche likely indicates a true ovarian or adrenal dysfunction and should be investigated.<sup>285</sup> Overall, a consensus exists in the recommendation for following adolescent patients closely for 2 years postmenarche prior to initiating an investigation for PCOS. In working up the possible diagnosis of PCOS in adolescents, the following should be used to help facilitate diagnosis:

- **Hyperandrogenism:** Hirsutism is the hallmark of hyperandrogenism, with acne and alopecia suggesting hyperandrogenism. In adolescent girls, the prevalence of acne is high and may be unrelated to PCOS. Hirsutism is also difficult to identify/quantify, as the Ferriman-Gallwey score was designed for testing in adult women. As such, in this younger patient population, there is emphasis placed on biochemical signs of excess androgens. Reference range for normal and abnormal values for testosterone in adolescents is not well defined; the lower “normal” limit in adolescents is likely lower than that in adult women,<sup>604</sup> and a transient increase in circulating levels of testosterone may be a physiologic pubertal phenomenon.<sup>605</sup>
- Given that multifollicular ovaries are a normal feature in adolescence, this alone cannot be used as a diagnostic criterion for PCOS in adolescents.<sup>285</sup>
- In general, PCOS diagnosis in adolescents must require the presence of either primary amenorrhea at and beyond 16 years of age (ruling out other causes as discussed in [Chapter 10](#)) or persistent oligomenorrhea.<sup>349</sup>

Although difficult, the diagnosis of PCOS in adolescence is important, so that long-term health consequences can be mitigated. As such, anovulatory adolescent girls are another group that warrants periodic screening for glucose intolerance and specific screening for insulin resistance, particularly if they are obese or had low birth weight.<sup>606,607</sup> Both

characteristics are associated with premature adrenarche and the development of PCOS during adolescence, and evidence indicates that hyperinsulinemia is a key pathogenic factor.<sup>341,342,344,345</sup> There is substantial evidence that early treatment with metformin can decrease hyperinsulinemia and hyperandrogenism, facilitate weight loss, and restore ovulatory menstrual function in girls with demonstrable insulin resistance.<sup>285,343,345</sup> The addition of combined hormonal oral contraceptives to metformin has also been associated with increased HDL, although also with a trend toward increased triglycerides. In adolescents not interested in hormonal therapy, metformin alone is reasonable. An antiandrogen can also help treat more bothersome acne and hirsutism in the adolescents; however, such a regimen must include a reliable contraceptive, given the teratogenic potential of antiandrogenic formulations.<sup>285</sup>

## **PCOS, Reproductive Aging, and Menopause**

There is a paucity of information on experiences of women with PCOS as they progress through stages of reproductive aging. Limited data however suggest that age at spontaneous menopause is likely delayed in women with PCOS.<sup>608</sup> Interestingly, with aging, the pattern of menstrual cycles often becomes regular and predictable with an increase in frequency of spontaneous anovulatory cycles. In a prospective cohort study, 118 hyperandrogenic women with PCOS were followed from ages 20 to 25 at 5-year intervals for 20 years, and their clinical, endocrine, and metabolic profiles were compared with two different groups of age-comparable controls without PCOS. In the PCOS population, the proportion of anovulatory cycles decreased from 100% at the start of this study to 73% by the time participants reached ages between 40 and 44 years.<sup>609</sup> Notably, in women with PCOS whose cycles became ovulatory with advancing age, the metabolic indices of insulin sensitivity and lipid profiles were comparable to seen in the controls; in contrast, PCOS women who remained anovulatory demonstrated evidence of dysmetabolism including higher insulin levels, lower QUICKI (reflecting insulin resistance), and worse lipid profiles (higher total C, LDL-C, non-HDL-C, and lower HDL-C). While resumption of spontaneous ovulatory cycles with advancing age confers endometrial and metabolic benefit, this shift in reproductive physiology does increase a likelihood of unplanned pregnancies for women with PCOS as they age; a greater appreciation of a need for reliable contraception is needed as women with PCOS age. As discussed earlier, women with PCOS are at a higher lifetime risk for developing endometrial cancer, and therefore new-onset abnormal uterine bleeding must be thoroughly evaluated in women with a history of PCOS. Their risk for breast and ovarian cancer is no higher than age-comparable women without PCOS. Long-term longitudinal studies are needed to better understand if women with PCOS view and experience menopause transition and postmenopausal period differently than those without PCOS.

## **PCOS and Psychological Well-Being**

Anxiety and depression are common in women with PCOS, more so than in the general population.<sup>25</sup> These mood disorders can have significant impact on quality of life. For adolescence, self-image can be impacted, while in women facing infertility, there can be a high level of anxiety regarding potential inability to conceive. Self-image in women of all ages can be negatively impacted as well. It is important to screen for anxiety and depression, and adolescents and women with PCOS should be encouraged to identify and seek resources to optimize psychological well-being.

# SUMMARY

---

We clearly are in an era of increasing understanding of both determinants and sequelae of PCOS, as well as are gaining access to an expanding range of options for the management of women with PCOS. In the past, we primarily prioritized treatment of the specific problems of infertility, abnormal uterine bleeding, and hirsutism. We now have a better understanding of the endocrine and metabolic corollaries and of their relevance to long-term health risks and have greater management options and opportunities, and indeed the obligation, to choose and offer interventions that can maximize benefits while helping prevent or reverse some of the metabolic consequences of the disorder that have an important impact on overall health and on the quality and quantity of life.

## Key Points: PCOS

- Polycystic ovary syndrome is not a specific endocrine disease but a syndrome represented by a collection of signs and symptoms, and no one sign, symptom, or test is diagnostic.
- Diagnosis of polycystic ovary syndrome is based primarily on the clinical history and physical examination. The major clinical features of polycystic ovary syndrome are hyperandrogenism and menstrual dysfunction.
- Although present in most women with chronic hyperandrogenic anovulation, polycystic ovaries do not establish and are not required for diagnosis of polycystic ovary syndrome.
- Insulin resistance and compensatory hyperinsulinemia are common in women and play an important role in the pathophysiology of polycystic ovary syndrome. Up to 35% of women with polycystic ovary syndrome exhibit impaired glucose tolerance and up to 10% meet criteria for type 2 diabetes mellitus.
- Gonadotropin levels or ratios are not a reliable criterion for diagnosis of polycystic ovary syndrome.
- Knowing and understanding the health implications and consequences of chronic anovulation and methods for their effective management are far more important than simply assigning a diagnosis of PCOS.
- Evaluation of women with suspected polycystic ovary syndrome should include:
  - Serum thyroid-stimulating hormone (TSH).
  - Serum prolactin.
  - 2-hour oral glucose tolerance test.
  - Fasting lipid profile.
  - Serum testosterone (in women with clinical evidence of hyperandrogenism).
  - Morning follicular phase serum 17-hydroxyprogesterone (in women with a

pre- or perimenarcheal onset of hirsutism, a family history of congenital adrenal hyperplasia, or high-risk ethnicity).

- Screening for hypercortisolism (by 24-hour urine-free cortisol estimation) should be considered in women with features suggestive of Cushing syndrome (obesity, hypertension, diabetes, easy bruising).
- Overnight dexamethasone suppression test should be considered in women with signs, symptoms, or biochemical evidence of hypercortisolism).

# Hirsutism

**Hirsutism** (Latin origin) is defined as excessive growth of **terminal** or coarse hair in a male-pattern distribution on the face and body and affects between 5% and 10% of reproductive age women.<sup>1</sup> Circulating androgen levels (discussed in detail in [Chapters 11 and 13](#)) are often, although not always, elevated, and hirsutism can be the initial or the only sign of androgen excess. Hirsutism in the setting of normal circulating androgen profile is termed “idiopathic.” Hirsutism is most frequently seen in women with polycystic ovary syndrome (PCOS, reviewed in [Chapter 11](#)). Unlike hirsutism, **hypertrichosis** (Greek origin) refers to a generalized overgrowth of soft, fine vellus hair ([Figure 12.1](#)) and is not caused by androgen excess but rather may be genetic or result from exposure to certain medications. **Virilization** describes the signs and symptoms of more severe androgen excess, which include deepening of the voice, temporal male-pattern balding (androgenic alopecia), breast atrophy, changes in body habitus that include an increase in muscle mass, and clitoromegaly. Unlike hirsutism, virilization is rare and most commonly results from congenital adrenal hyperplasia (CAH) or androgen-producing tumors of the ovary or adrenal (discussed in [Chapter 13](#)).

**FIGURE 12.1**

Hirsutism is both an endocrine and a cosmetic problem that can contribute to significant psychological stress and deserves a concerned and sympathetic response. Excessive hair growth on the face, chest, or abdomen may be quite distressing and raises a number of concerns about the possibility of underlying disease, effects on body image and fertility, and questions about availability and efficacy of existing treatments.

This chapter reviews the biology of hair growth and the causes and pathophysiology of hirsutism and presents a simplified, evidence-based approach to the diagnostic evaluation and effective clinical management.

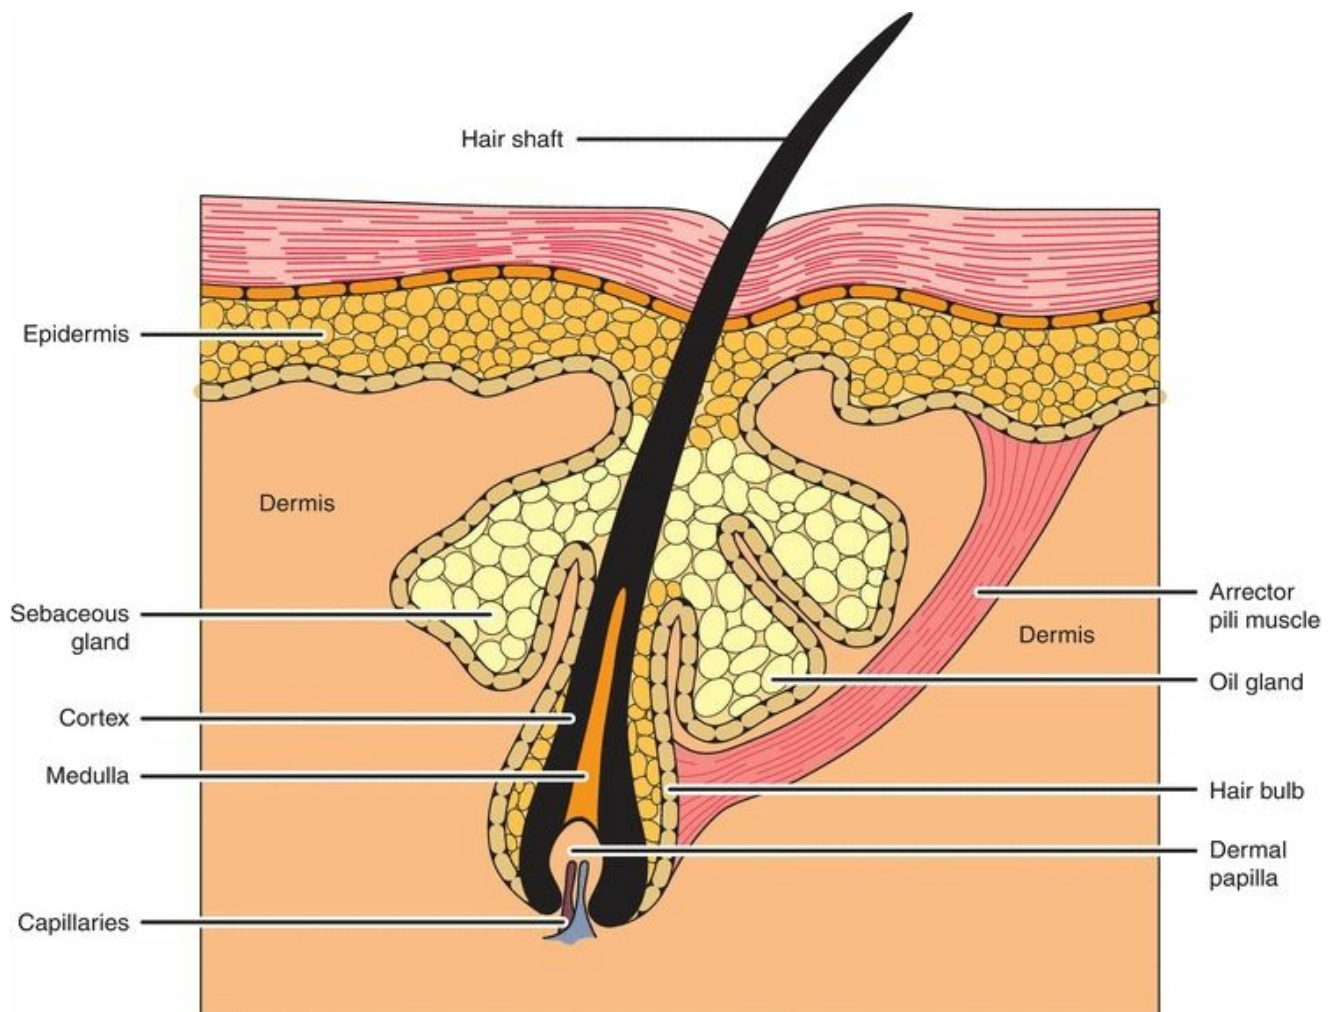

# THE BIOLOGY OF HAIR GROWTH

---

Hair is a distinguishing characteristic of mammals and serves a wide range of functions, including thermoregulation, physical protection, sensory activity, and social interactions. Androgens are required for development of sexual hair and sebaceous glands, but numerous other factors are also involved, including growth hormone, insulin, insulin-like growth factors (IGFs), glucocorticoids, estrogen, and thyroid hormones.<sup>2,3</sup>

# Embryology

Hair follicles develop at approximately 8–10 weeks of gestation from a small group of epidermal cells overlying undifferentiated mesenchyme. Members of the transforming growth factor beta (TGF $\beta$ ) superfamily, activins and bone morphogenetic proteins (BMPs) in particular, play an important role in the communication between the epithelial and the mesenchymal compartments during normal hair follicle development.<sup>4,5</sup> Initially, the hair follicle is composed of a solid column of cells that proliferates from the basal layers of the epidermis and extends downward into the dermis. As the column elongates, it encounters a cluster of mesenchymal cells (the dermal papilla) that envelop its bulbous tip (bulb). The solid epithelial column then hollows to create a hair canal, and the **pilosebaceous unit (PSU)** is formed. A PSU is composed of a hair follicle, the adjoining sebaceous gland, and the arrector pili (**Figure 12.2**), a small muscle that connects the hair follicle to the dermis, and when it contracts, it causes the hair to “stand” such as occurs in fear or following exposure to cold. Hair color is determined by the pigments produced by melanocytes located in the hair bulb.

**FIGURE 12.2**

One's total endowment of hair follicles is determined by 22 weeks of gestation, and no new hair follicles develop de novo thereafter. The concentration of hair follicles in facial skin does not differ significantly between the sexes but does differ between races and ethnic groups. Whereas Asian and Native American women generally have little body hair, women of Mediterranean descent typically have increased amounts of body hair, although serum androgen concentrations are similar in the three groups.<sup>6</sup> Differences in hair growth among races and ethnic groups probably also reflect differences in the local levels of 5 $\alpha$ -reductase activity, the enzyme that converts testosterone to the more potent and active androgen, dihydrotestosterone (DHT)<sup>7</sup> (Figure 12.3).

**FIGURE 12.3**

# The Hair Growth Cycle

Hair growth is cyclic, rather than continuous, and exhibits three distinct phases, known as **anagen** (growth phase), **catagen** (involution phase), and **telogen** (quiescent or resting phase)<sup>2</sup> (Figure 12.4). As growth (anagen) begins, cells in the epithelial matrix at the base of the hair follicle begin to proliferate, extending downward into the dermis in a column that elongates to approximately 4–6 times its resting length. With continued rapid growth, the epithelial column also pushes upward to the skin surface, breaking its tenuous contact with the previous hair, which gets shed. The most superficial epithelial cells differentiate to form a keratinized column, and growth continues as long as active mitosis persists in the basal epithelial cells. As the growth phase comes to a close, the column rapidly shrinks and the bulb at the base of the epithelial canal shrivels (catagen) before the hair follicle enters a quiescent phase (telogen).

**FIGURE 12.4**

The length of hair is determined primarily by the duration of the anagen (growth) phase. Scalp hair remains in anagen for 2–5 years and spends only a relatively short time in telogen (rest). Elsewhere, such as on the forearm, the hair cycle has a short anagen and a

long telogen, yielding a short hair of relatively stable length. The outward appearance of continuous growth or periodic shedding reflects the extent to which hair follicles act in synchrony with others in the area. Typically, scalp hair are asynchronous and, therefore, always appear to be growing; the resting phase of some hair (approximately 10–15%) is not apparent. If a larger proportion of hair becomes synchronous and enters telogen simultaneously, excess shedding may occur, a process known as **telogen effluvium**. Although women occasionally may notice and complain of scalp hair loss, the interval of shedding usually lasts no longer than 6–8 months. Growth resumes when asynchrony again becomes established. Telogen effluvium can be precipitated by pregnancy, by certain drugs including hormonal contraceptives, by febrile illness, and even by significant psychological stress.

Based on physical characteristics, bodily hair are categorized as **vellus** (fine, soft, short, and unpigmented) or **terminal** (long, coarse, and pigmented, see [Figure 12.1](#)).<sup>3</sup> Vellus hair that cover the body of infants are called **lanugo**. **Hypertrichosis** describes an uncommon condition characterized by a generalized increase in vellus body hair, usually associated with drugs (e.g., phenytoin, penicillamine, diazoxide, minoxidil, cyclosporine), systemic illness (e.g., hypothyroidism, anorexia nervosa, malnutrition, porphyria, dermatomyositis), or malignancy (as a paraneoplastic syndrome). Hirsutism implies an irreversible transformation from vellus to terminal hair.

## The Control of Hair Growth

The fate of a hair follicle depends on the health and function of the dermal papilla. Despite major injury to its epithelial component (e.g., from freezing or damage from x-rays), the hair follicle will regenerate and regrow the hair shaft provided the dermal papilla survives intact. Serious injury or degeneration of the dermal papilla (e.g., electrolysis or laser hair removal) results in permanent hair loss.

**Sexual hair are those which responds to sex steroids and grow primarily on the face, chest, lower abdomen, the pubis, and in the axillae.** In androgen-sensitive areas, androgens, particular if in excess, stimulate hair follicles, inducing the growth of thicker, longer, and darker hairs. **Thereafter, the hair exhibits typical cycles of growth, involution, and rest. However, once transformed from vellus to terminal fate, the coarse texture of the terminal hair does not revert back to the soft and fine vellus character, even if the androgen levels normalize.** Because androgen stimulation of hair follicles requires the conversion of testosterone to DHT, the sensitivity of hair follicles to androgens is determined, in part, by the local level of 5 $\alpha$ -reductase activity in the vicinity of the PSU, helping to explain the varying extent of hirsutism observed in women with similar serum androgen levels.<sup>8</sup>

**Based on data from animal studies and on patterns of human disease, the**

## following summarizes the effects of steroid hormones on hair growth:

1. Androgens, particularly testosterone, stimulate growth and increase the diameter and pigmentation of hair. Androgens also increase the proportion of time terminal hairs spend in anagen,<sup>9</sup> except on the scalp, where androgen decreases the duration of anagen.
2. Estrogens have actions opposite those of androgens, generally resulting in slower growth of finer and lighter hair.
3. Natural progesterone has little or no direct effect on hair growth. Synthetic progestins, particularly the 19-nortestosterone derivatives, may exert androgen like effects at the PSU.
4. Pregnancy, characterized by high levels of both estrogen and progesterone, can induce greater synchrony among hair follicles, leading to finite periods of synchronized growth (hair density appears to improve) followed by shedding (excessive hair shedding becomes apparent).

Observations in studies of the effects of male castration demonstrate an important clinical characteristic of hair growth. Males castrated before puberty do not grow a beard or other sexual hair, but when castrated after puberty is completed, the beard and sexual hair continue to grow, albeit more slowly and with finer caliber of hair.

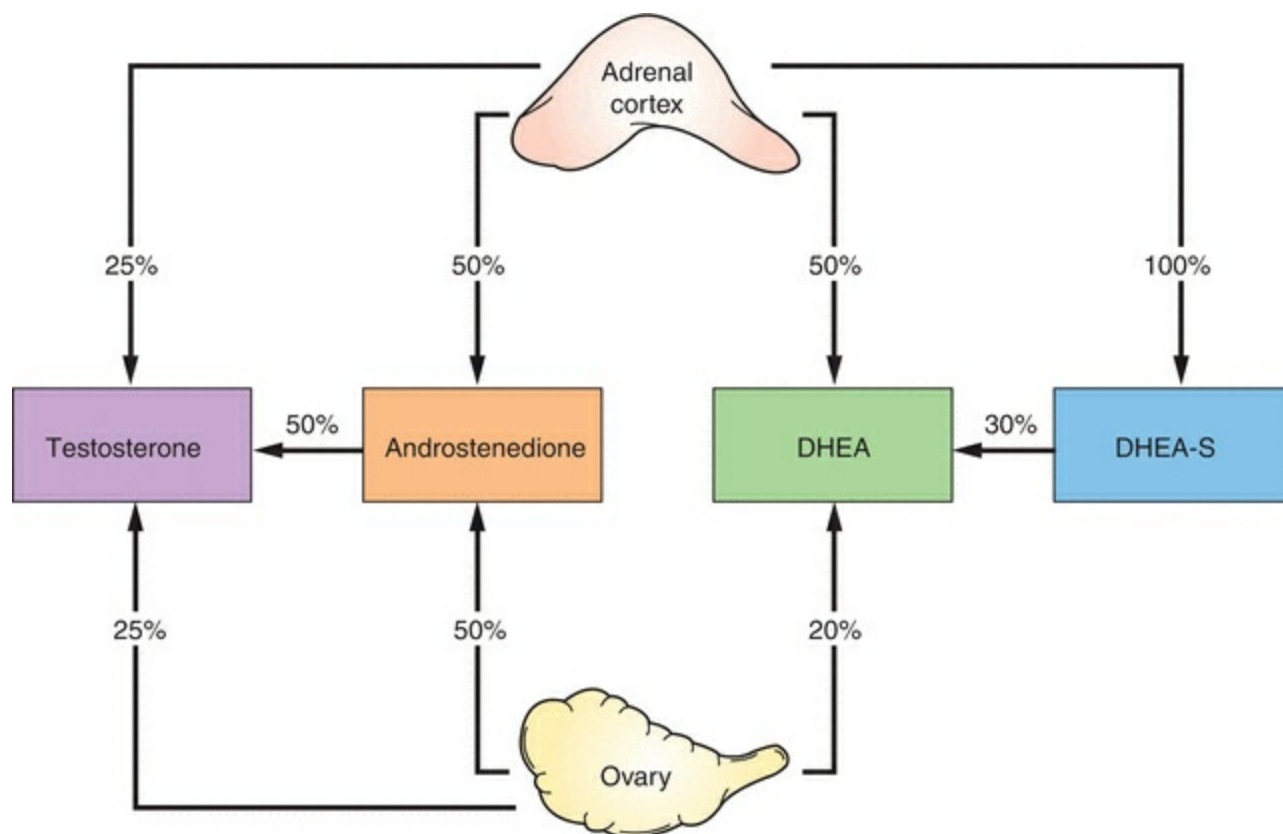

Endocrine disorders can affect the growth of both sexual and nonsexual hair. Hair growth is markedly reduced in individuals with hypopituitarism. Hypothyroidism sometimes is associated with hair loss on the scalp, the pubis, in the axillae, and, curiously, the lateral third of the eyebrows. Hyperthyroidism generally results in finer hair that are lost easily. Approximately 10–15% of patients with acromegaly are hirsute. IGF-1, which stimulates  $5\alpha$ -reductase activity,<sup>10</sup> often is increased in women with chronic anovulation, insulin resistance, and hyperinsulinemia.

Hair growth also can be influenced by other factors, such as local skin temperature, blood flow, and edema. Hair grow faster in the summer than in the winter.<sup>11</sup> Hair growth also can be observed in association with central nervous system pathology (e.g., encephalitis, cranial trauma, multiple sclerosis) and with certain drugs. Hair loss and thinning can be associated with micronutrient deficiencies, such as iron, biotin, folate, and B12 deficiencies.

# ANDROGENS IN WOMEN

Hirsutism reflects the interaction between circulating androgen levels and the sensitivity of hair follicles to androgen stimulation. Sources and types of androgens in women are discussed in detail in [Chapter 13](#) and [Chapter 11](#) and are briefly reviewed here. In women, the major circulating androgens (in descending order of serum concentration) are dehydroepiandrosterone sulfate (DHEA-S), dehydroepiandrosterone (DHEA), androstenedione, testosterone, and DHT ([Figure 12.3](#)).<sup>12</sup>

**Figure 12.5** outlines the sources and respective organ contributions to the circulating pool of androgens in women. **DHEA-S, DHEA, and androstenedione can be considered prehormones because they have little or no intrinsic androgenic activity and require conversion to testosterone to exert androgenic effects.**

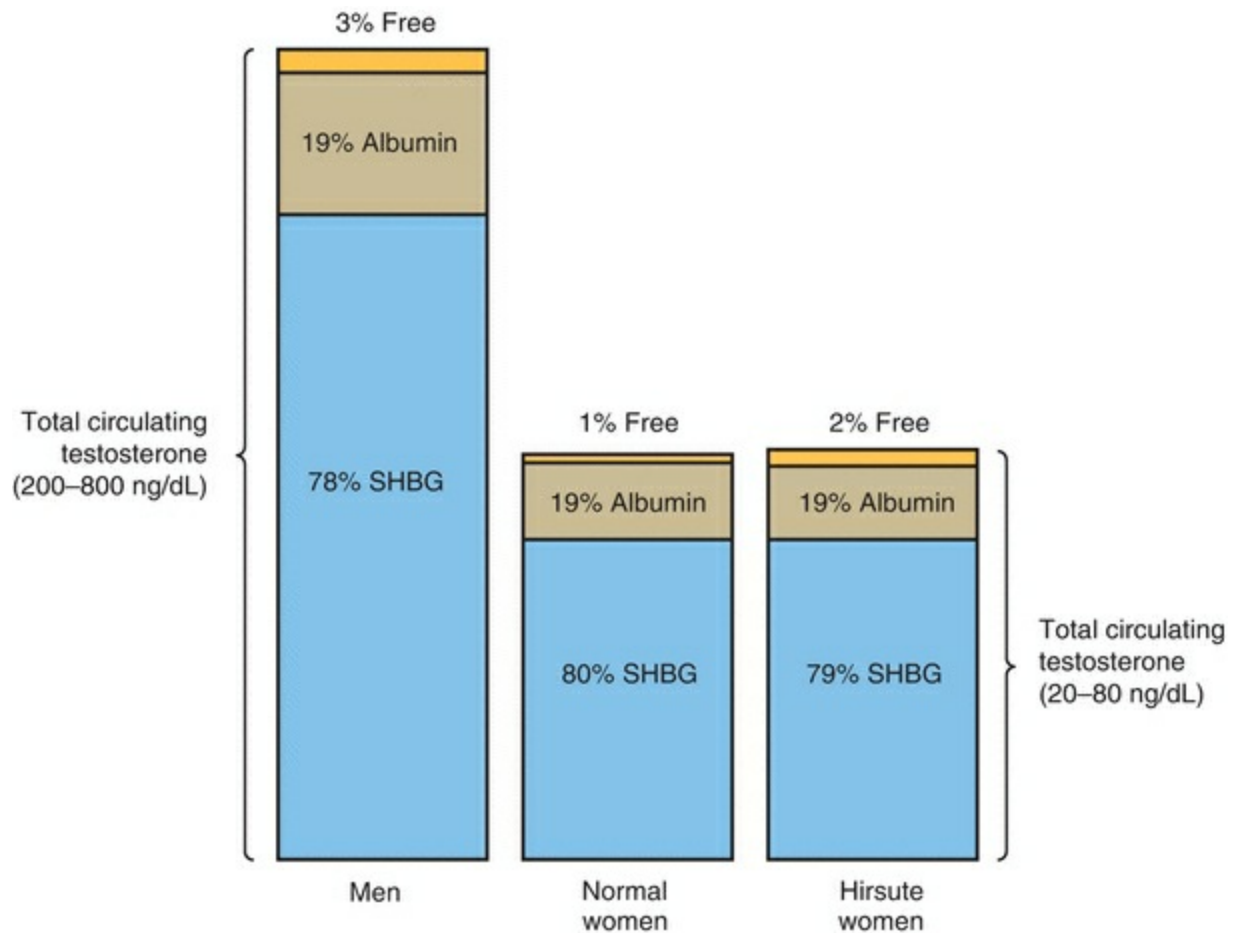

**FIGURE 12.5**

DHEA-S is produced almost exclusively by the adrenal glands, at a rate ranging between 3.5 and 20 mg/day<sup>13</sup>; the normal serum concentration is 100–350 µg/dL in most laboratories. DHEA is produced by both the adrenals (50%) and the ovaries (20%) and from the peripheral conversion of DHEA-S (30%). The production rate of DHEA is

between 6 and 8 mg/day,<sup>14</sup> and normal serum concentrations range between 1 and 10 ng/mL. Androstenedione production is divided equally between the ovaries and the adrenals; the production rate is between 1.4 and 6.2 mg/day, and the normal serum concentration is 0.5–2.0 ng/mL.<sup>15,16</sup>

Testosterone production derives from the adrenals (25%), the ovaries (25%), and from peripheral conversion of androstenedione (50%). The production rate ranges between 0.1 and 0.4 mg/day, and the normal serum concentration is 20–80 ng/dL; levels do not fluctuate widely but are lowest during the early follicular phase, and approximately 20% higher at midcycle.<sup>14</sup> In normal women, about 80% of circulating testosterone is bound to a beta globulin known as **sex hormone–binding globulin (SHBG)**, another 19% is loosely bound to albumin, leaving only about 1% unbound or free. Routine serum immunoassays for testosterone measure the total testosterone concentration, including both bound and unbound hormone. However, the androgenic actions of testosterone relate primarily to the amount of free hormone and, to a limited extent, to the fraction associated with albumin. Anything that affects the SHBG concentration also affects the concentration of free/active testosterone. Serum immunoassays for DHEA-S, DHEA, and androstenedione generally reflect the amount of biologically available hormone because unlike testosterone, none of these three is protein bound to any significant extent.

Androgens themselves decrease SHBG production in the liver. Consequently, testosterone binding capacity in men is lower than in normal women; approximately 3% of total testosterone circulates in the free, active form in men. Whereas insulin and glucocorticoids also decrease SHBG levels, estrogens and thyroid hormone increase SHBG production. Therefore, binding capacity is increased in women with hyperthyroidism, in pregnancy, and during treatment with estrogens. In hirsute women, excess androgen production (and hyperinsulinemia, when present) depresses SHBG levels, increasing the amount of free/active testosterone to approximately 2%, even though the total testosterone level may remain within the normal range. **Although specific assays to measure the level of free testosterone are available, they are costly and rarely necessary. The very presence of hirsutism or virilization indicates androgen excess. In hirsute women with “normal” serum total testosterone levels, decreased binding capacity and increased free testosterone can be assumed (Figure 12.6).**

**FIGURE 12.6**

In women with hirsutism, only about 25% of circulating testosterone arises from peripheral conversion; rather, most comes from direct secretion, with the ovary being the primary source of both increased testosterone and androstenedione.<sup>17</sup> By far, the most common cause of hirsutism is PCOS (discussed in [Chapter 11](#)), with the excess androgen production occurring in the ovaries. Adrenal causes of hyperandrogenemia (discussed in [Chapter 13](#)) as a cause of hirsutism are uncommon.

Although testosterone is the major circulating androgen, DHT is the major nuclear androgen in many androgen-sensitive tissues, including the hair follicles and sebaceous glands. DHT is produced only in the periphery, by intracellular conversion of testosterone (via the enzyme  $5\alpha$ -reductase). Circulating levels of DHT, therefore, do not reflect the tissue level of  $5\alpha$ -reductase activity.<sup>18</sup>  $3\alpha$ -Androstanediol is the peripheral tissue metabolite of DHT, and its glucuronide conjugate,  $3\alpha$ -androstanediol glucuronide ( $3\alpha$ -AG), can be used as a marker of peripheral androgen metabolism.<sup>19,20</sup> **Serum  $3\alpha$ -AG levels correlate highly with levels of  $5\alpha$ -reductase activity in the genital skin and are elevated almost uniformly in hirsute women,<sup>21</sup> including those with normal**

**serum androgen levels, indicating that “idiopathic” hirsutism likely results from increased peripheral 5 $\alpha$ -reductase activity.** After the menopause, the production rate and serum concentration of androstenedione fall by about half, with approximately 80% derived from the adrenals.<sup>22</sup> Testosterone production and serum levels also decline, primarily due to the decrease in peripheral production (i.e., via the conversion of androstenedione).<sup>23,24</sup> **Ovarian testosterone production is largely maintained after the menopause,** as demonstrated by the 40–50% decrease in serum testosterone levels after oophorectomy in postmenopausal women.<sup>25,26</sup> Because the decrease in estrogen production far exceeds that in androgen production after menopause, the postmenopausal ovary is primarily an androgen-producing organ.<sup>27</sup> The elevated pituitary gonadotropin levels that are a hallmark of menopausal state stimulate androgen synthesis in ovarian hilar and stromal cells.<sup>28,29</sup> Unlike the ovaries, the adrenal androgen production declines progressively with age; serum DHEA concentrations in women between ages 40 and 50 years are approximately half those in younger women.<sup>30</sup>

# CAUSES OF HIRSUTISM

---

In reproductive age women, PCOS (discussed in [Chapter 11](#)) is probably the most common cause of hirsutism. Almost 5–10% of cases, however, represent idiopathic hirsutism (IH). Other less common causes of hirsutism include specific endocrine disorders, such as classical and nonclassical CAH, androgen-secreting ovarian or adrenal tumors, Cushing syndrome, and the hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) syndrome. In a case series of 873 women presenting with symptoms of androgen excess, the prevalence of these disorders is described in [Table 12.1](#).<sup>31</sup>

## TABLE 12.1 Causes of Hirsutism

Diagnosis	Number	Prevalence (%)
<b>Specific Disorders</b>		
Androgen-secreting neoplasm	2	0.23
Classical congenital adrenal hyperplasia	6	0.69
Nonclassical congenital adrenal hyperplasia	18	2.06
HAIR-AN syndrome	33	3.78
<b>Disorders of Exclusion</b>		
Polycystic ovary syndrome	716	82.02
Idiopathic hirsutism	39	4.47
Hyperandrogenemia, hirsutism, and normal ovulation	59	6.75
<b>Total</b>	<b>873</b>	<b>100.00</b>

**PCOS is by far the most common cause of androgen excess in women.** The diagnostic criteria, clinical features, and treatment of PCOS are considered in-depth in [Chapter 11](#). The prevalence of PCOS among populations of hirsute women varies with differences in the diagnostic criteria proposed by the National Institutes of Health Conference on PCOS (The NIH Criteria, NIH, 1990),<sup>32</sup> the European Society of Human Reproduction and Embryology/American Society for Reproductive Medicine Consensus Workshop Group (The Rotterdam Criteria, ESHRE/ASRM, 2003),<sup>33</sup> and the Androgen

Excess Society (The AE-PCOS Criteria, AES, 2009).<sup>34</sup> All include oligo/anovulation and clinical or biochemical evidence of hyperandrogenism as diagnostic criteria, two of the three (the Rotterdam and AE-PCOS Criteria) regard polycystic ovarian morphology (as defined by ultrasonographic imaging) as a criterion, and all three require exclusion of other specific diagnoses (e.g., CAH, Cushing syndrome, androgen-secreting tumors, hypothyroidism, and hyperprolactinemia). In three large case series of women presenting with symptoms of androgen excess, the prevalence of PCOS ranged between 57% and 82%.<sup>31,35,36</sup>

**Hyperandrogenic insulin-resistant acanthosis nigricans (HAIR-AN) syndrome** has the same clinical features as PCOS but in the extreme. The primary underlying pathology is severe insulin resistance, with acanthosis nigricans being an epiphenomenon.<sup>37,38</sup> A compensatory chronic and severe hyperinsulinemia stimulates a marked increase in ovarian androgen production by signaling via theca cell receptors for insulin and IGF-1. The marked hyperinsulinemia additionally induces a profound decrease in hepatic synthesis of SHBG with suppression of serum SHBG concentrations, yielding a large increase in free testosterone levels. In turn, high circulating androgen levels exacerbate the underlying insulin resistance, resulting in a self-propagating positive feedback loop that increases in severity over time, ultimately causing severe hirsutism and, in many, even features of virilization (temporal balding, deepening of the voice, changes in body habitus, clitoromegaly). **Ovarian stromal hyperthecosis** is a histologic diagnosis, based on the observation of distinct clusters of luteinized thecal cells scattered throughout the ovarian stroma.<sup>39</sup> Patients with hyperthecosis typically are obese, severely hirsute, and often virilized, most having serum testosterone concentrations greater than 150 ng/dL and exhibiting severe insulin resistance and hyperinsulinemia.<sup>40</sup> It is likely that most, if not all, patients with the HAIR-AN syndrome have ovarian hyperthecosis. However, hyperthecosis can occur in postmenopausal women where elevated pituitary output of gonadotropins, specifically of luteinizing hormone (LH), is recognized as the driving mechanism for theca cell proliferation and testosterone production.<sup>41,42,43</sup>

**Idiopathic hirsutism** describes hirsutism in women who report regular menstrual cycles and who exhibit serum androgen levels in the normal range.<sup>8,44,45</sup> Although existence of subtle forms of ovarian or adrenal enzymatic dysfunction can be hypothesized in some with IH,<sup>46</sup> an increased sensitivity to androgens (mediated by increased peripheral 5 $\alpha$ -reductase activity)<sup>21</sup> is likely the most logical explanation, as improvement in hair growth is described with the use of inhibitors of 5 $\alpha$ -reductase. More recently, it has been appreciated that in many women previously assigned a diagnosis of IH, menstrual cycles are anovulatory despite their regularity. Thus, many previously classified as IH may in fact represent cases of PCOS.<sup>33</sup>

**Congenital adrenal hyperplasia (CAH)** is a specific but uncommon cause of hirsutism. The clinical features, diagnostic criteria, and treatment of CAH are discussed in detail in [Chapter 13](#). Whereas females with classical CAH usually are recognized at birth or during early infancy, the nonclassical form of the disorder (also known as late-onset CAH) presents later, at or after puberty, with hirsutism and menstrual irregularity or amenorrhea. In different studies, the prevalence of nonclassical CAH has ranged between 1% and 15%.<sup>47,48,49,50</sup> The most common cause of both classical and nonclassical CAH is an adrenal 21-hydroxylase (P450c21) deficiency, resulting in excess production of 17 $\alpha$ -hydroxyprogesterone (17OHP), which is a precursor for androgen synthesis ([Chapter 13](#)).

**Androgen-secreting neoplasms of the ovary or adrenal** are a rare cause of androgen excess and hirsutism. Androgen-secreting tumors account for only 5% of all ovarian tumors. Most are Sertoli-Leydig cell tumors, lipid and theca cell (stromal) tumors, or hilus cell tumors. Most are associated with frankly elevated serum testosterone concentrations (i.e., >150–200 ng/dL),<sup>51,52,53</sup> and most can be imaged by transvaginal ultrasonography. Although some adrenal adenomas secrete testosterone, most androgen-secreting adrenal tumors are carcinomas that secrete DHEA, DHEA-S, and cortisol, in addition to testosterone (discussed in [Chapter 13](#)).<sup>54</sup>

Some women with hirsutism also have mild **hyperprolactinemia**. Elevated serum prolactin concentrations can be associated with increased serum DHEA-S levels.<sup>55,56</sup> Prolactin receptors have been identified in the human adrenal, and prolactin can increase adrenal DHEA production in vitro.<sup>57</sup> Although DHEA-S is a weak androgen, it can be converted in the periphery to potent androgens such as testosterone and DHT. Prolactin stimulation of adrenal androgen production, excessive ovarian androgen production due to the chronic anovulation that often results from hyperprolactinemia (discussed in [Chapter 4](#)), and increased free testosterone levels consequent to anovulation may all be relevant to causation of hirsutism in women with chronic hyperprolactinemia.

Virilization during pregnancy should raise suspicion for a **pregnancy luteoma**, which is a hyperplastic mass of luteinized ovarian cells rather than a true tumor. Although most luteomas produce little androgen or have little or no androgenic effect, serum concentrations of androstenedione, testosterone, and DHT can be increased, sometimes dramatically<sup>58,59,60</sup>; only approximately one-third of reported pregnancy luteomas have been associated with maternal hirsutism or virilization,<sup>58,61</sup> probably because any increase in serum free testosterone is limited by the large increase in SHBG levels that occurs during pregnancy. Typically, luteomas are solid ovarian masses, yellow-brown in color and hence the name, that range in size between 6 and 10 cm; in approximately half of cases, they are bilateral.<sup>59,62</sup> Pregnancy luteomas typically

regress promptly after delivery, suggesting that the pregnancy hormone human chorionic gonadotropin (hCG) plays a role in stimulating or perpetuating their androgen production,<sup>63</sup> although most are identified late in gestation, long after the peak in maternal serum hCG concentrations ([Chapter 7](#)). Incidence of pregnancy luteomas may be higher in black compared to white women, although the mechanisms for this racial differential are unclear. In contrast to luteoma of pregnancy, **theca lutein cysts (hyperreactio luteinalis)** are functional androgen-producing ovarian cysts, which can develop during pregnancy, and almost always occur bilaterally. They are more often seen in pregnancies characterized by high maternal circulating levels of hCG, such as in women with multiple pregnancies, isoimmunized or diabetic mothers, and those with molar pregnancies or gestational trophoblastic disease. Similar to pregnancy-related luteomas discussed earlier, almost a third of women with theca lutein cysts manifest symptoms of androgen excess, which can be progressive and of varying degrees of severity. Rarely, mothers with preexisting hirsutism related to PCOS or ovarian stromal hyperthecosis also can develop theca lutein cysts and become hirsute or virilize.<sup>64,65,66</sup> In those who do, serum concentrations of testosterone and androstenedione are elevated. The placental enzyme aromatase acts as a safeguard against fetal exposure to maternal androgen excess by converting maternal testosterone and androstenedione to estrogens, although risk for virilization of a female fetus is plausible particularly when maternal hyperandrogenemia is severe and occurs early in the first trimester of pregnancy. Fetal virilization has been described more often with pregnancy luteoma compared to theca lutein cysts.<sup>58</sup>

# EVALUATION OF WOMEN WITH HIRSUTISM

---

Accepting that the large majority of women with hirsutism have PCOS or IH, the evaluation of hirsute women is aimed at quantifying the severity of hair excess and identifying the few having other causes that require additional specific evaluation and/or treatment (such as hyperprolactinemia, CAH, or androgen-secreting tumors). As always, evaluation should begin with a careful history and physical examination, which always provide important diagnostic clues. Laboratory investigation and imaging are used primarily to exclude other rare or potentially serious possibilities.

# History and Physical Examination

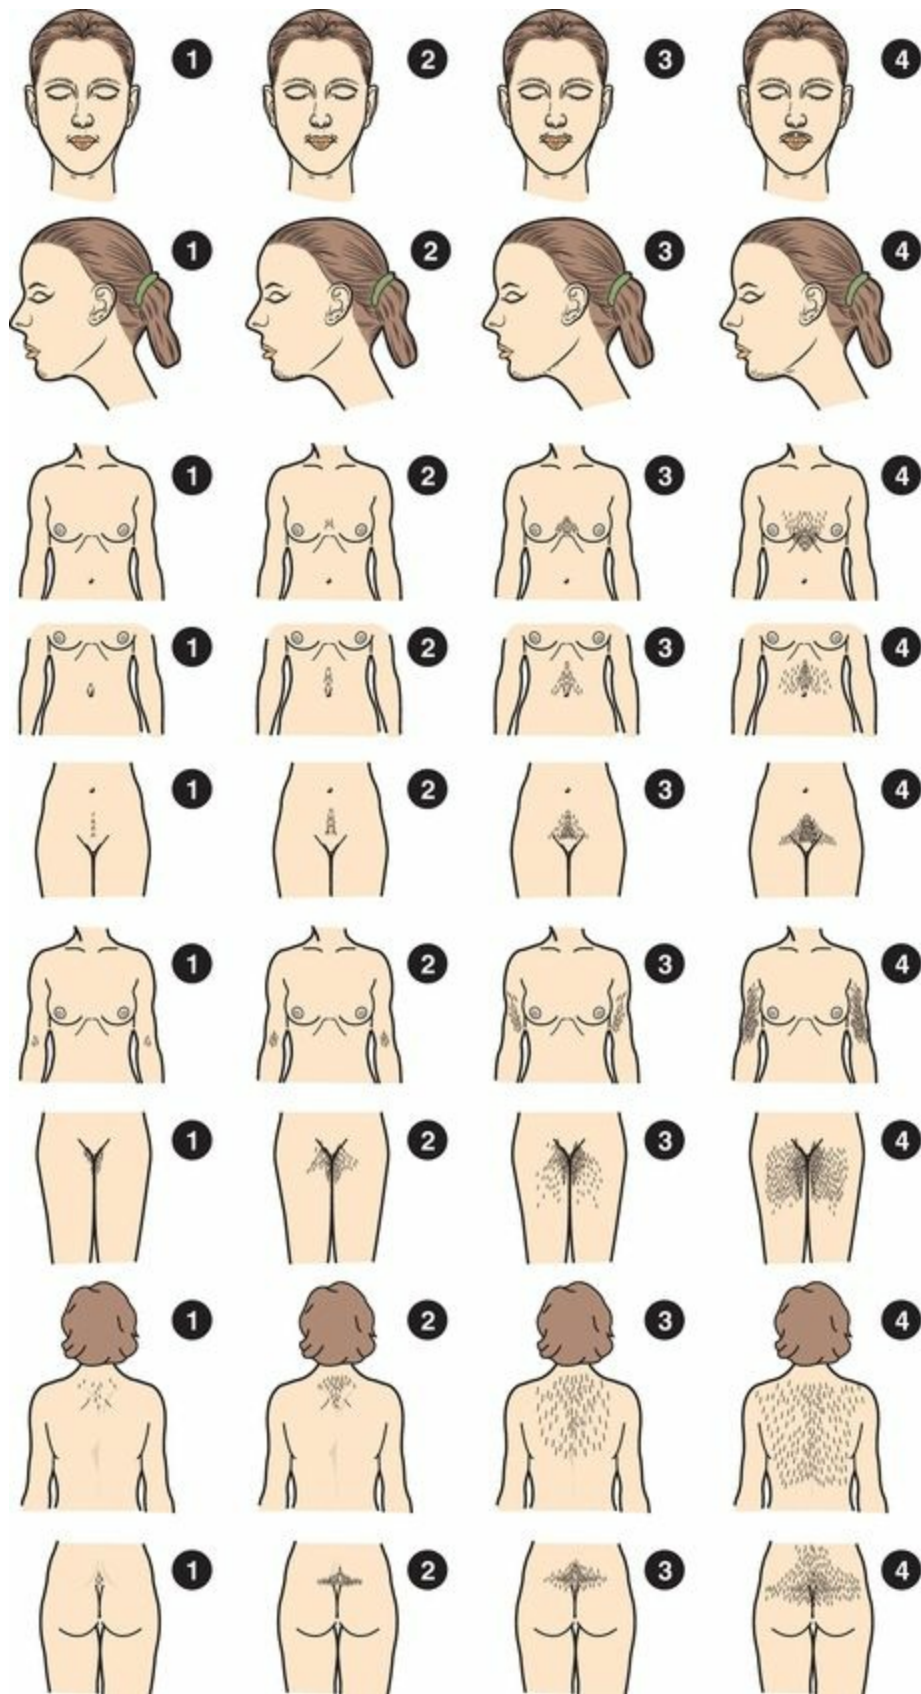

The key elements of the medical history in women with hirsutism include the menstrual history, the age at onset, and the rate of progression of hirsutism; other signs of androgen excess (such as acne and hair loss), symptoms and signs of virilization, family, and medication histories also provide important information.

The **menstrual history** should include age at menarche, the frequency as well as regularity of menses (eight or fewer menses per year is consistent with oligoovulation), a characterization of premenstrual molimina (breast tenderness, mood changes) presence of which is suggestive of ovulatory cycles, and information regarding any previous pregnancies and methods of contraception. Whereas women with PCOS typically report menstrual irregularity beginning at or soon after menarche, an abrupt departure from a previously established pattern of regular menses suggests another diagnosis. Although the clinical presentation of nonclassical CAH can closely resemble that of PCOS, hirsutism tends to present early in life and be more severe in women with CAH.<sup>67,68</sup> A later age at onset of hirsutism (after age 25) or rapid progression over a period of months are suggestive of an androgen-producing neoplasm. **It is important to correlate changes in menstrual pattern with changes in weight and to remember that previous hormonal contraception could have obscured or delayed the onset of symptoms of menstrual dysfunction or androgen excess.** Hirsutism in childhood usually is caused by classical CAH or an androgen-secreting tumor. Rare genetic causes of hirsutism, such as Y chromosome mosaicism or incomplete androgen insensitivity, usually present with signs of androgen excess at puberty ([Chapter 8](#)).

A **family history** of hirsutism, oligo/amenorrhea, obesity, and infertility are suggestive of a familial predisposition to PCOS, as well as should alert clinicians to consider nonclassical CAH as a differential diagnosis; the latter is more common in women with Hispanic, Mediterranean, Slavic, or Ashkenazi Jewish heritage.<sup>69</sup> Iatrogenic contributors to hair excess should also be considered. Drugs that can stimulate hair growth include methyltestosterone, anabolic steroids (e.g., norethandrolone), phenytoin, diazoxide, danazol, cyclosporine, and minoxidil. A variety of supplements are available over the counter containing DHEA or androstenedione, which can increase testosterone levels, and their use by women cause hirsutism and acne, even at relatively low doses. The hair growth caused by medications other than androgens is typically diffuse and vellus in nature (hypertrichosis). Recognizing that there are ethnic differences in hair density and texture, it is meaningful to enquire about whether the patient perceives herself as hairier than the remainder of female family members.

The **physical examination** should include a calculation of the body mass index

(BMI) and document the distribution and extent of hirsutism.<sup>70,71,72</sup> The modified **Ferriman-Gallwey (FG) score** is the most common method utilized for grading the presence and severity of hirsutism in clinical practice.<sup>73,74</sup> The modified FG method scores hair growth from 0 to 4 in each of 9 androgen-sensitive areas (the original version included 11 bodily areas, first described in 1961), including the upper lip, chin, chest, upper and lower abdomen, upper arm, thighs, and the upper and lower back; scale scores range from 0 to 36 and each point increase in site specific score reflects greater terminal hair density and involvement of greater affected body surface area (**Figure 12.7**).

**FIGURE 12.7**

## Modified Ferriman-Gallwey Scoring System for Hirsutism (Figure 12.7)

The originally described scoring method was based on studies undertaken in white women. Since its initial introduction in clinical practice, FG scoring system has been utilized to quantify hair excess in various ethnic populations, providing an understanding that ethnicity must be considered when categorizing threshold scores that differentiate normal from abnormal,<sup>75</sup> as both the number of hair follicles per unit skin area as well as rate of hair growth vary by ethnicity and race.<sup>76</sup> While there is no universally accepted cutoff score that defines hirsutism, a score  $\geq 8$  is generally used to define hirsutism in white and black women as approximately 95% will manifest a modified FG score less than 8; scores of 8–15 and greater than 15 are accepted to reflect mild to moderate and severe hirsutism, respectively. Given the recognized ethnic differences in hair growth, a higher FG score threshold has been suggested to define hirsutism in women of Mediterranean and Middle Eastern descent. In contrast, FG score as low as 3 is adequate for East Asian women (Chinese, Japanese, Thai, Korean) to be considered hirsute.<sup>72,77</sup> Notably, approximately 15% of women with scores less than 3 also consider themselves hirsute.

**There are no significant differences between white and black women with regard to the distribution of scores or the proportions that complain of hirsutism or use some method of hair removal.**<sup>78</sup> Taken together, these data indicate that it is quite normal for most women to have at least some hair growth in androgen-sensitive areas and that a score of 8 or higher reflects significant androgen excess that warrants evaluation. **Although the modified FG score is the accepted standard for clinical investigations involving hirsute women, it is difficult to use clinically, primarily because most women who seek medical attention for the complaint already are using one or more methods of hair removal. Moreover, the score is an unreliable indicator of hyperandrogenism for women in racial or ethnic groups having relatively little body hair (such as East Asian populations); although less likely to develop hirsutism, they can exhibit other signs of androgen excess, such as acne and thinning or loss of scalp hair. The easiest and most practical way to assess the severity of hirsutism is to determine the methods used to remove hair (e.g., shaving, plucking, waxing) and the frequency of their use, which also provides a clinically relevant measure for assessing the response to treatment.** Overall, approximately 25% women use some sort of cosmetic treatment for excess hair, such as bleaching, plucking, shaving, waxing, or electrolysis; the frequency of self-treatment correlates positively with the FG score.

The physical examination also should note other relevant skin manifestations as

well as any signs of virilization. Acne, seborrhea, and temporal balding are signs of androgen excess. Acanthosis nigricans (a gray or brown velvety discoloration of the skin, most commonly observed at the nape of the neck, groin, and axillae) indicates insulin resistance, and thin skin, broad pink-purple cutaneous striae, or easy bruising are signs of hypercortisolism. Frontal, temporal, or crown balding, deepening of the voice, increased muscle mass, breast atrophy, and clitoromegaly, are some signs of virilization. Normal clitoral size varies significantly among women<sup>79</sup>; in one study, the mean length of the glans clitoris was  $5.1 \pm 1.4$  mm and the mean width was  $3.4 \pm 1.0$  mm.<sup>80</sup> Clitoromegaly generally is defined by a clitoral glans longer than 10 mm or by a clitoral index (length times width) greater than  $35 \text{ mm}^2$ .<sup>81</sup> Other noteworthy physical findings include spontaneous or expressible galactorrhea, suggesting hyperprolactinemia, and abdominal or pelvic masses that may represent an androgen-secreting tumor. The large majority of functional ovarian tumors are palpable in women of normal body mass.

The physical manifestations of androgen excess generally reflect the extent to which androgen levels are elevated. Hirsutism is the most common complaint associated with androgen excess, and essentially all women with hirsutism have an increased production rate of testosterone and androstendione<sup>82</sup>; however, hirsutism can be seen in the presence of normal circulating androgen levels.<sup>8</sup> Worsening acne, increased libido, clitoromegaly, and virilization reflect progressively higher serum androgen levels.

**Scalp hair thinning or Alopecia** is an uncommon symptom of androgen excess that often is a cause of significant stress for the patient and is a vexing problem for the clinician. In many cases, alopecia is only temporary, resulting from telogen effluvium induced by some transient change that synchronizes a larger than normal proportion of scalp hair follicles, such as pregnancy or a febrile illness, and resolves after a period of 6–8 months. In a series of 109 consecutive women presenting with a complaint of diffuse alopecia, two thirds had no clinical evidence of hirsutism or menstrual dysfunction, two had nonclassical CAH, and two had hyperprolactinemia associated with a pituitary adenoma.<sup>83</sup> Of the 42 (38.5%) that had elevated serum androgens, 11 were ovulatory and not hirsute, 13 were ovulatory and hirsute, and 18 had both oligomenorrhea or amenorrhea and hirsutism.<sup>83</sup> While hair loss can be a normal consequence of aging, beginning in both sexes around the age of 50 years,<sup>84</sup> women with complaints of alopecia deserve evaluation for hyperandrogenism, as well as thyroid disorders (serum TSH) and chronic illness. Because alopecia can reflect increased scalp  $5\alpha$ -reductase activity, normal circulating androgen levels do not necessarily preclude effective treatment.<sup>85,86</sup> More than half (up to 60%) of women with acne and normal serum androgen concentrations exhibit evidence of increased peripheral  $5\alpha$ -reductase activity and may benefit from treatment for hyperandrogenism.<sup>87</sup> Some degree

of benefit for scalp hair can be anticipated with use of antiandrogen therapy in those where an up-regulation of scalp  $5\alpha$ -reductase activity is the underlying mechanism.

# LABORATORY EVALUATION

---

The relationship between hirsutism and circulating androgen concentrations is not entirely clear. Whereas some studies have found a correlation between hirsutism and androgen levels,<sup>88</sup> others have observed that only 50% of women with mild hirsutism have elevated free testosterone levels and that almost a third with moderately elevated free testosterone concentrations have no hirsutism.<sup>89</sup> These observations suggest that factors other than circulating androgen levels (such as insulin, individual variations in 5 $\alpha$ -reductase activity and in androgen sensitivity) have substantial influence on the development and severity of hirsutism. In a cross-sectional study of self-reported hair loss in women with PCOS, metabolic abnormalities including abnormalities of glucose homeostasis and dyslipidemia were significantly more prevalent in women acknowledging thinning of scalp hair.<sup>90</sup>

**Laboratory evaluation is indicated for many but not all women with hirsutism.<sup>91</sup>** The primary aim is to identify those having potentially serious endocrine disorders requiring specific treatment (such as nonclassical CAH, androgen-secreting tumors, Cushing syndrome). Thyroid disorders and hyperprolactinemia should be considered and excluded, particularly in women with menstrual dysfunction. **Laboratory evaluation is recommended for women with moderate or severe hirsutism, or hirsutism that is sudden in onset, rapidly progressive, or associated with symptoms or signs of virilization.<sup>92</sup>** Routine laboratory evaluation of women with isolated mild hirsutism is neither necessary nor cost-effective. In women with oligo/amenorrhea, mild hirsutism can be attributed confidently to increased ovarian androgen production resulting from chronic anovulation. In women with regular menses, hirsutism is most likely idiopathic, with increased sensitivity of PSUs to androgens as well as excessive peripheral 5 $\alpha$ -reductase activity as plausible underlying mechanisms.

**The serum total testosterone concentration provides the best overall measure of androgen production. Testing for nonclassical CAH is of highest yield for patients with an early onset of hirsutism (pre- or perimenarcheal onset, including those with premature adrenarche), women with a family history of the disorder, and those in high-risk ethnic groups (Hispanic, Mediterranean, Slavic, or Ashkenazi Jewish heritage); see Chapter 13 for a thorough discussion of such testing. The serum DHEA-S concentration can be grossly elevated ( $\geq 700$   $\mu\text{g/dL}$ ) in women with rare androgen-secreting adrenal tumors. However, as discussed in Chapter 13, serum testosterone levels also are greatly elevated in almost all such patients,<sup>93</sup> so the test has little or no clinical utility in the evaluation of hirsutism.**

# Serum Testosterone Concentration

Serum testosterone levels (normal 20–80 ng/dL) are elevated in most (70%), but not all, women with chronic anovulation and hirsutism. The total testosterone concentration can be normal in hirsute women because SHBG levels are depressed by androgen and insulin, thereby increasing the amount of unbound or free testosterone. Indeed, free testosterone levels are approximately twice normal (an increase from 1% to 2%) in women with PCOS.<sup>94</sup>

**Laboratory testing for elevated androgen levels should begin with a serum total testosterone concentration.** Total testosterone assays measure free testosterone, albumin-bound testosterone, and testosterone bound to SHBG. Although the free testosterone level is a more sensitive indicator of androgen excess, direct immunoassays of free testosterone are inaccurate,<sup>95</sup> yielding values only 20–60% of those measured by other, more precise methods.<sup>96,97</sup> The best method for measuring the free testosterone level is equilibrium dialysis, a method only offered by select laboratories.<sup>95</sup> In fact, surveys suggest that over 80% of U.S. clinical laboratories send free testosterone measurements to centralized reference labs.<sup>98</sup> The free testosterone concentration also can be calculated using equations derived from the laws of mass action, knowing the serum total testosterone, SHBG, and albumin concentrations, and the association constants for the interactions of testosterone with SHBG and albumin.<sup>99,100</sup> Calculated values generally correlate well with those determined by equilibrium dialysis, although accuracy varies with the specific assays used to measure total testosterone and SHBG. However, measurement or calculation of the free testosterone level generally is useful only in patients who have worsening hirsutism despite active treatment and normal total testosterone levels. **Total testosterone is most reliably evaluated in the early morning during the follicular phase for women with normal menstrual cycles. When undertaking testing in the setting of prolonged oligomenorrhea or amenorrhea, concomitant measurement of gonadotropins as well as estradiol and progesterone levels can allow reliable interpretation of hormone profile as a rise in total testosterone levels in the periovulatory period is quite normal.**

**A serum total testosterone concentration greater than 150 ng/dL identifies almost all women with a possible androgen-producing tumor.**<sup>35,51,52,54,101,102</sup> However, because serum testosterone concentrations can vary significantly in women with and without tumors,<sup>52</sup> a tumor still should be suspected, and excluded, in women with rapidly progressive hirsutism or signs or symptoms of virilization, even when the serum testosterone concentration is below the tumor threshold value. Nearly all women with PCOS have a testosterone level less than 150 ng/dL, as

do all women with IH, by definition. The suggested threshold value of 150 ng/dL has very high sensitivity and negative predictive value, indicating that it captures virtually all women with tumors as well as can effectively exclude this diagnosis.<sup>102</sup> The positive predictive value of a serum total testosterone level greater than 150 ng/dL, however, is quite low, indicating that only a few women demonstrating this degree of hyperandrogenemia will, in fact, have an androgen-secreting tumor, primarily because such tumors are very rare and the large majority will have PCOS or hyperthecosis. Taken together, the clinical history (age at onset, rate of progression of hirsutism, other symptoms of hyperandrogenism such as acne and hair loss), physical examination (severity of hirsutism, alopecia, signs of virilization, pelvic masses), and the serum total testosterone concentration will identify women with androgen-producing tumors.

It also is important to remember that testosterone levels are elevated significantly during normal pregnancy. Concentrations are greater than 100 ng/dL during the first trimester and can reach 500–800 ng/dL by term,<sup>103</sup> primarily due to the estrogen-induced increase in SHBG. Mother and fetus normally are protected from virilization because free testosterone levels rise only modestly and are rapidly converted to estrogen via placental aromatization. Because testosterone levels normally are lower in postmenopausal women, concentrations greater than 100 ng/dL should raise suspicion for a tumor.

## **Serum DHEA-S Concentration**

DHEA-S derives almost exclusively from the adrenal gland and is a direct measure of adrenal androgen activity. DHEA-S serves primarily as a prehormone, providing substrate for conversion to testosterone and DHT in the periphery.<sup>104</sup> **In evaluation of hirsutism, serum DHEA-S concentrations may offer guidance in identifying women with adrenal causes of hyperandrogenism. The serum DHEA-S concentration is moderately elevated in over half of women with PCOS.<sup>105</sup> Persistent elevation in serum DHEAS levels in the setting of hirsutism should also raise concerns regarding possibility of nonclassical CAH due to 3 $\beta$ -hydroxysteroid dehydrogenase deficiency.<sup>106,107</sup> The serum DHEA-S concentration can be grossly elevated ( $\geq 700$   $\mu\text{g/dL}$ ) in women with rare androgen-secreting adrenal tumors. However, in almost all such patients, serum testosterone levels also are greatly elevated,<sup>93</sup> via peripheral conversion of high circulating DHEA-S levels, or because the tumor also secretes testosterone. A serum DHEA-S concentration may be useful in women whose clinical presentation suggests strongly the possibility of a tumor, but the test otherwise has little or no clinical utility in the evaluation of hirsutism.**

# Evaluation for a Suspected Androgen-Producing Tumor

When the serum total testosterone concentration ( $>150$  ng/dL) or the clinical presentation (e.g., rapidly progressive hirsutism or symptoms or signs of virilization) suggests the possibility of a rare androgen-producing ovarian or adrenal tumor, evaluation is indicated to exclude the diagnosis or localize the lesion.

Androgen-secreting tumors of the ovary (in decreasing order of prevalence) include Sertoli-Leydig tumors, lipid cell tumors, hilar cell tumors, and rare androgen-producing theca cell and Brenner tumors; virtually all are associated with grossly elevated serum total testosterone levels ( $>150$  ng/dL). Occasionally, virilization results from a nonfunctioning ovarian tumor that creates a mass effect with resulting stimulation of the surrounding stroma.<sup>108</sup> Most functioning ovarian tumors are palpable on pelvic examination, but small tumors easily can go unrecognized, particularly in the overweight to obese women. **Transvaginal ultrasonography** can identify almost all solid ovarian mass lesions, although very small tumors located in the hilar region still can escape detection. Imaging approaches for detecting the rare androgen-producing adrenal adenoma or carcinoma, as reviewed in [Chapter 13](#), should be considered when in the setting of clinical suspicion, pelvic examination and transvaginal ultrasonography fail to reveal an ovarian tumor.<sup>109</sup> **Selective ovarian venous catheterization** can be considered for the rare patient having no demonstrable ovarian or adrenal mass lesion.<sup>53,101,110,111,112</sup> **However, because the overall clinical utility of the technique is still uncertain,<sup>113</sup> the procedure should be reserved only for women desiring future fertility (and thus desiring to avoid bilateral oophorectomy) in whom an ovarian androgen-secreting tumor is strongly suspected despite negative imaging.** An analysis of results obtained in 136 reported patients with hirsutism who had selective ovarian venous sampling yielded a number of important observations.<sup>113</sup> A right:left ovarian venous effluent testosterone ratio greater than 1.44 correctly identified 90% of right-sided tumors and lower values correctly identified 86% of women with left-sided or bilateral lesions. In three women with a left-sided tumor, the left:right testosterone ratio was greater than 15. The differing anatomy of the right (draining into the vena cava) and left ovarian vein (draining into the left renal vein) and the related technical difficulty of catheterization might explain why venous sampling was more effective for identifying right-sided ovarian tumors.

When suspicion for a tumor is insufficient to warrant ovarian venous catheterization, or the procedure reveals no significant gradient in testosterone concentrations, the likelihood of an occult ovarian tumor is very small, leaving the HAIR-AN syndrome or stromal hyperthecosis as the most likely cause of severe

hyperandrogenism. Both are associated with severe insulin resistance, which can be documented by performing an **oral glucose tolerance test including insulin levels**, as discussed below. The likelihood of an informative yield from open surgical exploration of the ovaries in the setting of negative imaging is slim; however, in resource poor settings, this may be necessary to establish a diagnosis; laparoscopic inspection and biopsy are not sufficient.

Dynamic endocrine evaluation, using dexamethasone, contraceptive steroids, or a GnRH agonist in attempts to isolate adrenal or ovarian androgen production, is not recommended, because results are unreliable and can be misleading.<sup>108,114,115,116</sup>

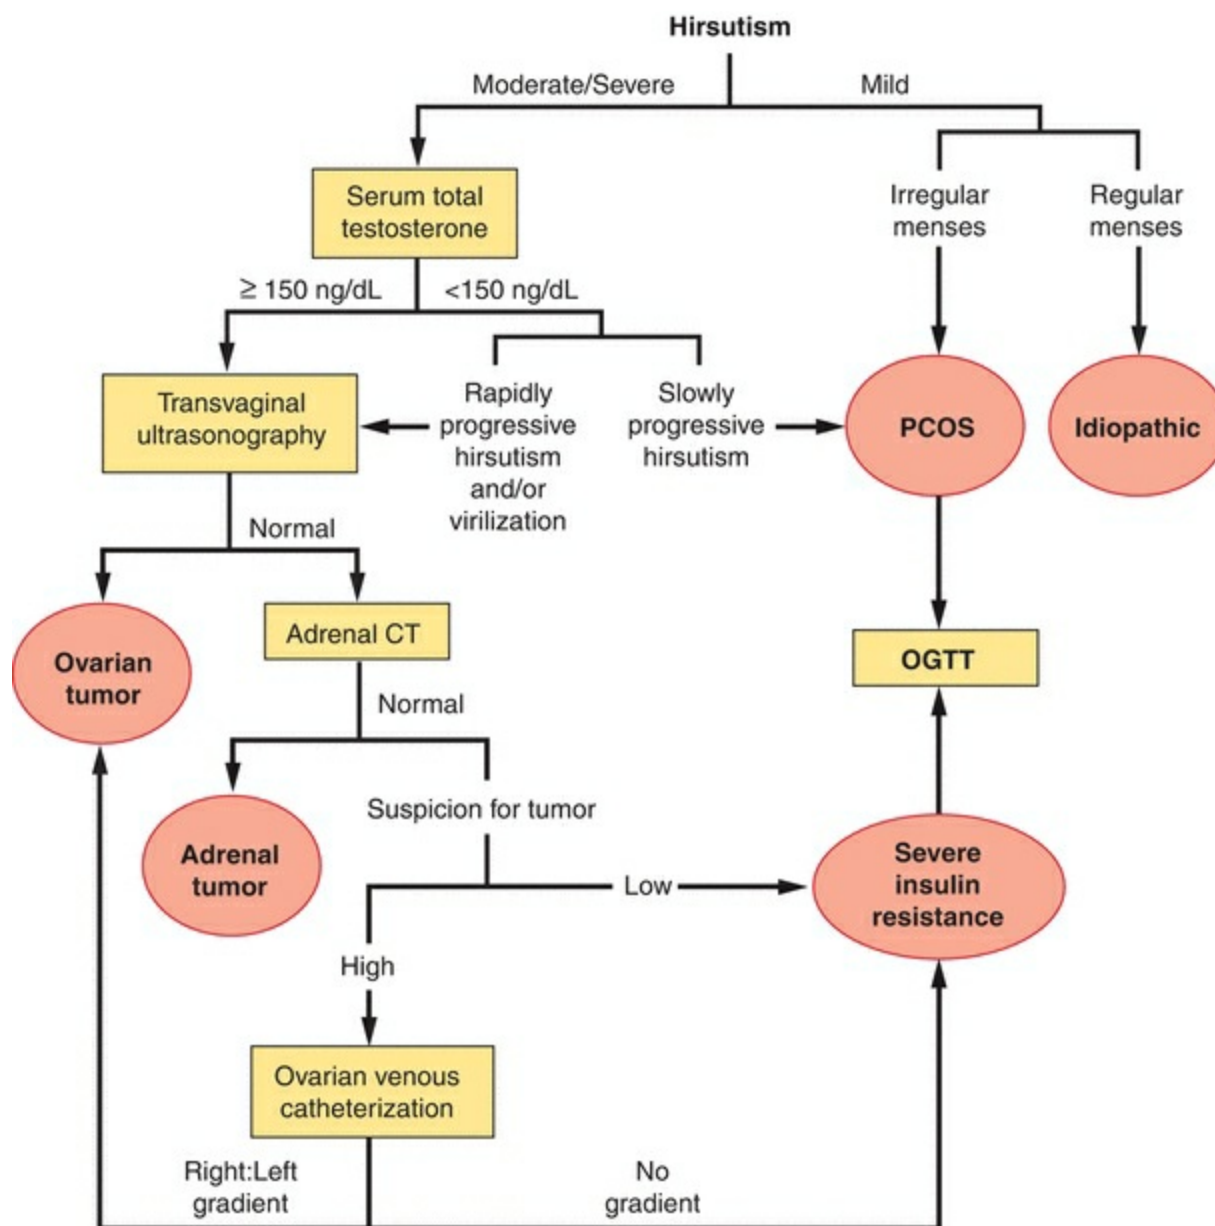

**Ovarian androgen-secreting tumors are sensitive to LH stimulation and thus respond to ovarian suppression and stimulation.**<sup>117,118,119</sup>

# Insulin Resistance

Insulin resistance is a common feature of women with PCOS and a key component of the HAIR-AN syndrome and ovarian stromal hyperthecosis. **Although high circulating androgen concentrations decrease insulin sensitivity, the primary pathology in women with HAIR-AN and hyperthecosis is severe insulin resistance, resulting in grossly elevated insulin levels that stimulate ovarian androgen production in theca cells (via insulin, IGF-1, and hybrid receptors) and markedly decrease hepatic SHBG production, thereby greatly increasing the amount of circulating free androgen.** Insulin resistance and hyperinsulinemia also explain the occasional elderly woman who presents with severe progressive hirsutism and elevated total testosterone levels. The problem does not simply reflect an ovarian response to elevated pituitary gonadotropin levels but actually relates to the development of hyperinsulinemia-driven hyperthecosis. Insulin appears to have a direct effect on the severity of hirsutism and a synergistic interaction with testosterone.<sup>120</sup> A number of methods have been described to quantify both insulin sensitivity and insulin resistance and are further discussed in [Chapter 11](#). Evidence of acanthosis nigricans is a reliable clinical indicator of significant insulin resistance.

**A baseline 2-hour oral glucose tolerance test (75-g glucose load) is recommended for all women with PCOS,<sup>33,121,122</sup> because up to 35% exhibit impaired glucose tolerance (glucose 140–199 mg/dL) and up to 10% have non-insulin-dependent diabetes mellitus (glucose  $\geq$ 200 mg/dL).<sup>123</sup>** In patients with severe hyperandrogenism having no evidence of an androgen-secreting tumor, the corresponding fasting and 2-hour insulin concentrations can be used to document the degree of insulin resistance, in support of the diagnosis of HAIR-AN syndrome or hyperthecosis; most have grossly elevated insulin levels.<sup>40</sup> The 2-hour glucose/insulin ratio (mg/dL/ $\mu$ U/mL) provides an estimate of insulin sensitivity, with values less than 1.0 indicating insulin resistance. Plasma insulin concentrations that exceed an upper limit of normal or a defined threshold value (e.g., a 2-hour plasma insulin  $>$ 80–100  $\mu$ U/mL) also have been used as a quantitative test for insulin resistance ([Figure 12.8](#)).

**FIGURE 12.8**

Although the use of insulin-sensitizing agents in women with PCOS has been associated with improvements in circulating androgen levels, any evidence that such an approach offers benefit against hirsutism is lacking and treatment with insulin-sensitizing agents specifically for hirsutism (i.e., in the absence of menstrual or metabolic abnormalities) is likely of minimal value.<sup>124</sup> **Consequently, routine assessment of insulin sensitivity in the evaluation of isolated hirsutism is not recommended.**

## Key Points: Evaluation of Hirsutism

- Laboratory evaluation is recommended for women with moderate or severe hirsutism, or hirsutism that is sudden in onset, rapidly progressive, or associated with symptoms or signs of virilization. Routine laboratory evaluation of women with mild hirsutism is unnecessary.
- The serum total testosterone concentration is the best overall measure of androgen production and is the first hormone that should be measured in women with hirsutism that merit evaluation.
- An androgen-secreting tumor should be suspected, and excluded, in women with rapidly progressive hirsutism, symptoms or signs of virilization, or a serum testosterone concentration 150 ng/dL or greater. However, most such patients will not have a tumor.
- Nonclassical congenital adrenal hyperplasia should be suspected, and excluded, in patients with an early onset of hirsutism (pre- or perimenarcheal, including those with a premature adrenarche), in women with a family history of the disorder, and those in high-risk ethnic groups (Hispanic, Mediterranean, Slavic, and Ashkenazi Jewish heritage).
- Cushing syndrome should be suspected, and excluded, in hirsute women manifesting symptoms and signs of hypercortisolism (discussed in [Chapter 13](#)). Coexistence of hypertension and diabetes in women with hirsutism should prompt consideration for screening for Cushing syndrome.

# TREATMENT OF HIRSUTISM

---

The treatment of hirsutism should be directed toward its cause, whenever possible, but also must consider the extent to which the patient views it as a problem, and her therapeutic and reproductive goals. Whereas laboratory evaluation is recommended only for women with moderate or severe hirsutism, treatment should be considered for all women who judge themselves hirsute. Excess facial and bodily hair can be a source of significant psychological stress, and many with mild hirsutism often seek treatment.<sup>78</sup>

Although hirsutism can be managed using cosmetic measures such as shaving, plucking, waxing, and depilatory agents, most women with hirsutism have increased androgen production, and hair growth promptly recurs if managed only by physical removal; most already are using one or more such methods. Consequently, almost all who seek treatment for hirsutism require and will benefit from pharmacologic therapy.

The severity of hirsutism should be defined before treatment begins to provide the means for monitoring response; the methods and frequency of hair removal provide the most practical and clinically relevant measure of treatment efficacy. **Serial measurements of serum androgen levels during treatment are neither necessary nor helpful. However, repeated hormonal evaluation is indicated when hirsutism progresses despite treatment.**

Before treatment begins, it also is important to foster reasonable expectations regarding its likely impact as well as timeline for anticipated benefit. Finer, lighter, and slower hair growth, and the prevention of new terminal hair growth, all can be expected; a complete cessation or elimination of hair growth however cannot. **No significant reduction in hair growth may occur for up to 6 months, which approximates the half-life of a hair follicle growth cycle.** After 6 months, a change in dose or drug, or the addition of a second drug, should be considered if the patient judges her response as inadequate. In general, treatment, once initiated, should be continued indefinitely or until the time that the patient is ready to pursue fertility because the problem of hair excess rarely goes away and almost always recurs following treatment discontinuation.<sup>125</sup> Almost all treatment options that are available for management of hirsutism either actively prevent the possibility of conception (such as hormonal contraceptive formulations) or are contraindicated for use in pregnancy (such as antiandrogens that due to known and potential teratogenic effects as in utero exposure of male fetus to antiandrogens can interfere with the normal development of male external genitalia).

Treatments for hirsutism are aimed at reducing the production, increasing the protein-bound proportion, and/or blocking the action of androgens. Combined estrogen-progestin hormonal contraceptives and antiandrogens are the primary weapons in the

therapeutic arsenal against hirsutism. It is important to emphasize that even women with IH relating to increased end-organ sensitivity to androgens can benefit from treatments that lower free/active androgen concentrations or block the androgen receptor<sup>126</sup>; clinical response correlates with circulating levels of 3 $\alpha$ -androstane-20-one glucuronide (the peripheral metabolite of DHT), supporting increased peripheral 5 $\alpha$ -reductase activity as the cause of IH.<sup>127</sup>

# Estrogen–Progestin Hormonal Contraceptives

Estrogen–progestin contraceptives have a number of complementary noncontraceptive actions that make them a logical and effective treatment for hirsutism ([Figure 12.9](#)):

**FIGURE 12.9**

## Key Points: Estrogen–Progestin Hormonal Contraceptives

- In hirsute women, ovarian androgen production usually is an LH-dependent process. The progestin component of the combination estrogen–progestin

contraceptives, through negative feedback, suppresses pituitary LH secretion and thereby also suppresses ovarian androgen production.<sup>128,129,130,131</sup>

- The high level of estrogen component in combination contraceptives stimulates hepatic SHBG production, thereby increasing binding capacity for circulating androgens and decreasing the amount of free/active androgen.<sup>131,132,133</sup>
- Directly or indirectly, combination estrogen–progestin contraceptives can also decrease adrenal DHEA-S secretion to variable degrees.<sup>134,135,136,137</sup>
- Certain synthetic progestogens (19-nor-derivatives such as levonorgestrel and norethindrone) in high doses can inhibit  $5\alpha$ -reductase activity in the skin,<sup>138</sup> which decreases the production of dihydrotestosterone (DHT), the major nuclear androgen in hair follicles and sebaceous glands. Others, such as cyproterone acetate (**Figure 12.10**) and drospirenone (**Figure 12.11**), inhibit androgen signaling at the level of the androgen receptor, thereby acting as antiandrogens.<sup>139,140,141,142</sup>

**FIGURE 12.10**

**FIGURE 12.11**

The large majority of the benefits resulting from treatment with estrogen–progestin contraceptives derive from the first two actions. In addition to these specific actions on androgen production, binding, and metabolism, combination contraceptives have other effects that often are equally important in the clinical management of women with hirsutism. Most women with hirsutism have underlying chronic anovulation and menstrual irregularity as well as episodic dysfunctional bleeding is often encountered in this population. Combinations of chronic anovulation and insulin resistance often predispose to abnormal patterns of endometrial growth. Treatment with estrogen–progestin contraceptives addresses not just the mechanisms underlying hirsutism but additionally offers endometrial protection due to continuous progestin exposure, thereby mitigating risk for developing endometrial pathology including hyperplasia and even cancer. The predictability of the induced withdrawal bleeding, lessening in volume and duration of menstrual flow, and thereby improved menstrual discomfort as well as reliable contraceptive efficacy are additional benefits that make combination estrogen–progestin contraceptive formulations as a first-line approach for managing hirsutism.

Current oral contraceptives contain ethinyl estradiol, in doses ranging from 20 to 50  $\mu\text{g}$  daily, and one of a variety of progestins. **In general, all low-dose oral contraceptives (containing 20–35  $\mu\text{g}$  ethinyl estradiol) have similar effectiveness in the treatment of acne and hirsutism.** Although estrogen induces a dose-dependent increase in serum SHBG concentrations,<sup>131,132</sup> low- and higher-dose pills suppress free testosterone levels to a comparable extent.<sup>143,144</sup> Although contraceptive progestins have varying impact on SHBG levels, most studies show no detectable differences in their overall clinical effectiveness.<sup>143,144,145,146,147</sup> **Notable, however, are a few studies that demonstrate superiority against symptoms of hyperandrogenism of formulations containing antiandrogenic progestins.**<sup>139,141</sup> Cyproterone acetate (CPA, [Figure 12.10](#)) is an antiandrogenic progestin that has long been available in combination with ethinyl

estradiol as oral contraceptive formulations in many countries; these, however, remain absent from the U.S. market. CPA has been shown to cause greater improvement to hirsutism (as measured by the modified FG score) than other contraceptive progestins after 12 months of use.<sup>139</sup> Drospirenone (**Figure 12.11**), a derivative of spironolactone, is a newer progestin that has some intrinsic antiandrogenic properties.<sup>148,149</sup> The dose of drospirenone utilized in contraceptive formulations (3 mg) is equivalent to approximately 25 mg spironolactone,<sup>92</sup> and although this low dose was considered ineffective in providing additive benefit beyond that already offered by the estrogen component of contraceptive formulations,<sup>139,150</sup> recent data demonstrate superiority of drospirenone-containing contraceptives against hyperandrogenism compared to formulations containing other progestins.<sup>141</sup> Yet another consideration that relates to the progestin component of a hormonal contraceptive formulation is that of androgenic potential. Progestins that are 19-nortestosterone derivatives (such as levonorgestrel, norethindrone), while being potent in their progestogenic effects, are innately androgenic and can theoretically worsen symptoms of hyperandrogenism, specifically acne.<sup>147,151</sup> **Although the evidence is limited that levonorgestrel-containing contraceptive formulations are less effective for hirsutism, it is prudent to preferentially choose contraceptive formulations containing less androgenic or even antiandrogenic progestin to manage hirsutism, particularly so when acne is also present.**

The transdermal contraceptive patch (delivering 20 µg ethinyl estradiol and 150 µg norelgestromin daily) and the vaginal contraceptive ring (releasing 15 µg ethinyl estradiol and 120 µg etonogestrel daily) are effective hormonal contraceptives. The average circulating ethinyl estradiol concentration in transdermal hormonal contraceptive patch users is approximately 60% higher than in women using an oral contraceptive containing 35 µg ethinyl estradiol, resulting in a greater increase in SHBG and thus a probability of greater benefit against hyperandrogenism; however, the overall decrease in androgen levels is no different from oral formulations.<sup>152</sup> Data regarding effects of transdermal and vaginal estrogen–progestin hormonal contraceptive formulations on hirsutism are nonexistent.

The progestin-only contraceptive formulations, and in particular higher-dose progestin regimens, such as medroxyprogesterone acetate 10–20 mg orally daily, or 150 mg intramuscularly every 3 months, may be considered in women with evidence of hyperandrogenemia in the setting of elevated LH levels for whom use of estrogen–progestin combination formulations is contraindicated. Although the progestin-alone regimen suppresses gonadotropins secretion to a lesser extent than estrogen–progestin regimens, LH still is suppressed sufficiently to cause a significant decrease in ovarian androgen production. In addition, testosterone clearance increases during treatment with

medroxyprogesterone acetate,<sup>153</sup> due to induction of hepatic enzyme activity. Although SHBG levels are decreased during treatment, the decrease in androgen production is so great that free testosterone levels still are decreased overall.<sup>154</sup>

Subjectively, 60–100% of women report improvement in their hirsutism during treatment with oral contraceptives,<sup>128,129,130,131,155</sup> which agrees with observations in studies using objective measures of hirsutism.<sup>131,132,155,156,157</sup> Combination oral contraceptives have similar effectiveness for improving acne and seborrhea.<sup>158,159</sup> Clinical improvement reflects the decrease in free/active androgen during treatment: new terminal hair growth decreases or stops, terminal hairs already present grow more slowly and produce finer hair, and acne gradually improves or disappears. **Hormone therapy must be continued for at least 6 months before judging its effectiveness.** In the meantime, the patient can continue to use her preferred method of hair removal (e.g., shaving, plucking, waxing). After 1–2 years, or when pregnancy becomes the goal, treatment can be discontinued and the patient observed for a return of ovulatory cycles, although most again will exhibit chronic anovulation. **Permanent hair removal by electrolysis or laser methods (discussed below) may be required ultimately, at least in some patients, but is best postponed until hormonal suppression has achieved its maximum benefits.**

# Antiandrogens

**Antiandrogens are an effective treatment for hirsutism but are best used in combination with hormonal contraceptives or another means of highly effective contraception because they have the potential to adversely affect sexual development in a genetic male fetus if the patient conceives during treatment.** In patients with contraindications to combined hormonal contraceptives, an alternative means of reliable contraception (e.g., an intrauterine device) should be provided during treatment with antiandrogens. Combination of hormonal contraceptives and antiandrogens also is a logical choice for patients who respond inadequately to contraceptives alone.

## Spironolactone

Spironolactone is an aldosterone antagonist having structural similarity to progestins that predominantly acts as an androgen receptor antagonist (**Figure 12.10**). Spironolactone competes with DHT for binding to the androgen receptor and, to varying extent, also inhibits ovarian and adrenal androgen synthesis.<sup>160</sup> Although serum androstenedione levels decrease, those of DHEA, DHEA-S, and cortisol do not significantly change during treatment with spironolactone.

The effects of spironolactone are dose dependent, and best results are achieved with doses of 50–100 mg twice daily.<sup>161,162,163,164</sup> In two clinical trials comparing spironolactone (100 mg daily) with placebo, active treatment resulted in significantly greater subjective improvement in hirsutism.<sup>165,166</sup> As with all treatments for hirsutism, maximal effects are observed only after approximately 6 months of therapy. Side effects are relatively few, including diuresis in the early days of treatment and occasional complaints of fatigue and abnormal uterine bleeding. Although spironolactone can cause hyperkalemia, the effect is rare and monitoring of potassium levels is not necessary in women with normal renal function.

The action of spironolactone, peripheral androgen receptor blockade, nicely complements the androgen lowering effects of combined oral contraceptives and may thus provide additional benefit for those who fail to achieve adequate results from oral contraceptives alone. Although the results achieved with combined treatment are not greatly different from monotherapy,<sup>167,168,169</sup> the predominant benefits of the combined approach include reliable contraception and avoidance of erratic uterine bleeding that can be encountered with use of spironolactone alone. The abnormal bleeding pattern associated with spironolactone use can often be avoided by deferring spironolactone until after implementation of a hormonal contraceptive (e.g., by the addition of spironolactone as a second agent after 6 months of oral contraceptive use).

## Cyproterone Acetate

Cyproterone is a derivative of  $17\alpha$ -hydroxyprogesterone (17OHP) having potent progestational activity that inhibits gonadotropin secretion but also acts as a competitive androgen receptor antagonist and inhibits enzymes involved in androgen synthesis, like spironolactone (**Figure 12.10**). Cyproterone acetate is the progestin in the combined estrogen–progestin oral contraceptive called “Diane” (2 mg CPA and 50  $\mu$ g ethinyl estradiol) in common use in many parts of the world but not available in the United States. The lesser estrogen dose formulation “Dianette” or “Diane 35” contains 2 mg CPA and 35  $\mu$ g ethinyl estradiol. The drug also has been used in higher doses (12.5–100 mg), alone or in combination with estrogen.<sup>170,171</sup> A systematic review including data from nine clinical trials concluded that combined treatment with CPA and ethinyl estradiol is more effective than placebo and yields results comparable to those achieved with oral contraceptives, spironolactone, and other treatments.<sup>172</sup> The most common side effects associated with cyproterone treatment are fatigue, edema, loss of libido, weight gain, and mastalgia.

## Finasteride

Finasteride inhibits  $5\alpha$ -reductase and thus blocks the conversion of testosterone to the more androgenic DHT. The enzyme  $5\alpha$ -reductase exists in two forms, with type 1 being most prevalent in the skin and type 2 predominating in reproductive tissues.<sup>173</sup> Although finasteride inhibits the type 1 enzyme only to a limited extent, evidence from clinical trials indicates its efficacy is comparable to those of spironolactone and another antiandrogen, flutamide.<sup>166,169,174</sup> Because fetal external male genital development requires the action of DHT, the risks of inadvertent finasteride treatment during pregnancy are a particular concern, and finasteride should not be used without a highly effective method of contraception (**Figure 12.12**).

## FIGURE 12.12

### Flutamide

Flutamide is a nonsteroidal androgen receptor antagonist used primarily in the treatment of prostate cancer. The drug (250–750 mg daily) inhibits hair growth directly and is as effective as spironolactone,<sup>157,166,169,175,176</sup> but its higher cost and potential for causing severe hepatotoxicity make it an unattractive therapeutic choice, by comparison<sup>177,178</sup> (Figure 12.13).

## FIGURE 12.13

In the absence of significant clinical benefit, combination of two different antiandrogen regimens (such as combining spironolactone and finasteride) has also been reported to offer benefit.<sup>179,180</sup>

# Insulin-Sensitizing Drugs

Given that PCOS is the most common cause of hirsutism and that insulin resistance is a common feature of the disorder, insulin-sensitizing drugs offer another potential approach to the treatment of hirsutism.<sup>92,181</sup> Treatment with metformin and thiazolidinediones (rosiglitazone, pioglitazone) decreases both circulating insulin and androgen levels in women with PCOS.<sup>182,183,184,185,186,187,188,189</sup> Improvements in hirsutism scores with use of metformin alone are described in the pediatric population.<sup>190</sup> However, a systematic review and meta-analysis including nine placebo-controlled trials concluded that insulin-sensitizing drugs have no important benefits for the treatment of hirsutism.<sup>124</sup> Accordingly, guidelines issued by the Endocrine Society suggest against their use for the treatment of hirsutism.<sup>92</sup>

## Other Treatments

The mainstay of medical treatment for hirsutism has been, and remains, estrogen–progestin contraceptives, with the addition of an antiandrogen as a second-line strategy, often introduced approximately 6 months after initiating trial of combination hormonal contraceptives if the desired cosmetic result has not yet been achieved. However, for women who are significantly bothered by symptoms of hyperandrogenism, and for those interested in use of levonorgestrel-containing intrauterine system, antiandrogen regimen can be initiated earlier and even concomitantly with contraceptive regimen.

## Gonadotropin-Releasing Hormone Agonists

In women with severe hyperandrogenism who fail to respond to or cannot tolerate treatment with estrogen–progestin contraceptives and antiandrogens, and particularly in those with evidence of LH dominance, GnRH agonist therapy can be considered. The effectiveness of GnRH agonist therapy relates directly to the suppression of LH-dependent ovarian androgen production. GnRH agonists (e.g., leuprolide, nafarelin, goserelin) are not recommended for routine use, primarily because they induce a severe hypoestrogenism but also because they are more costly and inconvenient to use.<sup>92</sup>

Serum androgen levels decrease dramatically during GnRH agonist treatment, typically falling to near-castrate levels within as little as a month.<sup>191,192,193,194</sup> The addition of estrogen to GnRH agonist therapy to eliminate estrogen deficiency symptoms and prevent bone loss does not diminish its efficacy for treating hirsutism. Cyclic or continuous treatment with estrogen (e.g., 0.3–0.625 mg conjugated estrogens daily, or equivalent) and progestin (e.g., 5–10 mg medroxyprogesterone), or an estrogen–progestin contraceptive, can be used as “add back” strategy, particularly when GnRH agonist use is planned for longer than 3-month duration. Combined treatment decreases free testosterone concentrations to lower levels than GnRH therapy alone, due to the added benefit of increased SHBG concentrations induced by estrogen.<sup>195,196,197,198</sup> **Nevertheless, combined treatment with a GnRH agonist and oral contraceptives is no more effective than treatment with a GnRH agonist alone, and somewhat less effective than combined treatment with oral contraceptives and an antiandrogen.**<sup>199</sup>

GnRH agonist therapy can also be considered in management of women with ovarian hyperthecosis who typically have severe hyperandrogenism. However, the impact of treatment on their hirsutism may be less than expected, even when gonadotropin secretion is suppressed profoundly, because most also have severe insulin resistance with hyperinsulinemia driving their androgen production.<sup>200</sup> Adequate suppression of ovarian androgens may not be achieved in obese women, given

concomitant insulin resistance. Although a combination of GnRH agonist and metformin can be considered in situations of significant insulin resistance, it is important to appreciate that there data on efficacy of this combination against hirsutism are currently lacking.

## Glucocorticoids

Glucocorticoids are used to suppress endogenous ACTH secretion in the long-term management of women with classical CAH. They also have been used for the treatment of hirsutism in women with the nonclassical, late-onset form of the disorder, with varying benefit. **Although glucocorticoids suppress serum adrenal androgen levels effectively in women with nonclassical CAH, they are less effective than oral contraceptives or antiandrogens for the treatment of hirsutism.**<sup>201,202</sup> Consequently, glucocorticoid treatment has even less to offer women with other causes for hirsutism.<sup>194,203,204</sup>

## Eflornithine Hydrochloride

Eflornithine hydrochloride (13.9% cream) is a topically applied inhibitor of ornithine decarboxylase, an enzyme active in the dermal papilla that is essential for hair growth; it is not a depilatory agent. In clinical trials, twice daily application produced noticeable improvement in facial hair growth within a few weeks in the majority of patients. However, the drug must be used continuously, because hair growth reverts to pretreatment characteristics within approximately 8 weeks after treatment is discontinued.<sup>205</sup> When used in conjunction with laser hair removal, eflornithine produces a more rapid response than laser treatment alone.<sup>206,207</sup> Treatment with topical eflornithine hydrochloride is perhaps best suited for patients with mild facial hirsutism.

# Permanent Hair Removal

A number of options exist for the removal of unwanted hair including plucking, waxing, shaving, or use of depilatory agents and are commonly utilized by women with hirsutism; while effective to varying degrees, the results achieved are only temporary. After removal by plucking, new hair become apparent at the skin surface after approximately 6–8 weeks. Waxing can be used on larger areas of the body, but results last no longer. Both methods remove the entire hair but typically not the dermal papilla. Because shaving removes hair to a level only slightly below the skin surface, its results are short-lived and most women will need to shave again within 1–3 days. Electrolysis and photoepilation (laser and pulsed light therapies) strategies are aimed at destruction of the dermal papilla, and results of these interventions vary both in the magnitude of benefit and in degrees of permanence of hair removal.

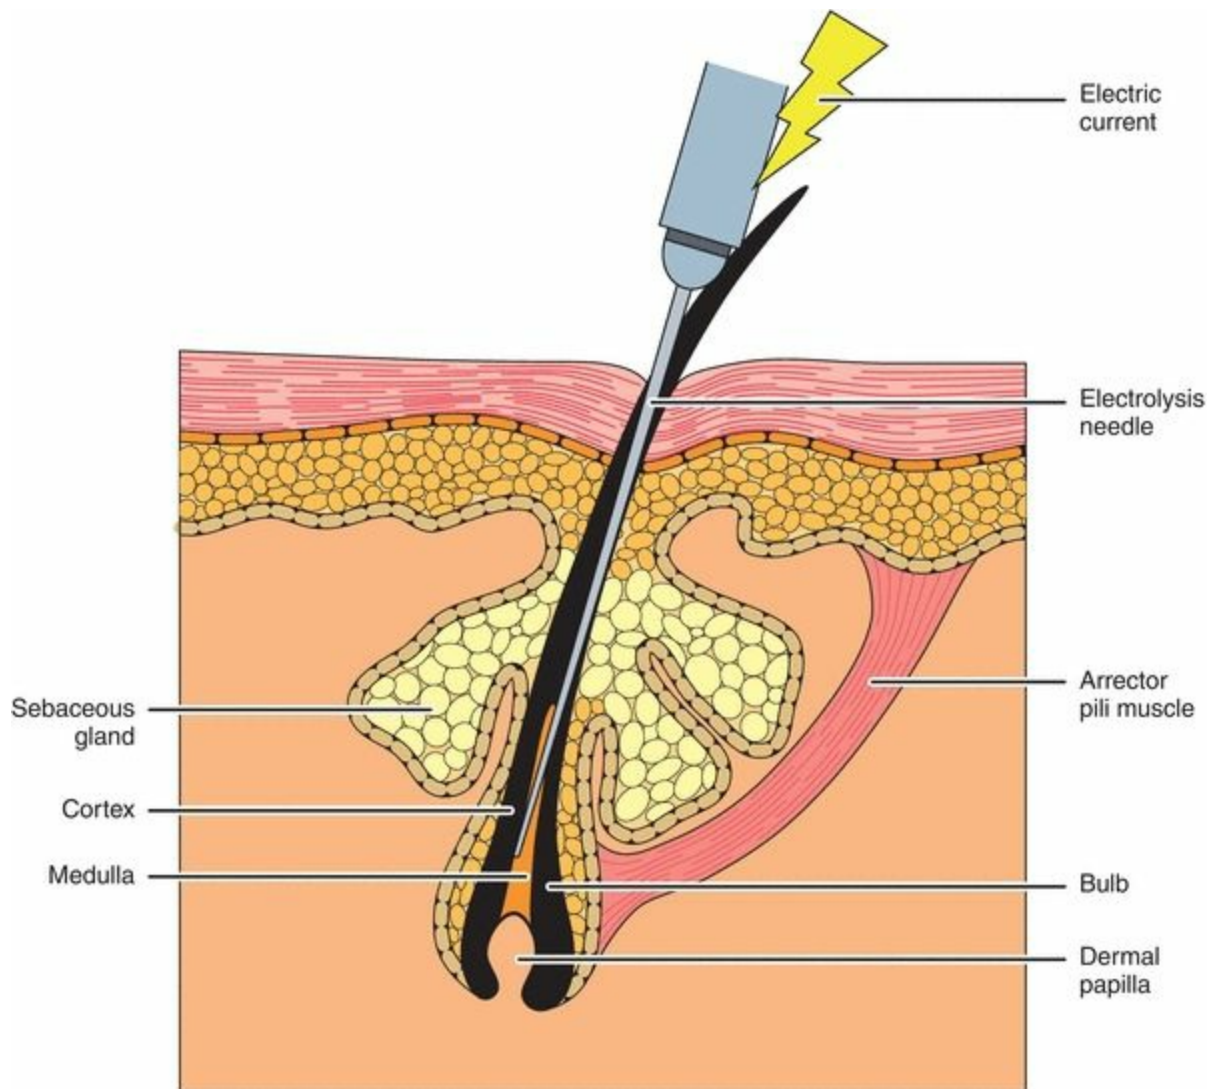

## Electrolysis

Electrolysis has been used as a method of permanent hair reduction for more than 100 years.<sup>208</sup> The earliest method, called galvanic electrolysis, used direct current applied to a fine needle inserted into the hair follicle, which produced sodium hydroxide from saline in tissues, causing a chemical destruction of the dermal papilla. Modern “thermolytic” techniques use high-frequency alternating current, causing thermal destruction of the hair follicle, or a “blend” of the two methods.<sup>209,210</sup>

Although electrolysis is an effective method of “permanent” hair reduction through damaging the dermal papilla,<sup>211</sup> hair growth recurs in up to 25% of women by 6 months after the treatment is discontinued.<sup>209,210</sup> In sensitive areas, topical anesthetic creams typically are applied first, because electrolysis can be painful. Electrolysis also can cause inflammation and erythema and, in some, pigmentation changes and scarring.

Unfortunately, there are no governing standards of practice for electrolysis and no formal training is required in many jurisdictions before starting a practice. In experienced hands, electrolysis can produce satisfying results, but the quality of care, and results, can vary considerably (**Figure 12.14**).

**FIGURE 12.14**

## Laser and Pulsed Light Therapies

Photoepilation therapies use laser or intense pulsed light to destroy hair follicles.<sup>212,213</sup> Both methods attempt to selectively target the hair bulb by using wavelengths absorbed specifically by melanin, but absorption by pigment in the epidermis also can occur. Consequently, they are best suited for light-skinned individuals with dark hair, in whom most of the energy will be absorbed by melanin in the hair bulb; the risk of burns and other complications such as postinflammatory pigment changes increases with the amount of skin pigmentation, although advances in technology are improving options for patients with darker skin.<sup>214,215,216</sup> Photoepilation therapies can be used for removal of any color of hair but, as might be expected, are more effective in patients with black or brown hair than in those with red or blonde hair.

Success rates achieved with laser and pulsed light therapies vary with hair growth

phase, skin and hair color, location, the type of laser, and the number of treatments.<sup>217,218</sup> Most patients require a series of four to six treatments at 4- to 6-week intervals to achieve the desired result,<sup>214</sup> followed by maintenance treatments every 6–12 months to remove any hairs that grow back.

Head-to-head split face comparison studies have demonstrated superiority of pulse light treatments over electrolysis in managing facial hirsutism.<sup>219</sup>

## Key Points: Treatment of Hirsutism

- The response to all medical treatments for hirsutism is relatively slow, generally requiring 6 months to achieve significant benefits, which approximates the duration of the life cycle of a hair follicle.
- In the absence of contraindications, the first treatment of choice for hirsutism, particularly if there is evidence of hyperandrogenemia, is a low-dose estrogen–progestin contraceptive.
- In patients having an inadequate response to treatment with estrogen–progestin contraceptives alone, an antiandrogen should be added, with spironolactone generally being the best choice.
- A trial of 5 $\alpha$ -reductase inhibitor can be considered in preference over spironolactone in hirsute women with normal circulating androgen profile.
- The use of GnRH agonists should be reserved for patients who fail to respond to or cannot tolerate more traditional treatments and particularly so in women with disproportionately high serum LH levels. GnRH agonist should be combined with sex steroid add-back therapy, which prevents the consequences of hypoestrogenism and does not diminish the efficacy of GnRH agonist treatment.
  - Permanent hair removal using electrolysis or photoepilation therapies (laser, pulsed light), when necessary, is best postponed until hormonal suppression has achieved its maximum benefits.

# Reproduction and the Adrenal

The adrenals are a pair of endocrine glands, one located along the upper medial pole of each kidney. Normal function of the adrenals is not just critical to survival but also contributes toward the earliest signs of physical and sexual maturity, namely, the development of axillary and pubic hair. Menstrual abnormalities such as oligomenorrhea or amenorrhea are often seen in women with adrenal disorders. On the other hand, certain adrenal disorders, the classic example being congenital adrenal hyperplasia (CAH), can mimic common gynecologic conditions, such as polycystic ovary syndrome (PCOS, discussed in detail in [Chapter 11](#)). **The goal of including this chapter in a gynecology textbook is to sensitize this readership to differential diagnoses to consider when evaluating women presenting with menstrual abnormalities, with features that mimic PCOS discussed in [Chapter 11](#), or manifesting certain clinical features that suggest the possibility of an underlying adrenal disorder.**<sup>1,2</sup> Detailed discussion on the management of adrenal disorders is beyond the scope of a gynecologist/reproductive endocrinologist, and patients should be referred promptly to an internist-endocrinologist for completion of evaluation and management.

Each adrenal gland is composed of two distinct hormone-producing compartments, the outer cortex, and the inner medulla ([Figure 13.1](#)). Adrenal cortical cells are organized into three distinct functional layers, each responsible for a distinct functional category of steroid hormones.<sup>3,4</sup> Cells constituting the outermost cortical layer, the zona granulosa, are responsible for secreting a class of hormones called mineralocorticoids. Mineralocorticoids, of which aldosterone is the prototype, are responsible for bodily fluid and electrolyte homeostasis, and their secretion is governed by the renal renin-angiotensin system. Glucocorticoids, of which cortisol is the prototype, are the second class of adrenal steroid hormones, which are secreted by cells that comprise the zona fasciculata of the adrenal cortex. Cortisol is critical to a number of biologic processes including cellular homeostasis, energy balance, and immunity. Adrenal secretion of cortisol is under the control of ACTH (adrenocorticotrophic hormone), and in turn, circulating cortisol maintains a tight control of secretion of both the ACTH (by the anterior pituitary) and of the hypothalamic CRH (corticotropin-releasing hormone) ([Figure 13.2](#)). It is the ACTH that drives the steps involved in the adrenal steroidogenic processes, starting from the initial step of transportation of the parent cholesterol from the cellular cytosol to the mitochondria, as well as regulating the synthesis of the

cytochrome P-450 enzymes that are involved in the steroidogenic pathways (**Figure 13.3**). The innermost layer of the adrenal cortex is the zona fasciculata, and cells of this layer contain the 17,21-lyase enzyme (CYP17/P450c17) that preferentially leads to production of the glucocorticoid precursors, 17-hydroxyprogesterone and 17-hydroxypregnenolone, intermediaries in the synthesis of androgens (see **Figure 13.3**).

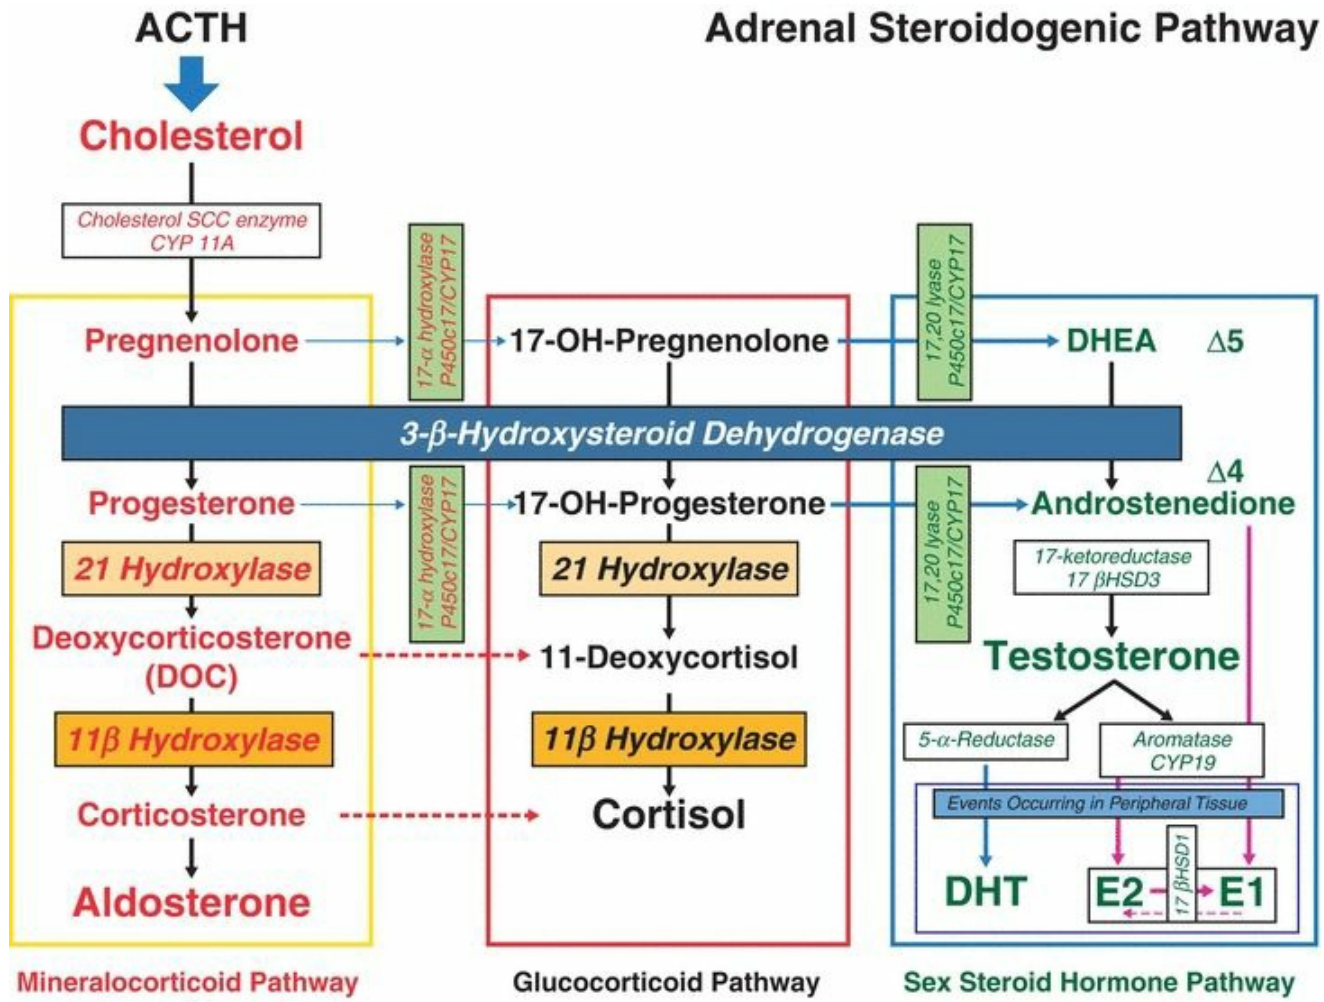

**FIGURE 13.1**

**FIGURE 13.2**

# Adrenal Steroidogenic Pathway

**FIGURE 13.3**

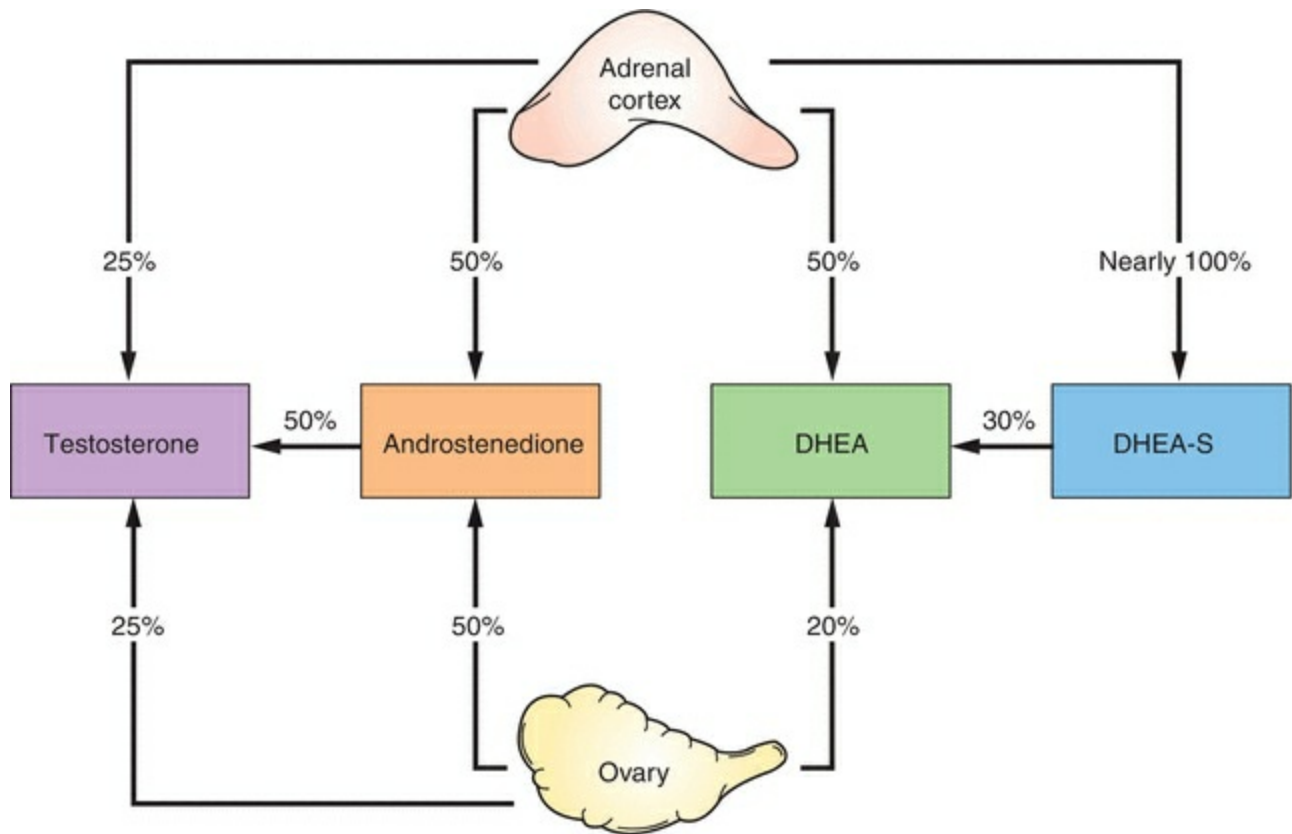

# ANDROGENS IN WOMEN

---

The ovaries and the adrenal cortex are the two major sources of circulating androgens in women. In women, the major circulating androgens (in descending order of serum concentration) are dehydroepiandrosterone sulfate (DHEA-S), dehydroepiandrosterone (DHEA), androstenedione, testosterone, and DHT.<sup>5,6,7,8</sup> **DHEA-S, DHEA, and androstenedione can be considered prehormones because they have little or no intrinsic androgenic activity and require conversion to testosterone to exert androgenic effects.** DHEA-S is produced almost exclusively by the adrenal glands, at a rate ranging between 3.5 and 20 mg/day<sup>3</sup>; the normal serum concentration is 100–350 µg/dL in most laboratories. DHEA is produced by both the adrenals (50%) and the ovaries (20%) and from the peripheral conversion of DHEA-S (30%). The production rate of DHEA is between 6 and 8 mg/day,<sup>6</sup> and normal serum concentrations range between 1 and 10 ng/mL. Androstenedione production is divided equally between the ovaries and the adrenals; the production rate is between 1.4 and 6.2 mg/day and the normal serum concentration is 0.5–2.0 ng/mL.<sup>7,8</sup> Serum immunoassays for DHEA-S, DHEA, and androstenedione generally reflect the amount of biologically available hormone because none of the three is protein bound to any significant extent.

In women, testosterone production derives from the adrenals (25%), from the ovaries (25%), and from peripheral conversion of androstenedione (50%) (**Figure 13.4**). The production rate ranges between 0.1 and 0.4 mg/day, and the normal serum concentration is 20–80 ng/dL; levels do not fluctuate widely but are lowest during the early follicular phase and approximately 20% higher at midcycle.<sup>6</sup> Testosterone bioavailability and metabolism, relevance of the hepatic sex hormone-binding globulin for tissue effects of androgens, and changes in the ovarian androgen production and in circulating profile in the postmenopausal period are discussed in **Chapter 12**. Adrenal androgen production is recognized to progressively decline with advancing age regardless of menopausal state; serum DHEA concentrations in women between ages 40 and 50 years are approximately half those in younger women.

**FIGURE 13.4**

Cells of the adrenal medulla are entirely distinct, both functionally and developmentally, from the cortex. The adrenal medulla is responsible for the production of catecholamines, norepinephrine and epinephrine, which play critical roles in regulating cardiovascular and renal systems. Although any major systemic disorder will ultimately affect reproductive function, disorders of the adrenal medulla are less likely to manifest as reproductive dysfunction and therefore will not be further discussed in this chapter.

# Adrenal Cortical Disorders Relevant to Female Reproduction

## Congenital Adrenal Hyperplasia (CAH)

Congenital adrenal hyperplasia (CAH) includes a group of autosomal recessive inherited endocrine disorders that are characterized by impaired cortisol synthesis due to inherited deficiencies in certain steroidogenic pathway enzymes.<sup>9,10,11,12,13,14,15,16,17,18</sup> Varying degrees of adrenal androgen excess are a hallmark. Clinical presentation is dictated by the severity of enzyme deficiency (and hence degree of cortisol deficiency) and consequent severity of androgen excess. Females with classical CAH (Table 13.1) usually are recognized at birth or during early infancy due to ambiguous appearance of genitalia (discussed in Chapter 8).<sup>11</sup> The nonclassical form of CAH (NCCAH, also known as late-onset CAH), however, tends to manifest later, with stigmata that are often subtle. NCCAH can present as premature adrenarche or precocious puberty (discussed in Chapter 9) and are often misdiagnosed as PCOS due to accompanying symptoms of hyperandrogenism (hirsutism and/or acne) and irregular menses (discussed in Chapter 11).<sup>19,20,21,22,23,24,25</sup> Data from neonatal screening programs for detection of classical CAH indicate that the overall prevalence of classical CAH is approximately 1 in 10,000 to 1 in 15,000 live births and varies with ethnicity. Among different races, the prevalence reportedly ranges from 1 in 28,000 Chinese<sup>26</sup> to between 1 in 5,000 and 1 in 23,000 Caucasians,<sup>27,28</sup> to as high as 1 in 280 Yupik Eskimos.<sup>29</sup> In the United States, the reported prevalence of classical CAH is 1 in 15,500 White and 1 in 42,000 African Americans.<sup>30</sup> In contrast to the general population, the prevalence of NCCAH among American White and Hispanic women with evidence of hyperandrogenism is higher, reported between 1% and 4%.<sup>14</sup> In other countries, prevalence has ranged from as low as 0.3% among Northern Italians to as high as 6–10% among women from Israel, India, and Jordan.<sup>15,16</sup> In different studies, the prevalence of nonclassical CAH has ranged between 1% and 15%.<sup>14,15,16,17</sup>

### TABLE 13.1 Congenital Adrenal Hyperplasia: Common Genetic Variants

Enzymatic Defects for Common CAH Variants	Affected Gene	Phenotype	Endocrine Hallmarks
21-Hydroxylase deficiency (most common cause of CAH)	CYP21A2	<p><b>Classic</b> (severe deficiency)</p> <ul style="list-style-type: none"> <li>• <b>Salt wasting accounts for 75% of cases:</b> Ambiguous genitalia in genetic female child, rapid-onset adrenal insufficiency in the first few weeks of neonatal life</li> <li>• <b>Simple virilizing (less severe deficiency)</b> <ul style="list-style-type: none"> <li>◦ Postnatal virilization, pseudoprecocious puberty</li> </ul> </li> </ul> <p><b>Nonclassic (least severe deficiency)</b></p> <ul style="list-style-type: none"> <li>• Hyperandrogenism during childhood, early activation of HPA and HPO axes (early adrenarche, early or precocious puberty)</li> <li>• May present a PCOS-like picture</li> <li>• May be asymptomatic</li> </ul>	<p>Elevated 17OHP (&gt;800 ng/dL)</p> <p>Elevated DHEA-S</p> <p>Elevated total testosterone</p> <p>Elevated ACTH</p> <p>As above (lesser degree of abnormalities)</p> <p>As above (lesser degree of abnormalities)</p> <p>ACTH may be in upper normal range</p>
11 $\beta$ -Hydroxylase deficiency (second most common cause of CAH)	CYP11B1	<p><b>Classic</b> (severe deficiency):</p> <ul style="list-style-type: none"> <li>• Ambiguous genitalia in genetic female child, postnatal virilization, hypertension</li> </ul> <p><b>Nonclassic (less severe deficiency)</b></p> <ul style="list-style-type: none"> <li>• Hyperandrogenism during childhood or early adulthood</li> <li>• Hypertension is common</li> <li>• May be asymptomatic</li> </ul>	<p>Elevated deoxycorticosterone</p> <p>Elevated deoxycortisol</p> <p>As above (lesser degree of abnormalities)</p>
3 $\beta$ -Hydroxysteroid dehydrogenase type 2 deficiency (least common cause of CAH)	HSD3B2	<p><b>Classic</b> (severe deficiency)</p> <ul style="list-style-type: none"> <li>• Ambiguous genitalia in both male and female infants, adrenal insufficiency and salt wasting in the first few weeks of neonatal life</li> </ul> <p><b>Nonclassic (less severe deficiency)</b></p> <ul style="list-style-type: none"> <li>• Hyperandrogenism during childhood or early adulthood</li> <li>• May be asymptomatic</li> </ul>	<p>Elevated DHEA-S</p> <p>Elevated 17OH pregnenolone</p> <p>Elevated 17OH pregnenolone to 17OH progesterone ratio (&gt;6 after ACTH stimulation test)</p>

The most common cause of both classical and nonclassical CAH is adrenal 21-hydroxylase (CYP21 or P450c21) deficiency caused by mutations in the CYP21A2 gene.<sup>12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27</sup> The enzyme 21-hydroxylase is responsible for a critical step in the synthesis of both glucocorticoids and mineralocorticoids (see [Figure 13.3](#)), and its deficiency results in accumulation and overproduction of the precursor steroidogenic hormone 17 $\alpha$ -hydroxyprogesterone (17OHP). 17OHP represents a steroid metabolism intermediary, which not only is the substrate for 21-hydroxylase enzyme but also represents a critical precursor for both adrenal cortisol and androgen synthesis (see [Figure 13.3](#)). Deficiency of 21-hydroxylase accounts for the vast majority of cases of CAH (almost 90%). Deficiencies involving 11 $\beta$ -hydroxylase (second most common type of CAH caused by mutations in CYP11B1) occur in 1 in 100,000 live births in the general population and account for approximately 5% of cases of CAH. Deficiency of 3 $\beta$ -hydroxysteroid dehydrogenase

represents the least common type of CAH that results from mutations in the HSD3B gene. Regardless of the involved enzyme, the pathophysiology of CAH stems from decreased cortisol production, which stimulates a compensatory increase in pituitary ACTH secretion; the net results of chronic ACTH excess are adrenal hyperplasia and excessive levels of steroid hormones proximal to the enzyme block, which then seek an alternative metabolic pathway, resulting in increased production of androgens. These disorders are also reviewed in a context-specific manner in [Chapters 8, 9, 11, and 12](#). The severity of hormonal abnormalities depends on the degree of the enzymatic impairment, which depends on the genotype.<sup>31, 32, 33</sup> Compound heterozygotes for two different mutations usually have a phenotype compatible with the milder mutation ([Table 13.1](#)).

Females with classical CAH (both salt-wasting and simple virilizing forms) typically present at birth with ambiguous genitalia. In clinical settings with appropriate resources, cases of classic CAH in female newborns are likely to be diagnosed early given the abnormal appearing genitalia. Unless biochemically screened, this diagnosis will be missed in the male newborns who exhibit normal-appearing male genitalia. Unless diagnosed in a timely manner, infants with classic CAH have a poor prognosis due to rapid onset of electrolyte and fluid imbalance (salt wasting) due to deficiencies of both mineralocorticoids and glucocorticoids. In the United States and many other countries, routine screening of newborns is instituted to ensure a timely initiation of supplementation with the deficient hormones and consequent normalization of adrenal androgens.<sup>18, 28, 34</sup> In contrast to the classic variant, those with the NCCAH or “late-onset” form of CAH present later, during childhood or early adolescence with precocious puberty, or as young adults with signs of hyperandrogenism, very much like those with PCOS.<sup>18, 19, 20, 21, 22, 23, 24, 25</sup> **NCCAH must be considered in the differential diagnoses of all girls and women presenting with signs and symptoms of hyperandrogenism<sup>25</sup> and particularly so for those having an early onset of hirsutism (pre- or perimenarcheal, including girls with premature adrenarche), those with a family history of the disorder, and girls and women in high-risk ethnic groups presenting with features of androgen excess (Hispanic, Mediterranean, Slavic, Ashkenazi Jewish, or Yupik Eskimo heritage).**

Diagnostic yield from routine screening of CAH is very low, because the disorder is uncommon.<sup>2, 13, 35</sup> The importance of a prompt diagnosis of NCCAH lies in timeliness of interventions to help minimize severity of androgen excess–related symptoms and to ensure access to preconception genetic counseling given the heritable nature of this disorder. The diagnosis of NCCAH itself is unlikely to change the choice of recommended treatment. Inclusion of glucocorticoids in the management of NCCAH has been shown to effectively improve hyperandrogenemia through suppressing the ACTH

drive by negative feedback. The field however, has long shifted away from using glucocorticoids as a first-line approach and currently recommended management strategies aim at targeting the symptoms, for example, using combined hormonal contraceptives and antiandrogens to manage hirsutism. Glucocorticoids are less effective than estrogen-progestin contraceptives and/or antiandrogens for the treatment of chronic anovulation and hirsutism in women with NCCAH.<sup>36,37</sup>

## Androgen-Secreting Neoplasms of Adrenals

**Adrenal neoplasms** are a rare cause of androgen excess. The majority of these are malignant, although testosterone production has been described by some adrenal adenomas. In addition to androgens (DHEA, DHEA-S testosterone), cortisol excess may be seen.<sup>38</sup> Clinical presentation can be quite similar to that of ovarian androgen-secreting tumors (as discussed in [Chapter 12](#)).

## Cushing Syndrome

A disorder of cortisol excess, Cushing syndrome, can be confused with PCOS as symptoms of hyperandrogenism, such as hirsutism, as well as menstrual irregularities are often seen. **However, the prevalence of Cushing syndrome in women presenting with hyperandrogenism is extremely low, well below 1%.**<sup>2, 35, 39</sup>

One must be alerted to symptoms and signs of hypercortisolism, which, however, may vary with the duration and extent of excess cortisol secretion. In addition to hirsutism, the classical features of Cushing syndrome include progressive central obesity, excess fat accumulation in the cheeks (“moon face”) or at the back of the neck (“buffalo hump”), severe fatigue and muscle weakness, hypertension, atrophy of the skin, and subcutaneous tissue (easy bruising and purple striae on the abdomen and flanks).<sup>40</sup> Hyperpigmentation is also common<sup>41, 42</sup> and can be particularly prominent in cases of Cushing disease (caused by excess secretion of  $\alpha$ -melanocyte-stimulating hormone, a by-product of ACTH synthesis from proopiomelanocortin, the common precursor molecule) in areas most exposed to light (the face, neck, and back of the hands) or areas subject to chronic mild trauma, friction, or pressure (the elbows, knees, knuckles, and shoulders). Hypertension, diabetes, osteoporosis, and depression are common ([Table 13.2](#)).<sup>43, 44, 45, 46</sup>

### TABLE 13.2 Causes of Cortisol Excess

Iatrogenic (commonest cause)  
ACTH-driven cortisol excess (80%)  
    ACTH-secreting pituitary tumor (80%)  
        Adenomas  
        Carcinomas  
    Ectopic ACTH production (20%)  
ACTH independent  
    Autonomous adrenal overactivity (20%)  
Rare causes  
    Ectopic CRH release  
    Primary pigmented nodular adrenal disease  
    McCune-Albright syndrome

---

The clinical presentation of Cushing syndrome can also be caused by (1) long-term ingestion of prescribed glucocorticoids for chronic medical conditions, (2) an ACTH-secreting pituitary corticotroph adenoma (termed Cushing disease, accounting for most cases of cortisol excess), (3) cortisol-secreting adrenal adenomas and carcinomas, or (4) ectopic CRH or ACTH secretion by tumors (commonly bronchial carcinoids). The use of prescribed glucocorticoids (oral, rectal, inhaled, topical, or injected) is the most common cause of Cushing syndrome overall. **The first step in the evaluation of suspected Cushing syndrome is to exclude exogenous glucocorticoid exposure.**

# EVALUATION OF WOMEN WITH SUSPECTED ADRENAL DISORDERS

---

Gynecologists in general and reproductive endocrinologists in particular may be the first to encounter patients with adrenal disorders as menstrual dysfunction is a common initial presentation in reproductive-age women. Additionally, adrenal conditions that result in excessive production of glucocorticoids and/or androgens may mimic features of PCOS, the most common endocrine disorder of reproductive-age women. Gynecologists and reproductive endocrinologists therefore should be familiar with the initial screening process aimed at identifying the few who will benefit from prompt referral to endocrinologists for additional specific evaluation and definitive management. **As always, evaluation should begin with a careful history and physical examination, which always provide important diagnostic clues.** Laboratory investigation and imaging are used primarily to exclude other rare or potentially serious possibilities.

# HISTORY AND PHYSICAL EXAMINATION

---

Adrenal disorders should be considered in the differential diagnosis of any girl or woman presenting with features of androgen excess as well as menstrual irregularity. Similar to evaluation of hirsutism ([Chapter 12](#)), the key elements of the medical history in women with suspected adrenal disorders include the menstrual history, presence, timing of onset, and rate of progression of features of androgen excess (such as acne, hirsutism, hair loss, or features of virilization discussed in [Chapters 11 and 12](#)). Information on race and ethnicity and family history is particularly important when considering genetic disorders of an autosomal recessive inheritance, such as the nonclassical CAH.

Although the clinical presentation of nonclassical CAH can closely resemble that of PCOS, hirsutism tends to present earlier in life and be more severe in women with CAH often accompanied by history of early-onset adrenarche and precocious puberty.<sup>47,48</sup> A relatively short history and later age at onset of hirsutism (after age 25) or rapid progression over a period of months are highly concerning for an androgen-producing neoplasm. Symptoms of androgen excess (hirsutism, acne) if accompanied by progressive weight gain, easy bruising, and depressive symptoms should lead one to consider Cushing syndrome as a differential diagnosis.

A **family history** of hirsutism, menstrual irregularity, obesity, and infertility should raise concerns for possibility of nonclassical CAH, which is more common in women of Hispanic, Mediterranean, Slavic, or eastern European Jewish (Ashkenazi) heritage.

The **physical examination** should include attention to the general appearance with particular vigilance for signs and symptoms that can suggest a possibility of an underlying adrenal disorder. The classic descriptions of an excess glucocorticoid milieu include distinct physical features such as moon facies; buffalo hump and facial plethora; presence of wide cutaneous striae of purple hue along the anterior and lateral abdominal wall; proximal muscle weakness; evidence of hypertension, hyperglycemia, hypokalemia, and osteoporosis and tendency toward easy bruising and depression. Features of androgen excess due to nonclassical CAH are often confused with PCOS presentation, whereas signs of virilization (such as worsening hirsutism, male pattern baldness, clitoromegaly, deepening of voice, increasing libido, and changes in physique that include a regression in breast size and an increase in muscle mass) should alert one to the possibility of an underlying androgen-secreting tumor, particularly when the onset of symptoms is recent and progression is rapid (months and not years). Clitoral size varies significantly among women<sup>49</sup>; in one study, the mean length of the glans clitoris was  $5.1 \pm 1.4$  mm and the mean width was  $3.4 \pm 1.0$  mm.<sup>50</sup> Clitoromegaly generally is defined by a clitoral length greater than 10 mm or by a clitoral index (length times

width) greater than 35 mm<sup>2</sup>.<sup>51</sup> Other relevant physical findings include spontaneous or expressible galactorrhea, suggesting hyperprolactinemia (discussed in [Chapter 4](#)), and abdominal or pelvic masses that may represent an androgen-secreting tumor. As discussed in [Chapter 12](#), the modified **Ferriman-Gallwey score** is commonly utilized to quantify the severity of hirsutism.<sup>52</sup>

# LABORATORY EVALUATION

---

As discussed in [Chapter 12](#), the relationship between symptoms of hyperandrogenism such as hirsutism and circulating androgen concentrations is not entirely clear. The primary aim is to identify those having potentially serious endocrine disorders requiring specific treatment (nonclassical CAH, androgen-secreting tumors, Cushing syndrome). Thyroid disorders and hyperprolactinemia should be excluded in women with menstrual dysfunction. Elevated serum prolactin concentrations can be associated with increased serum DHEA-S levels,<sup>53</sup> prolactin receptors have been identified in the human adrenal, and prolactin can increase adrenal DHEA production in vitro.<sup>54</sup>

# Screening for Congenital Adrenal Hyperplasia

## Serum 17 $\alpha$ -Hydroxyprogesterone Concentration

In both normal women and those with NCCAH, the normal diurnal pattern of pituitary ACTH secretion is reflected in serum 17-hydroxyprogesterone (17OHP) concentrations, which peak in the morning and nadir late in the day. Morning serum 17OHP levels during the follicular phase of the menstrual cycle are clearly higher in women with NCCAH than in normal women, whereas evening concentrations may overlap significantly. **A follicular-phase morning serum 17OHP concentration less than 200 ng/dL (<2 ng/mL) effectively excludes the diagnosis of nonclassical CAH.**<sup>19,55,56</sup> Levels greater than 1,000 ng/dL (>10 ng/mL) are virtually diagnostic for 21-hydroxylase deficiency, and concentrations between 200 and 800 ng/dL (2–8 ng/mL) strongly suggest the diagnosis, which should be confirmed by performing an ACTH stimulation test.<sup>57</sup>

ACTH stimulation test is performed by obtaining blood samples before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24, 0.25 mg intramuscularly or intravenously). **In most affected women, the response to ACTH stimulation is exaggerated, and the 17OHP level rises above 1,500 ng/dL (Figure 13.5).**<sup>17,55,56,58</sup>

## Genetic Screening

More than 95% of CAH cases are caused by mutations of the CYP21A2 that encodes 21-hydroxylase, a cytochrome P-450 type II enzyme of 495 amino acids.<sup>58</sup> The functioning CYP21A2 gene and its duplicated, but nonfunctional pseudogene (CYP21A1P), are both located on the short arm of chromosome 6 (band 6p21.3).<sup>59</sup> A variety of structural abnormalities ranging from deletions, gene duplications, rearrangements, substitutions, and point mutations to splicing mutations have been described to impact the enzyme activity, which in turn is a determinant of the degree of virilization.<sup>60,61,62,63,64,65,66</sup> Because of the high degree of sequence homology between CYP21A2 and its pseudogene, recombination occurs, and more than two-thirds of CYP21A2 disease-causing mutations are pseudogene-derived variants due to gene conversion, the transfer of deleterious pseudogene mutations to the active CYP21A2 gene.<sup>14</sup> De novo mutations in CYP21A2 that are not carried by either parent and uniparental disomy of chromosome 6 are rare mechanisms accounting for less than 2% of the cases.<sup>65,66</sup> Genotyping should be considered for confirming the diagnosis or elucidating a carrier state. Genotype correlates with disease severity, and the information provided is essential for preconception counseling. Heterozygote carriers exhibit lesser responses to ACTH stimulation that overlap with those of normal subjects,<sup>67</sup> (Figure 13.5).

## Diagnosis of Androgen-Producing Adrenal Tumor

### Hormones

**Testing for elevated androgen levels should begin with a serum total testosterone concentration.** Serum testosterone levels (normal 20–80 ng/dL) are elevated in most (70%), but not all, women with chronic anovulation and hirsutism. **A serum total testosterone concentration greater than 150 ng/dL identifies almost all women with a potential androgen-producing tumor.**<sup>68,69,70</sup> However, because serum testosterone concentrations can vary significantly in women with and without tumors, a tumor still should be suspected and excluded, in women with rapidly progressive hirsutism or signs or symptoms of virilization, even when the serum testosterone concentration is below the threshold value. DHEA-S circulates in higher concentration than any other steroid and derives almost exclusively from the adrenal gland. It is, therefore, a direct measure of adrenal androgen activity. The upper limit of normal in most laboratories is approximately 350 µg/dL, but ranges vary among laboratories. DHEA-S serves primarily as a prehormone, providing substrate for conversion to testosterone and henceforth to dihydrotestosterone in the periphery.

**Although the serum DHEA-S concentration would seem useful for identifying women with adrenal causes of hyperandrogenism, the test lacks both sensitivity and specificity for that purpose.** DHEA-S levels frequently are not grossly elevated in women with nonclassical CAH or Cushing syndrome and often are elevated in women with PCOS.<sup>71</sup> However, unlike NCCAH, the levels of ACTH are not elevated in women with PCOS.<sup>72,73</sup> **Serum DHEA-S concentration can be grossly elevated ( $\geq 700$   $\mu\text{g/dL}$ ) in women with rare androgen-secreting adrenal tumors. However, in almost all such patients, serum testosterone levels also are greatly elevated,<sup>74</sup> via peripheral conversion of high circulating DHEA-S levels or because the tumor also secretes testosterone. A serum DHEA-S concentration may be useful in women who's clinical presentation suggests strongly the possibility of a tumor, but the test otherwise has little or no clinical utility in the evaluation of hirsutism.**

**Adrenal CT (Computed Tomography) imaging is extremely sensitive for detecting the rare androgen-producing adrenal adenoma or carcinoma, and this step should be undertaken when a tumorous source for androgen excess is suspected and when pelvic examination and transvaginal ultrasonography fail to reveal an ovarian tumor.<sup>38</sup> Most androgen-secreting adrenal tumors are malignant.<sup>38,75,76</sup>** Adrenal adenomas typically are smaller (<4 cm in diameter) than carcinomas and have smooth borders and characteristically low unenhanced CT attenuation values; irregular margins, areas of necrosis, hemorrhage, or calcification suggest a carcinoma.<sup>77</sup> When needed, additional information to help define the nature of an adrenal mass lesion can be obtained by magnetic resonance imaging (MRI), by functional nuclear imaging with scintigraphy using a labeled cholesterol analog (<sup>131</sup>I-6-iodomethyl norcholesterol),<sup>78</sup> or by positron emission tomography (PET) scanning.

Findings of bilateral disease require further evaluation to distinguish among the causes, which include metastatic cancer (most commonly from the breast, kidney, or lung), adrenal hyperplasia (caused by long-term stimulation by pituitary or ectopic sources of ACTH and by rare forms of ACTH-independent macro- and micronodular disease),<sup>79,80</sup> infection (tuberculosis and fungal), hemorrhage, pheochromocytoma, and amyloidosis.

Routine adrenal imaging is not recommended and can be misleading, because nonfunctioning adrenal masses (incidentalomas) are common and their incidental detection demands additional, otherwise unnecessary, evaluation.<sup>81</sup> In autopsy studies, the prevalence of incidental adrenal adenomas approaches 10%.<sup>82,83</sup> In two case series of patients having abdominal CT scanning for a variety of indications, the prevalence of adrenal incidentaloma was 3–4%.<sup>84,85</sup>

Incidentally detected adrenal masses require evaluation to determine whether they

are functional; up to 15% secrete excess hormones, such as cortisol, catecholamines, and aldosterone.<sup>86</sup> The requisite tests include a 24-hour urine collection for fractionated metanephrines and catecholamines (pheochromocytoma), blood samples for fractionated metanephrines, testosterone and DHEA-S (adrenal carcinoma), plasma aldosterone and renin activity (primary aldosteronism), and an overnight dexamethasone suppression test (Cushing syndrome).<sup>81</sup> Fine-needle aspiration (FNA) biopsy may be indicated when there is reason to suspect a malignancy outside of the adrenal gland or in patients undergoing staging evaluation of a known cancer.<sup>83,87</sup> Although FNA is a relatively safe procedure, potential complications include adrenal hematoma and abscess, abdominal pain, hematuria, pancreatitis, and pneumothorax.<sup>88,89</sup> Because inadvertent FNA of a pheochromocytoma can precipitate an acute hypertensive crisis, the diagnosis always should be excluded by biochemical tests before FNA is performed.<sup>90</sup> When testing detects no evidence of hormone function and there is no reason to suspect a cancer, expectant management is appropriate; current recommendations include repeated imaging after 6, 12, and 24 months (to detect evidence of progressive growth) and repeated endocrine evaluation annually (to detect autonomous function not identified at baseline) for at least 4 years.<sup>81,91,92</sup>

## Diagnosis of Cushing Syndrome

**When symptoms of androgen excess are accompanied by distinct symptoms and signs of hypercortisolism, screening for Cushing syndrome is indicated.** However, because Cushing syndrome is rare, the risk of false-positive diagnostic tests is high. Widespread screening of overweight and obese women has a negligible yield and results in false-positive tests and needless anxiety.<sup>93</sup> Therefore, screening is best limited to individuals having a relatively high pretest probability of having the disorder. The currently recommended testing strategy is aimed at reducing the number of false-positive tests while using threshold values with high sensitivity to minimize false-negative results and emphasizes the most convenient and least costly tests.<sup>40</sup>

There are three methods of screening for Cushing syndrome that have comparable diagnostic accuracy<sup>94</sup>: the 24-hour urinary free cortisol excretion (measured twice), the late-night (11:00 P.M.–midnight) plasma or salivary cortisol level (measured twice), and the overnight dexamethasone suppression test.

The **24-hour urinary free cortisol excretion** provides a direct and reliable integrated measure of the serum free cortisol concentration.<sup>95,96</sup> Because a reliable 24-hour urine collection can be difficult to obtain, creatinine excretion should be measured in the same specimen to judge compliance with instructions. A systematic review and meta-analysis of diagnostic tests for Cushing syndrome reported a likelihood ratio of

10.6 (95% CI = 5.5–20.5) for an abnormal result and 0.16 (95% CI = 0.08–0.33) for a normal result (reflecting how the odds of the condition increase when the test is abnormal and decrease when the test is normal).<sup>94</sup> **Whereas values for 24-hour urinary free cortisol excretion greater than 3 times the upper normal limit are clearly abnormal, lower abnormal values are equivocal and more likely to represent a false-positive result.**<sup>97</sup> Patients must be instructed to avoid excessive fluid intake and the use of any products containing glucocorticoids during the collection. Because the hypercortisolism of Cushing syndrome can wax and wane, the test should be performed at least twice before judging the result.

The **late-night salivary cortisol level** is based on the fact that whereas serum cortisol levels normally peak at 7:00–9:00 A.M. and fall throughout the day to very low levels late at night, the normal circadian rhythm is lost in patients with Cushing syndrome.<sup>98,99</sup> Moreover, because free cortisol in the blood is in equilibrium with cortisol in saliva,<sup>100</sup> the late-night salivary cortisol (11:00 P.M.–midnight) level can be used to establish a diagnosis of Cushing syndrome.<sup>101,102,103,104,105</sup> Saliva is easy to collect by the patient at home, by passive drooling or after chewing on a cotton pledget for 1–2 minutes. Specimens are stable at room or refrigerator temperature for several weeks.<sup>40</sup> In contrast to salivary sex steroid hormone assays, salivary cortisol assays yield reliable results. Results are interpreted by comparison to established normal ranges, which vary among studies, probably due to differences in assays. The meta-analysis of diagnostic tests for Cushing syndrome reported a likelihood ratio of 9.5 (95% CI = 1.7–54.1) for an abnormal result and 0.09 (95% CI = 0.08–0.33) for a normal result.<sup>94</sup> Again, because the hypercortisolism of Cushing syndrome can fluctuate, the late-night cortisol level should be performed at least twice. Patients should be advised to avoid using licorice, chewing tobacco, and smoking, which may falsely elevate salivary cortisol levels. The method also probably is not the best choice for shift workers and those with bedtimes well after midnight.

The **overnight dexamethasone suppression test** is based on the concept that dexamethasone (a potent synthetic glucocorticoid) should suppress ACTH secretion by the normal pituitary gland, thereby also suppressing cortisol secretion. The test is performed by administering 1.0 mg of dexamethasone by mouth, between 11:00 P.M. and midnight and measuring the serum cortisol at 8:00 A.M. the next morning; values less than 1.8 µg/dL are normal.<sup>40</sup> The aforementioned systematic review and meta-analysis reported a likelihood ratio of 16.4 (95% CI = 9.3–28.8) for an abnormal result and 0.06 (95% CI = 0.03–0.14) for a normal result.<sup>94</sup> A 2-day low-dose dexamethasone suppression test also can be used (0.5 mg dexamethasone every 6 hours for a total of 8 doses beginning at 9:00 A.M. on day 1, with measurement of serum cortisol 6 hours after the last dose), applying the same criteria for normal suppression (<1.8 µg/dL).

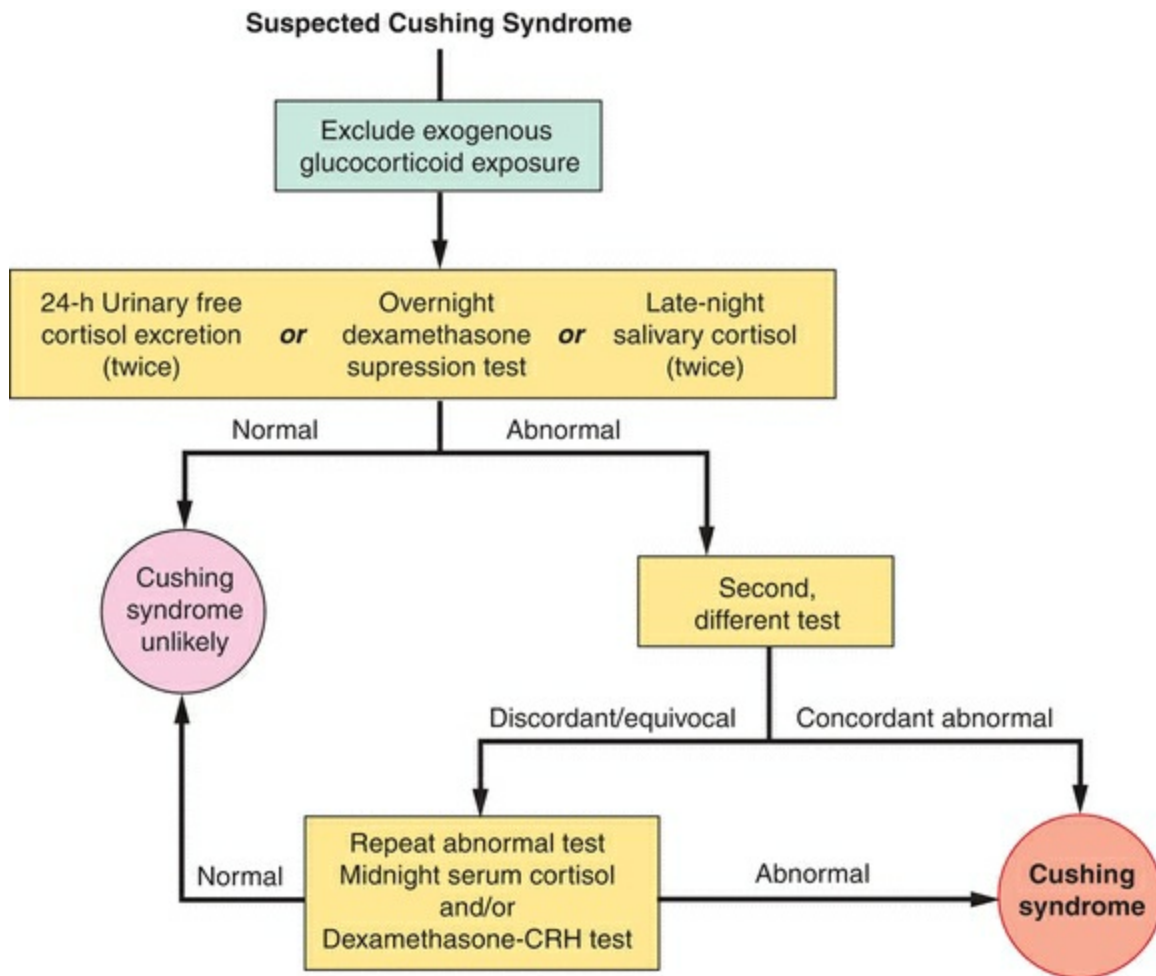

However, the 2-day test has lower diagnostic accuracy than the overnight test, with a likelihood ratio of 7.3 (95% CI = 3.6–15.2) for an abnormal result and 0.18 (95% CI = 0.06–0.52) for a normal result.<sup>94</sup> **Given its simplicity and ability to discriminate, the overnight dexamethasone suppression test is the best first test to perform when Cushing syndrome is suspected in patients with hirsutism.** Because estrogens increase the cortisol-binding globulin concentration and serum assays measure total cortisol, false-positive overnight dexamethasone test results are common in women using oral contraceptives.<sup>106</sup> Therefore, whenever possible, estrogen-containing drugs should be discontinued for 6 weeks before testing or retesting.<sup>107</sup>

**If the first screening test is normal, Cushing syndrome is excluded and no further testing is necessary, unless clinical suspicion (based on clinical presentation) is strong; re-evaluation in 6 months or sooner is indicated if symptoms or signs of Cushing syndrome progress. If the first test yields an abnormal result, a second, different, test should be performed. The diagnosis of Cushing syndrome is confirmed when two different tests are unequivocally abnormal. Patients with discordant or equivocal test results require further evaluation.**<sup>40</sup>

When necessary, additional evaluation should begin by repeating the abnormal test. Expanded evaluation also should include a midnight serum cortisol concentration and/or the dexamethasone-CRH test.

The **midnight serum cortisol concentration** has the same rationale as the late-night salivary cortisol level. Although the test is difficult to perform, it can be useful when 24-hour urinary free cortisol excretion or the overnight dexamethasone suppression test is normal but clinical suspicion for Cushing syndrome is high. A sleeping midnight serum cortisol greater than 1.8  $\mu\text{g/dL}$  or an awake midnight value greater than 7.5  $\mu\text{g/dL}$  increases the probability of Cushing syndrome.<sup>108,109</sup> Conversely, when the clinical suspicion for Cushing syndrome is low, as in simple obesity, but 24-hour urinary free cortisol excretion or the overnight dexamethasone suppression test is mildly abnormal, a sleeping midnight serum cortisol less than 1.8  $\mu\text{g/dL}$  or awake value less than 7.5  $\mu\text{g/dL}$  effectively excludes Cushing syndrome.<sup>109</sup> The test has similar utility in patients receiving anticonvulsant medications, which can accelerate metabolism of dexamethasone, causing a false-positive overnight dexamethasone suppression test<sup>110</sup> (**Figure 13.6**).

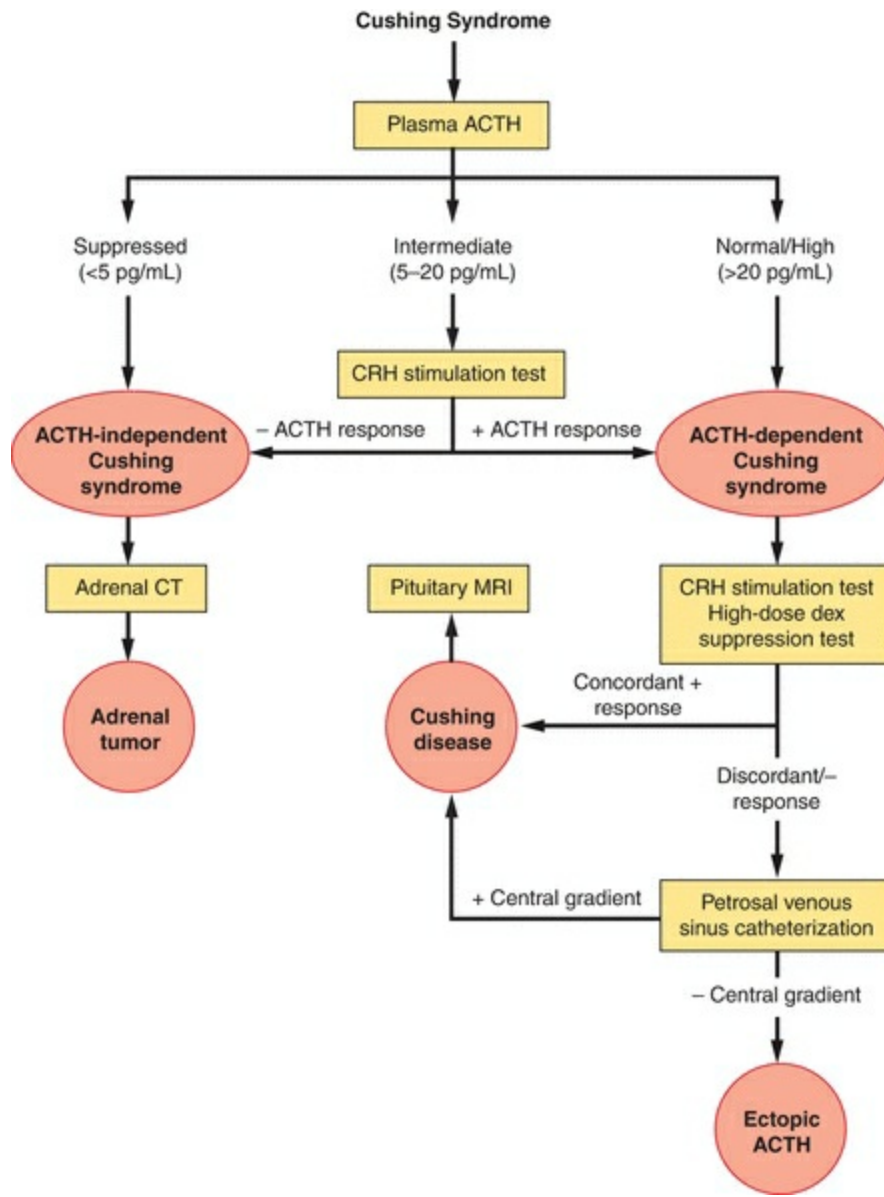

**FIGURE 13.6**

The **dexamethasone-CRH test** helps to differentiate patients with Cushing syndrome from those whose hypercortisolism relates to physical or psychological stress or depression (pseudo-Cushing syndrome).<sup>97</sup> The test is performed by administering dexamethasone 0.5 mg every 6 hours over 2 days for a total of 8 doses, administering CRH (1 µg/kg, intravenously) 2 hours after the last dose of dexamethasone, and measuring the serum cortisol 15 minutes later; in patients with pseudo-Cushing syndrome, values generally are less than 1.4 µg/dL.

## Establishing Cause of Cortisol Excess (Figure 13.7)

**FIGURE 13.7**

Once the diagnosis of Cushing syndrome is made, its cause must be determined. The tests used for diagnosis of Cushing syndrome cannot distinguish between pituitary, adrenal, and other causes of the disorder, because normal pituitary corticotrophs behave and respond in much the same way as a corticotroph adenoma. **The evaluation required to establish the cause of Cushing syndrome can be challenging and complicated and is best conducted by an endocrinologist having the necessary training and experience.**

The first step in the process is to measure the **plasma ACTH concentration**, to determine whether the hypercortisolism is ACTH dependent (due to an ACTH-secreting tumor) or ACTH independent (due to a primary adrenal source). The best ACTH test is

a two-site immunoradiometric assay.<sup>111</sup> Although plasma ACTH levels normally exhibit a circadian rhythm (20–80 pg/mL at 8:00 A.M., falling to <20 pg/mL at 4:00 P.M. and to <10 pg/mL within an hour after the usual time of falling asleep), ACTH can be measured at any time in patients with hypercortisolism, because the normal circadian rhythm is lost. At least two measurements should be obtained. Values less than 5 pg/mL indicate ACTH-independent disease,<sup>112</sup> and values greater than 20 pg/mL indicate ACTH-dependent disease. Values in between are less easily interpreted but usually are associated with ACTH-dependent disease; in such unusual cases, a CRH stimulation test can help steer evaluation in the right direction.

The **CRH stimulation test** (described below) is based on the fact that plasma ACTH and serum cortisol concentrations increase promptly after CRH stimulation in most patients with an ACTH-secreting pituitary adenoma, but not in those with a primary adrenal source, because pituitary ACTH secretion is suppressed.<sup>113,114,115,116,117</sup> An ACTH response to CRH stimulation thus indicates ACTH-dependent Cushing syndrome, and the lack of response indicates ACTH-independent disease.<sup>80,118</sup>

## **ACTH-Independent Cushing Syndrome**

For patients with ACTH-independent Cushing syndrome, the workup follows as described earlier under section “Diagnosis for androgen secreting adrenal tumors”. A **thin-section computed tomography (CT)** imaging of the adrenal glands should be considered as first line approach, seeking to identify an adrenal mass. If imaging reveals a unilateral adrenal adenoma, no further testing is necessary, and patient should be referred to an endocrine surgeon for definitive management. Findings suggesting a possible carcinoma require additional evaluation to stage the suspected cancer. Whereas most benign cortisol-secreting adenomas produce relatively little androgens, most androgen-secreting adrenal tumors are malignant.<sup>75,76</sup> Findings of bilateral disease also require further evaluation to determine whether bilateral masses are both functional or if one is a nonfunctional incidentaloma or to distinguish among the various causes of bilateral adrenal hyperplasia, which include long-term adrenal stimulation by pituitary or ectopic sources of ACTH and rare forms of ACTH-independent macro- and micronodular disease.<sup>79,80</sup>

## **ACTH-Dependent Cushing Syndrome**

For patients with ACTH-dependent Cushing syndrome, evaluation is aimed at identifying the source of ACTH secretion. By far, most such patients will have a pituitary corticotroph adenoma (Cushing disease). Ectopic ACTH-secreting or CRH-secreting tumors are rare.

The **CRH stimulation test** helps to distinguish pituitary from ectopic sources of

ACTH, for the same reason that it helps distinguish ACTH-dependent from ACTH-independent Cushing syndrome in women with equivocal plasma ACTH concentrations. ACTH and cortisol levels increase promptly after CRH stimulation in most patients with an ACTH-secreting pituitary adenoma, but not in those with ectopic sources of ACTH because pituitary ACTH secretion is suppressed.<sup>113,114,115,116,117</sup> After a period of fasting for 4 hours or more, blood samples are obtained 15 minutes and immediately before administering an intravenous bolus of synthetic ovine or human CRH (1 µg/kg or 100 µg total dose) and every 15 minutes for 60 minutes thereafter; samples are assayed for both ACTH and cortisol.<sup>114,115,116,117,118,119</sup> There are no established uniform criteria for interpretation of the CRH stimulation test in patients with Cushing syndrome. In various studies, a 35–50% increase in ACTH and a 20–50% increase in cortisol over basal concentrations excluded all patients with ectopic ACTH secretion and correctly identified over 90% of patients with Cushing disease.<sup>113,114</sup> In approximately 8–10% of patients with Cushing disease, ACTH levels do not rise appreciably in response to CRH.<sup>120</sup>

The **high-dose dexamethasone suppression test** also helps to distinguish pituitary from ectopic sources of ACTH. The test is based on the fact that ACTH-secreting pituitary adenomas are only relatively resistant to negative feedback by glucocorticoids; low doses of dexamethasone do not suppress their ACTH secretion, but high doses typically do.<sup>121</sup> In contrast, ectopic sources of ACTH are completely resistant to glucocorticoid suppression because they are not controlled by feedback inhibitory mechanisms.<sup>122</sup> The overnight high-dose dexamethasone suppression test is easier to perform than the standard 2-day test (2 mg every 6 hours for a total of 8 doses) and has comparable sensitivity and specificity.<sup>123</sup> The test is performed by administering 8 mg of dexamethasone between 11:00 P.M. and midnight and measuring the serum cortisol level at 8:00 A.M. the next morning; the cortisol concentration is less than 5 mg/dL in most, but not all, patients with an ACTH-secreting pituitary adenoma (Cushing disease).<sup>124</sup> Alternatively, the morning serum cortisol on the days before and after dexamethasone treatment can be compared, with 50% or greater suppression indicating Cushing disease.<sup>123,125,126</sup>

Combined, results obtained with the CRH stimulation test and the high-dose dexamethasone suppression test point to the source of ACTH in most patients with ACTH-dependent Cushing syndrome. Those whose cortisol levels are suppressed by high-dose dexamethasone (positive test) and stimulated by CRH (positive test) almost certainly have a pituitary ACTH-secreting adenoma.<sup>127,128</sup> Patients with discordant or negative test results are still more likely to have Cushing disease than ectopic ACTH secretion but require additional evaluation to establish the source of ACTH.

**Petrosal venous sinus catheterization** is the most direct way to demonstrate the

presence or absence of excessive pituitary ACTH secretion, by comparing the ACTH concentrations in the petrosal venous sinuses (draining the pituitary via the cavernous sinus) to that in the peripheral blood.<sup>129,130,131</sup> Blood samples are obtained from the petrosal sinuses and from a peripheral vein before and within 10 minutes after administration of CRH. A petrosal venous ACTH concentration twofold or greater than the peripheral venous concentration, or threefold or greater after CRH stimulation, distinguishes pituitary from ectopic sources of ACTH, with rare exceptions.<sup>120,132,133,134</sup> Some have reported that an ACTH concentration gradient between the two petrosal sinuses of 1.4 or greater can predict the location of the pituitary adenoma,<sup>120</sup> but others have found the measure unreliable.<sup>135,136</sup> Petrosal venous sinus catheterization also has significant potential risks, including cerebrovascular accident, cranial nerve palsies, pulmonary embolus, and deep vein thromboses and hematomas. Therefore, the procedure is difficult to justify solely for the purpose of localizing a tumor.

**Pituitary MRI** (unenhanced and gadolinium-enhanced) is more sensitive than CT for detecting corticotroph adenomas but still identifies only about half of such tumors.<sup>137</sup> The imaging protocol (field of view and repetition time/echo time value) should be optimized for detection of corticotroph adenomas.<sup>138</sup> When results obtained with CRH stimulation and high-dose dexamethasone suppression support the diagnosis of Cushing disease and imaging demonstrates an obvious tumor (>6 mm), no further evaluation is required. When endocrine test results are discordant or negative, petrosal venous sinus catheterization generally is required to isolate the source of ACTH, although preliminary pituitary imaging to exclude an obvious tumor still is prudent, in order to avoid unnecessary petrosal sinus sampling and its attendant risks.

Ectopic ACTH-secreting tumors can be difficult to localize. Chest CT or MRI is the logical first step because that is where most such tumors (e.g., bronchial carcinoids) are found<sup>139</sup> (see **Figure 13.7**).

## Key Points: Evaluation of Adrenal Disorders

- Adrenal sources of androgen excess should be considered in women presenting with features of hyperandrogenism.
- Nonclassical CAH should be suspected, and excluded, in patients with an early onset of hirsutism (pre- or perimenarcheal, including those with a premature adrenarche), in women with a family history of the disorder, and those belonging to high-risk ethnic groups (Hispanic, Mediterranean, Slavic, and Ashkenazi Jewish heritage). Reproductive endocrinologists should be familiar with the hormones of steroidogenic pathway to be able to interpret data (**Table 13.3**), as

well as be familiar with the rationale and methodology of some tests ([Table 13.4](#)) that are often utilized in the evaluation of suspected adrenal disorders.

- Androgen-secreting adrenal tumor should be considered in the differential diagnosis if symptoms of androgen excess are of short duration, are severe, and are rapidly progressive, serum total testosterone level is greater than 150 ng/mL, and the ovaries appear unremarkable on imaging. Elevated serum DHEA-S levels identify adrenals as source of androgen excess.
- Cushing syndrome should be suspected, and excluded, in women with symptoms and signs of hypercortisolism ([Table 13.4](#)).

## **TABLE 13.3      Circulating      Steroid      Hormones, Interpretation and Considerations**

	Intervention	Testing	Normal Response	Interpretation
<b>Dexamethasone (Dex) suppression test (DST)</b>				
• Overnight DST	• Oral 1 mg Dex between 11 PM and midnight	• Plasma/serum cortisol (drawn between 8 and 9 A.M.)	Normal <1.8 µg/dL	Suppression of cortisol levels rules out Cushing syndrome or adrenal tumor as a cause for cortisol excess
• 2-d DST	• Oral Dex 500 µg every 6 h starting at 9 A.M. × 8 doses for a total dose of 2 mg	• Plasma/serum cortisol drawn 6 h after last dose	Normal <1.8 µg/dL	
<b>ACTH stimulation test</b>	250 µg of synthetic ACTH (Cortrosyn) given intramuscularly or intravenously	<ul style="list-style-type: none"> <li>• 0- and 60-min blood sampling for assessment of 17OP</li> <li>• Testing of other steroidogenic hormones can offer additional information in certain circumstances, such as DHEA-S, 17OHPreg, 11-deoxycortisol, and cortisol</li> </ul>	<ul style="list-style-type: none"> <li>• Patients with classic and NCCAH will have 17OHP values &gt;1000 ng/dL</li> <li>• &lt;1000 ng/dL excludes CAH</li> </ul>	<ul style="list-style-type: none"> <li>• Screening test for CAH</li> <li>• Ratio of 17OHPreg to 17OHP of &gt;6 on ACTH stimulation is suggestive of 3βHSD deficiency</li> <li>• Also used to screen for primary adrenal insufficiency when lower ACTH dose (1 µg) is suggested</li> </ul>

**TABLE 13.4 Commonly Utilized Provoked Tests in the Evaluation of Adrenal Disorders**

<b>Steroid Hormones</b>	<b>Interpretation</b>	<b>Considerations</b>
<b>17-Hydroxyprogesterone</b>	Elevated in CAH due to 21-hydroxylase and 11-hydroxylase deficiencies Baseline normal <2 ng/mL Baseline >10 ng/mL is diagnostic of CAH	May be elevated in periovulatory period Best assessed in early follicular phase of menstrual cycle Measure in morning
<b>17-Hydroxypregnenolone</b>	Elevated in CAH due to 3 $\beta$ -hydroxysteroid dehydrogenase deficiency	May be elevated in periovulatory period. Best assessed in the early follicular phase of menstrual cycle
<b>Total testosterone</b>	Level >150 ng/mL should raise concerns for androgen-secreting tumor	May be elevated in periovulatory period. Best assessed in the early follicular phase of menstrual cycle
<b>DHEA-S</b>	Almost entirely adrenal source	May be elevated in periovulatory period. Best assessed in the early follicular phase of menstrual cycle
<b>ACTH</b>	Elevated in all types of CAH Elevated in Cushing disease (>20 pg/mL) Suppressed in Cushing syndrome (<5 pg/mL)	Suppressed with iatrogenic glucocorticoid use Preferably drawn between 8 and 9 A.M.
<b>Cortisol</b>	Elevated in Cushing syndrome and disease May be normal in nonclassical CAH	Midnight plasma/serum cortisol >7.5 $\mu$ g/dL has 95% diagnostic accuracy for Cushing syndrome (normally cortisol levels are lowest at midnight and peak in between 7 and 9 A.M.) Midnight salivary cortisol thresholds vary by assay Integrated 24-h urine free cortisol (UFC)
<b>11-Deoxycortisol</b>	May be elevated in CAH due to 11- $\beta$ hydroxylase deficiency	Hypertension is often encountered in cases of CAH due to 11- $\beta$ hydroxylase deficiency

# MANAGEMENT OF ADRENAL DISORDERS

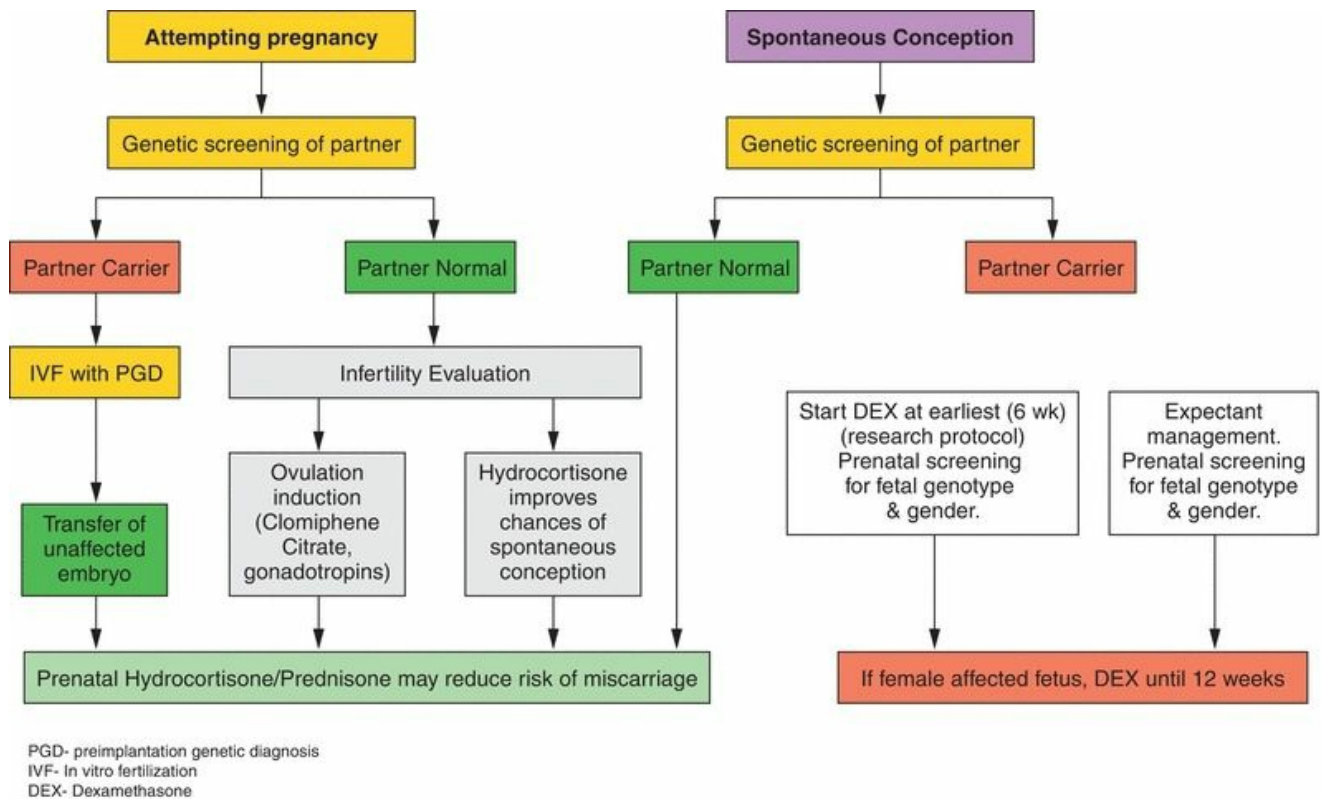

---

As mentioned at the start, our aim for including this chapter is not for gynecologists to practice endocrinology. Rather, our goal is to familiarize obstetricians, gynecologists, and reproductive endocrinologists with certain disorders of the adrenal gland where the presentation may mimic common gynecologic conditions. Glucocorticoids are used to suppress endogenous ACTH secretion in the long-term management of women with classical CAH, as well as for management of hirsutism in women with NCCAH, although with limited benefit. **While glucocorticoids suppress serum adrenal androgen levels effectively in women with NCCAH, they are less effective than oral contraceptives or antiandrogens for the treatment of hirsutism.**<sup>36,37</sup> Consequently, glucocorticoid treatment has even less to offer women with other causes for hirsutism.

# Unique Considerations

Girls and women with nonclassical CAH are likely to present to gynecologists for evaluation of menstrual dysfunction and symptoms of androgen excess, and providers should be alert to the possibility of nonclassical CAH as a differential diagnosis for this presentation. Particular vigilance is required of reproductive endocrinologists catering to fertility needs of women, as this differential diagnosis must be entertained and ruled out for patients presenting with features of chronic hyperandrogenism and ovulatory dysfunction. Given that nonclassical CAH can mimic PCOS (discussed in [Chapter 11](#)), a timely diagnosis and appropriate partner screening can mitigate the risk of conceiving a baby affected with classical CAH.

## Fertility and Pregnancy in Women at Risk for Conceiving CAH-Affected Child ([Figure 13.8](#))

**FIGURE 13.8**

### Infertility

Ovulatory disturbances are common in nonclassic forms of CAH, and fertility treatment,

either ovulation induction or assisted reproductive technology, may be required to achieve pregnancy, although spontaneous conceptions are well described.<sup>140,141,142,143,144</sup> Spontaneous ovulation is likely to resume with use of corticosteroids. Steroid-induced suppression of ACTH secretion with consequent suppression of the HPA axis and lowering of androgens and progesterone levels and thereby improved endometrial receptivity is an additional mechanism that could explain improved fertility rates described with the use of steroids in women with CAH.<sup>18,144,145</sup>

It is important to identify women at risk for conceiving a child with the more severe classical form of the disorder; the risk among women with hyperandrogenism is limited to those who carry one classic mutation and a variant allele associated with mild enzyme deficiency (compound heterozygotes), also having a male partner who carries an occult classic mutation. When both patient and partner are identified as genetic carriers of one of the common mutant genes or for women and couples with a prior CAH-affected child, judicious consideration of assisted reproductive technologies, such as in vitro fertilization (IVF) with preimplantation genetic diagnosis (PGD, also called preimplantation genetic testing for monogenic disorders, PGT-M), can virtually eliminate the risk of transmission of mutant genes to the next generation, and thereby eliminating the risk of a child affected by CAH.<sup>146,147</sup>

## **Fetal Risks and Risk Reduction**

If risk elimination through the use of IVF with PGD is not a feasible option, maternal supplementation with glucocorticoids that can reach the fetal circulation by crossing the placenta (such as dexamethasone) has been utilized as a strategy to reduce the risk of ambiguous genitalia in a CAH-affected female fetus.<sup>18,60,148,149,150</sup> The premise of this approach is based on assumptions that (1) the conceptus is homozygous for the mutant gene (CYP21 being the commonest) and (2) is a genetic female. Among women diagnosed with nonclassic CAH, the probability of conceiving an affected child is much higher than in the general population. Assuming a population prevalence of heterozygosity for severe CYP21A2 mutations at 1:60 and assuming that almost ½ of the women with the nonclassic CAH are actually compound heterozygotes (carrying a combination of one severe and one mild), the likelihood of women with nonclassic CAH for having a CAH-affected child is calculated at 1:480, which is dramatically higher than the risk in the general population (1:12,000–1:23,000 or even higher).<sup>13,142</sup> In an affected fetus, the specific steroidogenic enzyme deficiency (21-hydroxylase being the commonest) causes a reduction in fetal cortisol production, which in turn results in an up-regulation in fetal ACTH production through suppression of negative feedback (see **Figure 13.2**). The resulting high levels of fetal ACTH strive to stimulate the steroidogenic pathway in attempts to achieve normal cortisol levels; this perpetual stimulation of the steroidogenic pathway results in shunting of steroid precursors

proximal to the enzymatic block toward androgen production (**Figure 13.3**), resulting in hyperandrogenemia within the fetal compartment. The role of androgens in the development of normal and abnormal sexual development is discussed in **Chapter 8**. Given that it is cortisol deficiency that serves as the prime mechanism for HPA axis overdrive in pregnancies affected by CAH, by increasing fetal cortisol levels through maternal supplementation with a glucocorticoid that can cross the placenta without being metabolized (such as dexamethasone-DEX), down-regulation of fetal ACTH and thereby normalization of fetal androgen levels are achievable. Proponents of this approach recommend utilization of this approach from earliest knowledge of pregnancy (by 6 weeks at the latest) until the fetal gender can be determined using prenatal genetic screening (discussed in detail in **Chapter 31**).<sup>151,152,153,154,155,156</sup> Maternal supplementation can be safely discontinued for male fetuses as high androgen levels confer no risk of deformity of male external genitalia. If the affected fetus is genetically female, maternal supplementation within the first 8–12 weeks of gestation, when the external genitalia are differentiating, can reduce the risk as well as magnitude of virilization and thereby, future need for reconstructive surgery. Using a similar rationale, maternal use of corticosteroids through the course of pregnancy is described as a strategy to prevent fetal virilization. Available data on maternal glucocorticoid use to prevent fetal virilization thus far are entirely observational and comparative, and in recent years, the practice of maternal supplementation with corticosteroids has been placed in question, particularly given the lack of long-term safety data. Consensus by a number of professional societies including the Endocrine Society is that maternal supplementation with corticosteroids for fetal benefit be considered experimental, studies be conducted under purview of institutional review boards, and long-term surveillance of in utero steroid-treated children be prioritized.<sup>18</sup> Prenatal utilization of corticosteroids for fetal benefit in cases of CAH represents an off-label use of this class of drugs. Women with nonclassical CAH are deemed at a higher risk for spontaneous miscarriage compared to unaffected population, and this risk may be lower in women being treated with glucocorticoids in early pregnancy.<sup>18</sup> Glucocorticoid therapy may shorten time to pregnancy. Hydrocortisone and prednisone are preferred glucocorticoids for this indication as these get metabolized by placental 11 $\beta$ -hydroxysteroid dehydrogenase type 2, with minimal fetal exposure.

## Key Points

- Although management of adrenal endocrine disorders is deemed beyond the scope of practice of gynecologists, gynecologists must familiarize themselves with commoner adrenal disorders that may mimic PCOS, so as to ensure that patients

are appropriately referred for definitive care.

- Gynecologists should be familiar with screening tests for evaluation of common adrenal disorders such as CAH and Cushing syndrome (Tables 13.3 and 13.4) and be familiar with symptoms and signs that may suggest an underlying tumor as a mechanism for androgen excess symptoms.
- Rapidly progressive signs and symptoms of hyperandrogenism should alert clinician to possibility of an androgen-secreting tumor. If the ovaries appear normal on transvaginal ultrasound, adrenal glands as a source of androgen excess must be considered.
- Nonclassic congenital adrenal hyperplasia should be ruled out in young women manifesting features of androgen excess and menstrual irregularities.
- Late-onset CAH due to 11 $\beta$ -hydroxylase deficiency (second most common type of CAH) and Cushing syndrome should be considered when evaluating women with features of chronic hyperandrogenism and menstrual irregularities.
- Preconception genetic counseling should be made available to all girls/women as well as men who are diagnosed with CAH and prenatal genetic diagnosis used where feasible.
- In women with known NCCAH, prenatal use of corticosteroids (hydrocortisone/prednisone) in the first trimester may offer some benefit against risk of spontaneous miscarriage.
- Routine maternal treatment with dexamethasone to minimize risk of virilization in an affected female fetus is currently discouraged, except under research settings. If considered, treatment should be initiated at the earliest (around 6 weeks of gestation) and then continued until at least the completion of developmental stages of the external genitalia (around 12 weeks). Long-term follow-up of exposed children is recommended.

# Menstruation-Related Disorders

Since antiquity, the temporal relationship between menses and the lunar phases has inspired names for menstruation, such as the “period.” The regularity of menses was easily appreciated by the ancients, even if they had no understanding of its cause or purpose. Ancient physicians viewed menstruation as a process of detoxification, and throughout history, myths and superstitions have perpetuated negative attitudes toward menses.<sup>1</sup>

The health care profession has an obligation to provide and to promote education on menstruation and related subjects. Clinicians must have a thorough understanding of reproductive physiology before they can impart that knowledge to their patients and must be sensitive to the need to present the information in a positive and culturally appropriate context that fosters healthy attitudes toward sexual and reproductive functions. An educated understanding of normal reproductive processes is a powerful tool for addressing the symptoms and disorders of menstruation.

Some menstrual disorders, such as dysmenorrhea, can be explained in a physiologic framework that both educates and provides the foundation for appropriate treatment. Unfortunately, others, such as the premenstrual syndrome (PMS), still remain relatively poorly understood. **This chapter considers several medical problems that are temporally linked with menstruation** and their pathophysiology when that is known.

# HISTORICAL VIEWS OF MENSTRUATION AND MENSTRUATING WOMEN

---

Recorded history includes a wide variety of myths regarding menstruation and menstruating women. In ancient times, menstruating women commonly were thought possessed by an evil spirit. Aristotle (384–322 B.C.), the Greek philosopher, student of Plato, and teacher of Alexander the Great, said that a menstruous woman could dull a mirror with a look and that the next person to peer into it would be bewitched. Pliny, born in 23 A.D., consulted approximately 2,000 available books by physicians while writing his treatise, *Historia Naturalis*, a resource used throughout the Dark Ages; more than a hundred copies, all 37 volumes, still exist. Pliny wrote extensively on menstruation, including the following<sup>2</sup>:

Contact with it turns new wine sour, crops touched by it become barren, grafts die, seeds in gardens are dried up, the fruit of trees falls off, the edge of steel and the gleam of ivory are dulled, hives of bees die, even bronze and iron are at once seized by rust, and a horrible smell fills the air; to taste it drives dogs mad and infects their bites with an incurable poison. If a woman strips herself naked while she is menstruating and walks around a field of wheat, the caterpillars, worms, beetles, and other vermin will fall off from the ears of corn. All plants will turn of a yellow complexion on the approach of a woman who has the menstrual discharge upon her. Bees will forsake their hives at her touch, for they have a special aversion to a thief and a menstruous woman, and a glance of her eyes suffices to kill a swarm of bees.

Throughout early history, the fear of blood spawned many ancient taboos. Almost universally, menstruating women were isolated and prevented from handling food. Most primitive peoples regarded women as unclean during menstruation and subjected them to segregation and special rituals. It is therefore not surprising that, even with growing sophistication, negative attitudes toward menstruation persisted into modern times.

In 19th and early 20th century Europe, menstruation was commonly associated with antisocial behavior.<sup>3</sup> In 1845, a domestic servant who murdered one of her employer's children was acquitted on the grounds of insanity due to obstructed menstruation. In 1851, a woman was acquitted of murdering her baby niece due to insanity arising from disordered menstruation. As recently as 1984, Dalton argued that the premenstrual phase of the cycle was associated with an increased incidence of crime, jailing for alcoholism, poor academic performance, sickness in industry, and hospitalization for accidents.<sup>4</sup> However, careful studies have found no significant variations in cognitive or

motor functions across the menstrual cycle,<sup>5,6,7,8</sup> suggesting that, to a large extent, behaviors merely reflect societal expectations. Unfortunately, even today, expectations and attitudes toward menstruation are influenced heavily by old traditions and social and cultural beliefs.

# THE PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

The simplest definition of the premenstrual syndrome (PMS) is a common sense one: cyclic physical and behavioral symptoms that appear in the days preceding menses, are bothersome enough to interfere with work or lifestyle, and are followed by a symptom-free interval (Figure 14.1). Premenstrual dysphoric disorder (PMDD) describes a severe form of PMS that some consider a distinct clinical entity, characterized by prominent symptoms of irritability, anger, internal tension, dysphoria, and mood lability.<sup>9</sup>

**FIGURE 14.1**

Historically, the phrase “premenstrual syndrome” was used first by Greene and Dalton in their report of 84 cases in 1953.<sup>10</sup> However, R.T. Frank, then the chief of obstetrics and gynecology at Mt. Sinai Hospital in New York City, generally is credited with having first described PMS, in 1931<sup>11</sup>:

The group of women to whom I refer especially complains of a feeling of

indescribable tension from 10 to 7 days preceding menstruation, which in most instances continues until the time that the menstrual flow occurs. The patients complain of unrest, irritability, like jumping out of their skin, and a desire to find relief by foolish and ill-considered actions. Their personal suffering is intense and manifests itself in many reckless and sometimes reprehensible actions. Not only do they realize their own suffering, but they feel conscience-stricken toward their husbands and families, knowing well that they are unbearable in their attitude and reactions. Within an hour or two after the onset of the menstrual flow, complete relief from both physical and mental tension occurs.

An extraordinary array of different physical and behavioral symptoms has been attributed to PMS. The most common physical symptoms include abdominal bloating, extreme fatigue, breast tenderness, and headaches, all occurring in 50–90% of cases. The most prevalent behavioral symptoms of PMS are mood lability, irritability, depressed mood, increased appetite, forgetfulness, and difficulty with concentration, occurring in 50–80% of cases. Other less common symptoms include anxiety or tension, easy crying, thirst, acne, gastrointestinal upset, hot flushes, palpitations, dizziness, and lower extremity edema. Symptoms of PMS typically arise during the last 7–10 days of the menstrual cycle.<sup>12</sup>

Premenstrual symptoms are very common, reported by up to 75% of women with regular menstrual cycles. However, because women naturally relate symptoms and behaviors to menstruation retrospectively, estimates of their frequency are subjective and inherently biased.<sup>13</sup> Moreover, both men and women have been conditioned to expect symptoms during the premenstrual phase of the cycle, such as fluid retention, pain, and emotional lability, and not surprisingly, they report such symptoms when asked in retrospect.<sup>14</sup> The power of conditioned response was illustrated in a classic study by Ruble, in which 44 undergraduates at Princeton University were deliberately deceived about the phase of their menstrual cycle.<sup>15</sup> A mock electroencephalogram was performed, complete with electrodes attached to the head, after being described as a new technique that could predict the onset of menstruation. Subjects were informed that they were premenstrual (expected menses in 1–2 days) or intermenstrual (expected menses in 7–10 days), and only those led to believe they were premenstrual reported increased symptoms of pain, water retention, and changes in eating habits—a self-fulfilling prophecy. Subjects tend to comply with what they believe is the investigator's hypothesis, and in studies of PMS, no differences in symptoms can be demonstrated when the purpose of the study is disguised or expectations are manipulated.<sup>16,17,18</sup> Carefully designed prospective studies have revealed that some women who have no demonstrable cyclic premenstrual symptoms or changes in cognitive function

nonetheless believe that they do,<sup>13</sup> even including some diagnosed with PMDD.<sup>5,19,20</sup>  
**When strictly defined based on prospective symptom diaries, clinically significant PMS occurs in 20–30% and PMDD affects 2–8% of women.**<sup>9,21,22,23,24</sup>

# Diagnostic Criteria

The diagnosis of both PMS and PMDD depends on the presence of typical symptoms, their timing, severity, and the exclusion of other diagnoses. **Both diagnoses require a prospective symptom diary documenting specific cyclic symptoms associated with the luteal and menstrual phases of the cycle and are severe enough to adversely impact social functioning and quality of life of the affected women.**<sup>25</sup> The specific collection of symptoms in a given individual is much less important than the cyclic nature of the symptom complex and its temporal relationship with menses. When symptoms are charted accurately, as much as 40% of women presenting with presumed PMS do not exhibit the distinctly cyclic pattern required for diagnosis and actually have an underlying mood or anxiety disorder.<sup>26</sup>

The most commonly used criteria for diagnosis of PMS are those proposed by investigators at the University of California at San Diego (UCSD).<sup>12,27</sup> The diagnostic criteria were based on prospective symptom diaries of women in whom underlying medical conditions and psychiatric disorders were carefully excluded and on an analysis of cycle phase defined by daily urinary steroid metabolites.<sup>27</sup> A symptom survey instrument known as the Calendar of Premenstrual Experiences (COPE) was constructed, including the 10 most commonly reported physical symptoms and the 12 most commonly reported behavioral symptoms, with each ranked on a 4-point Likert scale of severity across the menstrual cycle (**Figure 14.2**).<sup>12,28</sup>

Calendar of Premenstrual Experiences<sup>12, 28</sup>

Name \_\_\_\_\_ Month/Year \_\_\_\_\_ Age \_\_\_\_\_

Begin your calendar on the first day of your menstrual cycle. Enter the date below the cycle day. Day 1 is your first day of bleeding. Shade the box above the cycle day if you have bleeding.  Enter an X for spotting .

If more than one symptom is listed in a category (i.e., nausea, diarrhea, constipation), you do not need to experience all of these. Rate the most disturbing of the symptoms on the 0–3 scale below.

Weight: Weigh yourself before breakfast. Record your weight in the box below date. Symptoms: Indicate the severity of your symptoms by using the 1–3 scale below. Rate each symptom at about the same time each evening.

- 0 = None (symptoms not present)                    2 = Moderate (interferes with normal activities)  
 1 = Mild (noticeable but not troublesome)        3 = Severe (intolerable, unable to perform normal activities)

Other Symptoms: If there are other symptoms you experience, list and indicate severity.  
 Medications: List any medications taken and enter an X on the corresponding day(s).

The COPE survey instrument yields reliably reproducible scores that correlate well with those derived from administering the Profile of Mood States<sup>29</sup> and the Beck Depression Inventory.<sup>30</sup> Although a number of other scales can be used for diagnosis of PMS (Table 14.1), the COPE survey remains among the most popular, primarily because analysis of data derived from its use has revealed that virtually all women with PMS can be identified using a simplified list of six behavioral symptoms and four physical symptoms, yielding a set of diagnostic criteria that can be applied easily in a patient interview, as follows<sup>12</sup>:

**TABLE 14.1 Survey Tools for Assessing Premenstrual Syndrome and Premenstrual Dysphoric Disorder**

Tool Acronym/Abbreviation	Tool (Full) Title	Reference and Resources
COPE	Calendar of Premenstrual Experiences	See Ref. <sup>12</sup>
MDQ	Moos Menstrual Distress Questionnaire	See Ref. <sup>31</sup>
PAF	Premenstrual Assessment Form	See Ref. <sup>32,33</sup>
PRISM	Prospective Record of Severity of Menstruation	See Ref. <sup>34</sup>
DRSP	Daily Record of Severity of Problems	See Ref. <sup>35</sup>
PSST	Premenstrual Symptoms Screening Tool	See Ref. <sup>36</sup>

1. Self-report of 1 or more affective symptoms **and** 1 or more somatic symptoms during the 5 days preceding menses in each of three menstrual cycles. See Table 14.2.
2. Relief from symptoms within 4 days after the onset of menses, without recurrence before cycle day 12 in a 28-day cycle.
3. Absence of any medications, hormone therapy, drug, or alcohol use.
4. Social dysfunction and personal distress, as indicated by one of the following:
  - Discord in the relationship with a partner, confirmed by the partner
  - Parenting difficulties
  - Poor work/school performance or attendance
  - Increased social isolation
  - Legal problems
  - Suicidal ideation
  - Seeking medical care for somatic symptoms

## **TABLE 14.2 Affective and Somatic Symptoms**

## Affective Symptoms

## Somatic Symptoms

Depression

Breast tenderness

Angry outbursts

Abdominal bloating

Irritability

Headache

Confusion

Swollen extremities

Social withdrawal

Fatigue

According to the guidelines from the National Institute of Mental Health (NIMH),<sup>37</sup> the diagnosis of PMS also should require at least a 30% increase in the severity of symptoms over the 5 days before menses, compared with the 5 days after onset of menses. **Based on the UCSD and NIMH criteria, it is estimated that approximately 5% of women of reproductive age can be diagnosed with disruptive PMS.**<sup>38,39,40</sup>

The most commonly used criteria for the diagnosis of PMDD are those proposed by the American Psychiatric Association, as they appear in the current Diagnostic and Statistical Manual of Mental Disorders (DSM-V)<sup>41</sup>:

- A. In the majority of menstrual cycles, at least five symptoms must be present in the final week before the onset of menses, start to improve within a few days after the onset of menses, and become minimal or absent in the week postmenses.
- B. One (or more) of the following symptoms must be present:
  1. Marked affective lability (e.g., mood swings; feeling suddenly sad or tearful, or increased sensitivity to rejection).
  2. Marked irritability or anger or increased interpersonal conflicts.
  3. Marked depressed mood, feelings of hopelessness, or self-deprecating thoughts.
  4. Marked anxiety, tension, and/or feelings of being keyed up or on edge.
- C. One (or more) of the following symptoms must additionally be present, to reach a total of five symptoms when combined with symptoms from Criterion B above.

1. Decreased interest in usual activities (e.g., work, school, friends, hobbies).
2. Subjective difficulty in concentration.
3. Lethargy, easy fatigability, or marked lack of energy.
4. Marked change in appetite; overeating; or specific food cravings.
5. Hypersomnia or insomnia.
6. A sense of being overwhelmed or out of control.
7. Physical symptoms such as breast tenderness or swelling, joint or muscle pain, a sensation of “bloating,” or weight gain.

**Note:** The symptoms in Criteria A–C must have been met for most menstrual cycles that occurred in the preceding year.

D. The symptoms are associated with clinically significant distress or interference with work, school, usual social activities, or relationships with others (e.g., avoidance of social activities; decreased productivity and efficiency at work, school, or home).

E. The disturbance is not merely an exacerbation of the symptoms of another disorder, such as major depressive disorder, panic disorder, persistent depressive disorder (dysthymia), or a personality disorder (although it may co-occur with any of these disorders).

F. Criterion A should be confirmed by prospective daily ratings during at least two symptomatic cycles. (**Note:** The diagnosis may be made provisionally prior to this confirmation.)

G. The symptoms are not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition (e.g., hyperthyroidism).

**It is important to note that whereas the diagnosis of PMS requires both affective and somatic symptoms, the diagnosis of PMDD can include, but does not require, somatic symptoms.** Another distinction between the two disorders is that PMDD may be superimposed on another psychiatric disorder, whereas the diagnosis of PMS can only be made in their absence.

**The diagnoses of PMS and PMDD must be differentiated from other underlying psychiatric disorders, which are common among women with similar symptoms.**<sup>26,42,43</sup> Medical conditions, such as hyperthyroidism and hypothyroidism, also should be excluded. A study involving a group of women evaluated in a specialty PMS clinic found that 13% had a distinct affective psychiatric disorder, 38% had premenstrual exacerbation of an underlying depressive or anxiety disorder, and only 44% of PMS-like presentations actually met strict diagnostic criteria for PMS.<sup>44</sup> Women with PMS often have a history of a previous major depressive episode and also are at increased risk for major depression in the future.<sup>45,46</sup> **Women who have no**

**demonstrable symptom-free interval during the follicular phase of the cycle merit careful evaluation for a mood or anxiety disorder.**

Migraine headache and symptoms of chronic fatigue syndrome and irritable bowel syndrome frequently are more pronounced during the premenstrual phase of the cycle. However, in women with these syndromes, symptoms also occur at other times in the cycle.<sup>47</sup>

# Pathophysiology

Scientific evidence for the mechanism(s) involved in PMS and PMDD has been difficult to produce, but there has been no shortage of theories; the list is impressive:

- Low progesterone levels
- High estrogen levels
- Falling estrogen levels
- Changes in the estrogen/progesterone ratio
- Increased aldosterone activity
- Increased rennin-angiotensin activity
- Increased adrenal activity
- Endogenous opiate withdrawal
- Subclinical hypoglycemia
- Central changes in catecholamines
- Responsiveness to prostaglandins
- Vitamin and mineral deficiencies
- Excess prolactin secretion

In his original description of PMS, R.T. Frank summarized 15 cases, theorized that the problem resulted from an excess of female sex hormones due to inadequate excretion, and reported that he could provide relief by withdrawing blood from his patients. Accordingly, he applied treatments designed to increase excretion, such as calcium lactate, caffeine, and laxatives. For severe cases, he prescribed pelvic irradiation to cause ovarian failure. In 1934, S. Leon Israel proposed the opposite theory—that PMS was caused by defective luteinization, progesterone deficiency, and relative hyperestrogenism.<sup>48</sup>

The role of ovarian steroid hormones in PMS is suggested strongly by the lasting response to oophorectomy in women unresponsive to medical therapy<sup>49,50</sup> and by the dramatic decrease in symptoms after suppression of the hypothalamic-pituitary-ovarian axis by treatment with a long-acting gonadotropin-releasing hormone (GnRH) agonist.<sup>51,52,53,54</sup> However, studies comparing serum estrogen and progesterone levels have failed to identify any consistent differences between women with and without PMS/PMDD.<sup>55,56,57</sup> Moreover, an early onset of menses induced by treatment with a progesterone antagonist during the luteal phase does not decrease or otherwise change the symptoms of PMS, even when progesterone levels are maintained by simultaneous treatment with hCG.<sup>58,59</sup> In women with PMS treated with a GnRH agonist, symptoms recur when exogenous estrogen or progesterone is added to the treatment regimen, but not in those receiving add-back placebo treatment and not in normal women receiving

the same treatment.<sup>60</sup> Studies involving well-defined patient populations also have failed to demonstrate any differences in the levels of testosterone, follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin, sex hormone-binding globulin, and aldosterone between women with and without symptoms of PMS, in any phase of the menstrual cycle.<sup>61</sup> **Taken together, these observations suggest that the symptoms of PMS are not caused directly by endocrine events during the luteal phase but reflect an abnormal response to normal cyclic changes in ovarian steroid hormone levels.**

The menstrual cycle is associated with significant changes in the opioid,<sup>62</sup> gamma-aminobutyric acid (GABA),<sup>63</sup> and serotonin neurotransmitter systems,<sup>64</sup> suggesting a possible pathophysiologic mechanism for PMS. Lower midcycle and luteal phase serum  $\beta$ -endorphin levels have been observed in women with PMS, compared to normal women.<sup>65,66,67</sup> The anxiolytic actions of certain progesterone metabolites that act as ligands for the GABA-A receptor<sup>63</sup> and the effectiveness of alprazolam (a short-acting benzodiazepine) in relieving symptoms of PMS<sup>68</sup> suggest the disorder might involve a disturbance in the GABAergic system. However, studies comparing the levels of anxiolytic progesterone metabolites in women with and without PMS have observed no consistent differences.<sup>57,69</sup> Several lines of evidence suggest that the mood symptoms of PMS may relate to serotonin depletion. Whole blood serotonin concentrations and platelet serotonin uptake and imipramine binding (a marker of CNS binding and serotonergic activity) during the luteal phase are lower in women with PMS than in asymptomatic women.<sup>70,71,72,73,74</sup> Symptoms of PMS are aggravated by acute dietary tryptophan depletion, which suppresses brain serotonin synthesis,<sup>75</sup> and relieved by treatment with fenfluramine, a serotonin agonist,<sup>76</sup> or fluoxetine, a selective serotonin reuptake inhibitor (SSRI). Moreover, mood symptoms in women with PMDD receiving treatment with fluoxetine promptly return after treatment with metergoline, a serotonin antagonist.<sup>77</sup> **The weight of current evidence thus suggests strongly that PMS and PMDD result from an abnormal or exaggerated effect of cyclic changes in ovarian steroid hormones on central neurotransmitter mechanisms and that serotonin, in particular, plays an important role in their pathophysiology.**

In general, thyroid function is normal in women with PMS.<sup>78</sup> Approximately 10% of women with PMS have demonstrably abnormal thyroid function, but the prevalence is not significantly different from that of subclinical hypothyroidism in the general population. Overall, the thyroid-stimulating hormone (TSH) response to thyroid-releasing hormone (TRH) is normal. Although abnormal responses (both exaggerated and blunted) are observed more often in women with PMS,<sup>79</sup> they occur just as often during the follicular phase as in the luteal phase. Moreover, the effect of treatment with

thyroxine is no different from that of placebo, even in patients with an abnormal response to TRH.

Studies of twins have found evidence to suggest that genetic factors might predispose to PMS and PMDD.<sup>80,81</sup> The correlation between menstrual symptoms in mothers and daughters and between sisters suggests a genetic influence but also might merely reflect a learned or conditioned response, at least to some extent.<sup>82,83</sup> Whereas many have speculated that differences in personality, stress levels, or coping mechanisms may play a role in PMS, there is little or no evidence to support the hypothesis.<sup>84,85,86</sup>

Some evidence suggests that women with PMS ingest more alcohol than others and that women with a family history of alcoholism exhibit more premenstrual anxiety and other behavioral symptoms, but a link between alcoholism and PMS has not been established.<sup>87,88</sup> Efforts have examined roles for vitamin and mineral deficiencies in women with PMS. Studies comparing serum levels of vitamin A and vitamin E in women with and without PMS have observed no significant differences.<sup>89,90</sup> The results of treatment with vitamin B<sub>6</sub> generally are unimpressive and inconsistent.<sup>91,92</sup> A number of studies have found that intracellular and circulating magnesium concentrations are lower in women with PMS than in asymptomatic control women, but the significance of these observation remains unclear.<sup>93,94,95,96,97</sup> Vitamin D insufficiency has been linked with PMS, and dietary intake of calcium and vitamin D has been shown to relate to risk for PMS.<sup>98,99</sup>

# Treatment

The key to effective treatment of PMS and PMDD is accurate diagnosis, which rests primarily on the collection of objective evidence that the patient's symptoms are clearly cyclic, as documented by use of the COPE survey or other similar calendar-based screening tool over the interval spanning three menstrual cycles.

A number of medications have proven beneficial to women with PMS or PMDD, including SSRIs,<sup>100,101</sup> alprazolam (a benzodiazepine),<sup>68,102,103</sup> and GnRH agonists (Table 14.3).<sup>53,104</sup> Accumulated evidence indicates that certain oral contraceptives,<sup>105,106,107</sup> exercise,<sup>108,109</sup> relaxation techniques,<sup>110,111</sup> spironolactone,<sup>112,113,114,115</sup> and danazol<sup>114</sup> also have some value. Older treatment regimens involving progesterone or progestins,<sup>117,118,119,120,121</sup> tricyclic antidepressants, monoamine oxidase inhibitors, lithium, evening primrose oil,<sup>122</sup> essential free fatty acids,<sup>123</sup> dietary restrictions, vitamin supplements, and ginkgo biloba generally are not effective. Improvements in symptoms have been described with vitamin D and calcium supplementation.<sup>99,124,125,126,129</sup>

## TABLE 14.3 Treatments for Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Demonstrated as Effective	Possibly Effective	Ineffective
Selective serotonin reuptake inhibitors	Oral contraceptives	Progesterone
Alprazolam	Spironolactone	Vitamins B, E
GnRH agonists	Exercise	Dietary restrictions
Drospirenone containing OCP's	CBT	
Danazol	Magnesium	

## The Placebo Response

The strange-sounding word placebo is derived from the Latin verb meaning “I shall please.” Clinicians and patients have been conditioned to observe a prescription ritual. Many patients seem to feel that their complaints are not taken seriously unless a medication is prescribed. However, placebo is more than a pill; it is a process.<sup>128</sup>

The process begins with confidence in the clinician and extends to the patient’s own healing system. Interaction with a clinician provides a better understanding of a patient’s symptoms, eliminates some unfounded fears, and offers hope for improvement. Many of the treatments for PMS that provide women with a greater sense of control, even simple measures such as changes in diet and lifestyle, can yield benefits. The very process of making detailed, prospective observations of events in life can improve one’s sense of self-control, which is intrinsically therapeutic.

Leon Eisenberg penned some very insightful thoughts regarding the placebo response, which plays a prominent role in the therapeutics of PMS and PMDD<sup>129</sup>:

So emphatically does the phrase “placebo response” discredit the psychosocial aspects of the therapeutic encounter that it may be time to eradicate it from our language. Let us replace it by some such term as “the response to care,” “the response to the doctor,” or “the healing response” in order to emphasize that it is (a) powerful, (b) no less “real” than drug actions, and (c) embedded in every therapeutic transaction. Its mechanisms are some compound of the arousal of hope, the comfort of reassurance, taking an active rather than a passive role in managing the illness experience, and reinterpreting the meaning of the illness. It is perverse that “placebo” has almost become an epithet implying charlatanism rather than a descriptor of a fundamental characteristic of medical practice. We ought equally to seek an understanding of the healing response rather than disdaining it, as the “hard” scientist does, or being deceived by it, as practitioners often are.<sup>130</sup>

## **Selective Serotonin Reuptake Inhibitors (SSRIs) and Selective Serotonin and Norepinephrine Reuptake Inhibitors (SNRIs)**

There is substantial evidence for the effectiveness of SSRIs in the treatment of PMS and PMDD.<sup>100,101,131</sup> Fluoxetine (Prozac), in a daily dose of 20 mg, has demonstrated sustained efficacy for relieving both somatic and mood symptoms and generally is well tolerated.<sup>132,133,134,135</sup> Other SSRIs also are effective, including sertraline (Zoloft, 50–150 mg daily),<sup>136,137</sup> paroxetine (Paxil, 20–30 mg daily),<sup>138</sup> and citalopram (Celexa, 20–30 mg daily).<sup>139</sup> Venlafaxine (Effexor, 50–200 mg daily), an SNRI, also has efficacy,<sup>140</sup> as do other antidepressants that inhibit serotonin reuptake or antagonize its action, such as clomipramine<sup>141,142</sup> and nefazodone.<sup>143</sup>

Although SSRIs and related drugs are administered most commonly on a continuous daily basis, an intermittent treatment regimen limited to the luteal phase, or one beginning at the onset of symptoms, can be equally or more effective while offering the potential advantages of lower cost and fewer side effects.<sup>139,142,144,145</sup> In some clinical trials, treatment for as few as 3 days was effective.<sup>146,147</sup> However, some women require higher doses or continuous treatment to achieve benefit.<sup>148,149,150</sup> **If SSRIs and SNRIs are initiated as a continuous regimen, it is important for prescribers to ensure that these agents should be discontinued gradually to minimize withdrawal symptoms; luteal regimens do not require taper.**

## **Alprazolam**

Alprazolam, a benzodiazepine, is another medication that may be useful in the treatment of PMS and PMDD,<sup>68,102,103</sup> although its effectiveness may be limited to the relief of depressive symptoms. Because the drug also has addictive potential, it generally is considered a second-line agent and is best used only intermittently.

## **Gonadotropin-Releasing Hormone Agonists**

The clinical utility of GnRH agonists in the treatment of PMS/PMDD was first demonstrated in 1984.<sup>151</sup> Although now an established treatment,<sup>53,104</sup> GnRH agonists generally are more effective for relieving irritability and physical symptoms than for the treatment of prominent symptoms of depression or dysphoria.<sup>53,152</sup> GnRH agonist treatment is associated with the well-known symptoms of hypoestrogenism (e.g., hot flashes), which can be severe, and prolonged use invites longer-term consequences (bone mineral depletion).<sup>52</sup> However, these limitations can be negated largely by simultaneous “add-back” treatment with low doses of estrogen or estrogen and progestin, which does not reduce the overall efficacy of GnRH agonist therapy.<sup>51,153,154,155</sup>

## **Combined Hormonal Contraceptives**

Combined oral contraceptives (COC's) are one of the oldest and simplest methods for treatment of PMS/PMDD, based on the idea of substituting a constant hormonal environment for the dynamic cyclic pattern of the normal menstrual cycle. Early clinical studies found that oral contraceptives helped to relieve breast pain and symptoms of bloating but had no detectable benefits for relieving mood symptoms.<sup>156</sup> More recent studies involving the use of an oral contraceptive containing the progestin drospirenone have observed that treatment can achieve modest improvement in a wide range of symptoms, including behavioral and mood symptoms, particularly when the usual 7-day pill-free interval is shortened to 4 days.<sup>105,106,157,158</sup> Extended regimens can be superior to cyclic by providing a relative hormonal steady state. Similar to oral contraceptives, improvement in PMS is described with use of vaginal combined hormonal contraceptive ring.<sup>159</sup>

## **Complementary Therapies**

### **Exercise and Relaxation Techniques**

There is some evidence to indicate that aerobic exercise,<sup>108,109</sup> relaxation,<sup>110</sup> and reflexology<sup>111</sup> can help to relieve the symptoms of PMS. These approaches are of particular relevance for women who may not tolerate the hormonal or neuromodulator

options discussed earlier. Existing data suggest that their efficacy is not compelling and may reflect only a placebo response.

## Alternative Therapies

Alternative therapies are limited, although inconsistent benefits have been implied in trials of chasteberry and St. John's Wort.<sup>130,160,161</sup>

## Spironolactone

Spironolactone is a potassium-sparing diuretic having structural similarity to steroid hormones and has been used widely in the treatment of PMS. In clinical trials, spironolactone has proven more effective than placebo in relieving symptoms of irritability, depression, bloating, breast tenderness, and food craving.<sup>113,114,115</sup> In one placebo-controlled randomized trial, a significant difference in serum androgen levels from the follicular to the luteal phase of the cycle was observed in those who subsequently responded to treatment with spironolactone.<sup>112</sup>

## Progesterone

In the past, progesterone treatment by injection or suppository was used commonly in the management of PMS, having been actively promoted by Dalton.<sup>4</sup> Early studies that failed to detect a benefit were criticized for the size of the study population and doses of progesterone that were employed.<sup>162,163,164,165</sup> In a study that attempted to negate the placebo response by eliminating any contact with the investigators or any health care providers during the trial, both progesterone and placebo failed to achieve any measurable benefits.<sup>166</sup> Controversies regarding the value of progesterone treatment were largely put to rest by the results of large double-blind, placebo-controlled trials finding that the effects of progesterone (400, 800, 1,200 mg daily) were not different from those of placebo.<sup>117,167</sup> A meta-analysis including 10 trials of progesterone therapy involving 531 women and 4 trials of progestin therapy involving 378 women found that neither is effective for management of the symptoms of PMS.<sup>118</sup> A recent Cochrane systematic review concluded the available data do not indicate that progesterone is an effective treatment for PMS.<sup>168</sup>

## Danazol<sup>169</sup>

A synthetic derivative of 17 $\alpha$ -ethinyltestosterone with diverse modes of actions that include suppression of pituitary gonadotropins, receptor-mediated androgenic and progestational effects, as well as immunomodulation. Danazol has demonstrated

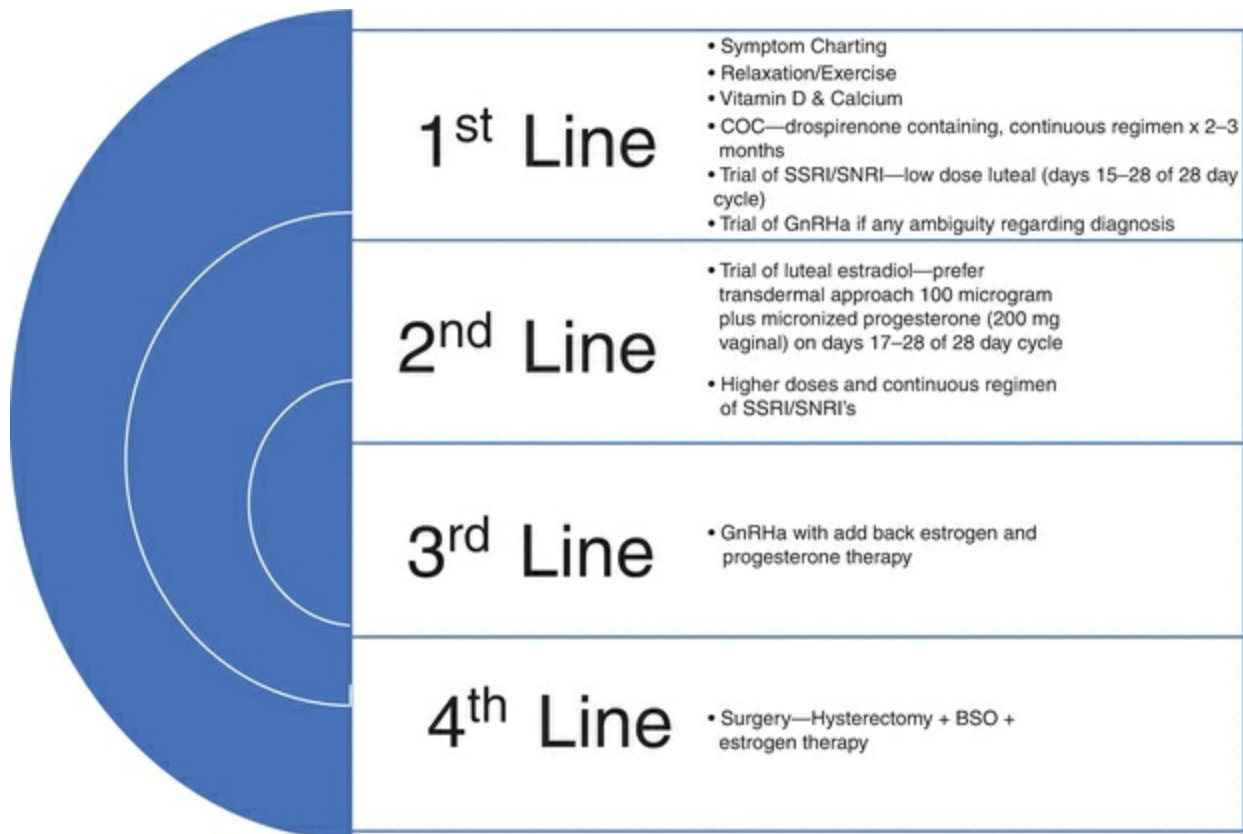

efficacy in the management of endometriosis as well as reduced severity of PMS symptoms when used in 200 mg twice daily regimen.<sup>116</sup>

## Role of Surgery

Hysterectomy and bilateral salpingo-oophorectomy have on rare occasions shown to offer benefit in severe cases of PMS/PMDD,<sup>170,171</sup> when medical therapy has failed, when patient is unwilling to commit to long-term use of GnRHa, or when additional gynecologic comorbidities such as symptomatic fibroids exist. Proven efficacy of benefit from ovarian suppression with GnRHa and tolerance of add-back estrogen therapy should precede a decision to proceed with surgery. Hormone therapy is advised following surgical menopause to minimize symptom burden of resulting hypoestrogenemia and the long-term sequelae therefrom (discussed in detail in [Chapter 17](#)). While removal of the ovaries alone will confer benefit, retention of the uterus necessitates a need for adding progesterone (which is associated with PMS-like symptoms) to hormone therapy regimen. Surgical absence of the uterus simplifies hormone therapy as there is no more need for adding progesterone to the hormone replacement regimen.

## Choice of Treatment

When symptoms are mild and evidence of significant psychosocial dysfunction is lacking, a trial of relaxation strategies and aerobic exercise can be tried as first-line approach. If symptoms of bloating and fluid retention are prominent, a trial of spironolactone can be justified. Women in need of contraception are logical candidates for treatment with oral contraceptives, with a shorter than usual pill-free interval, or in a daily continuous regimen. **In our opinion, drospirenone containing combined hormonal contraceptives, dispensed as a continuous regimen, should be considered as a first-line pharmaceutical approach to bothersome PMS ([Figure 14.3](#)).**

COC: Combined oral contraceptive  
 SSRI: Selective serotonin reuptake inhibitor  
 SNRI: Selective norepineprine reuptake inhibitor  
 GnRHa: GnRH agonist  
 BSO: Bilateral salpingo-oophorectomy

**FIGURE 14.3**

**Women who meet strict criteria for diagnosis of PMS or PMDD, including psychosocial dysfunction, are candidates for treatment with an SSRI (fluoxetine, sertraline, paroxetine) or an SNRI (venlafaxine); based on the severity of both, these agents can be administered daily or only during the luteal phase. Common side effects of SSRIs include nausea, jitteriness, and headache. When side effects prove limiting, a trial with a lower dose or alternative drug is warranted. Sexual dysfunction, including anorgasmia and diminished sexual interest, is perhaps the most significant potential adverse effect of SSRI treatment, and women should be advised of this specific possibility before treatment begins.** Unfortunately, lower doses often do not eliminate this side effect. Approximately 30–40% of women may not respond to treatment with an SSRI over several cycles; a switch to another drug in the class is reasonable and often effective. Those who fail to respond to intermittent luteal phase treatment or to daily therapy may do better with the alternative treatment regimen. When SSRI treatment proves unsuccessful, low-dose alprazolam is a logical choice to try, although sedating side effects may limit its usefulness.

**In women diagnosed with PMS or PMDD who fail to respond to the treatments usually effective, it is important to consider underlying conditions such as major depression, a generalized anxiety disorder, or substance abuse.** In those with severe PMDD unassociated with such disorders, treatment with a GnRH agonist can be considered, preferably administered with low doses of add-back estrogen or estrogen/progestin. In those who respond well to this last-resort therapy, GnRH agonist treatment with add-back can be extended beyond the usual 6 months without risk for loss of bone density.

# DYSMENORRHEA

Dysmenorrhea is pain with menstruation, usually cramping in nature and centered in the lower abdomen (Figure 14.4). Dysmenorrhea generally is classified as primary or secondary.<sup>172</sup> **Primary dysmenorrhea is associated with ovulatory cycles and results from myometrial contractions, in the absence of demonstrable disease. Secondary dysmenorrhea refers to pain during menstruation that is associated with pelvic pathology, such as endometriosis, adenomyosis, or uterine myomas (Figure 14.5).**

FIGURE 14.4

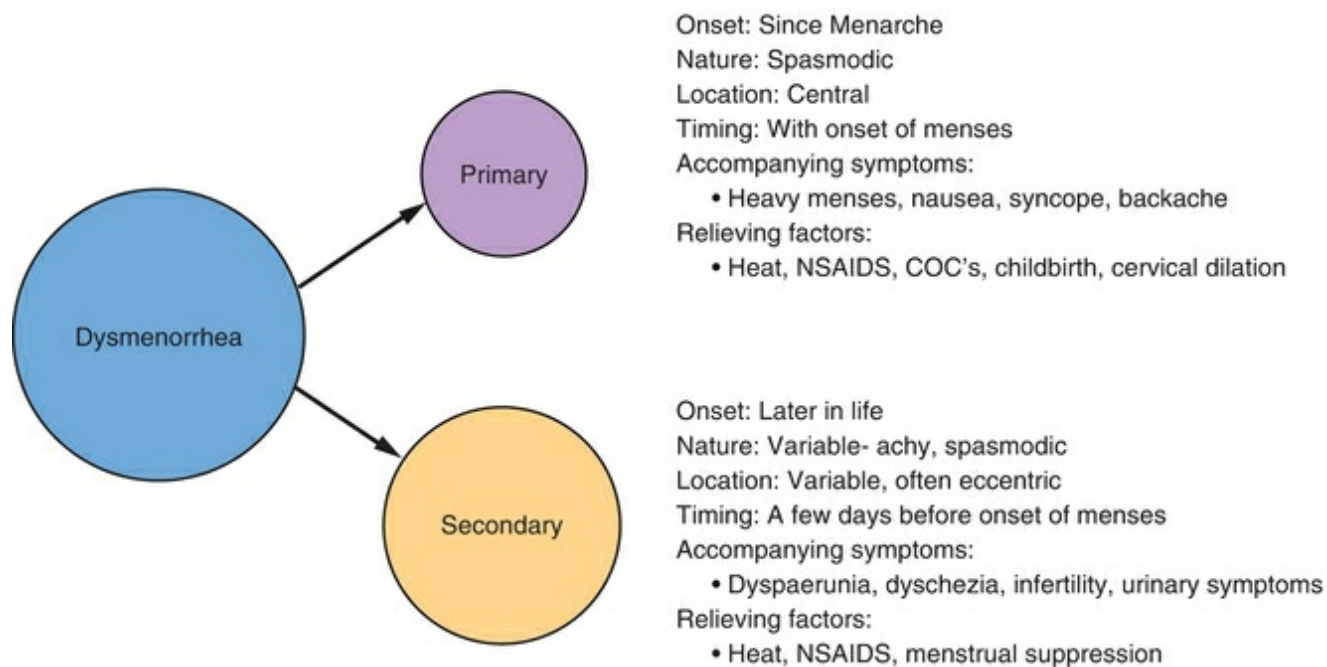

FIGURE 14.5

# Epidemiology

Dysmenorrhea is one of the most common gynecologic problems in reproductive age women. Primary dysmenorrhea usually begins during adolescence, but only after ovulatory cycles are established; 20–45% of teenage girls are ovulatory by 2 years after menarche, and 80% by 4–5 years.<sup>173</sup>

The overall prevalence of primary dysmenorrhea among adolescent girls is between 60% and 90% and decreases as age increases.<sup>174,175,176,177</sup> However, only approximately 15% of adolescent girls seek medical attention for complaints of menstrual pain.<sup>177</sup> In a random sample of 19-year-old women in Göteborg, Sweden, 72% reported dysmenorrhea, 38% regularly used medication, 15% had to limit their daily activity despite use of medication, and 8% missed school or work during every menses.<sup>178</sup> The severity of dysmenorrhea related directly to the volume and duration of menstrual flow. A later survey of the same cohort of women found that the prevalence of dysmenorrhea was decreased to 67% by age 24, with 10% still reporting limitation of daily activities.<sup>179</sup> The severity of dysmenorrhea also was reduced in women who had delivered a child in the intervening years, but not in those who had a miscarriage or abortion, and also was decreased in oral contraceptive users. A Canadian survey in a random sample of over 1,500 menstruating women observed that the prevalence of moderate or severe dysmenorrhea was 60%, resulting in decreased activity in 50% and missed school or work in 17%.<sup>180</sup> In the United States, approximately 60% of menstruating adolescents report dysmenorrhea, causing 14% to miss school regularly.<sup>177</sup> In a longitudinal American study of college women ages 17–19 years, 13% reported severe pain in more than half of their menstrual periods and 42% indicated that dysmenorrhea interfered with daily activities at least once.<sup>181</sup>

Risk factors for dysmenorrhea include a body mass index less than 20, early menarche (before age 12), longer intermenstrual intervals and duration of bleeding, irregular or heavy flow, premenstrual molimina, previous sterilization or history of sexual assault, and smoking.<sup>182</sup> Oral contraceptives, exercise, being married or in a stable relationship, and higher parity decrease the likelihood of dysmenorrhea.<sup>182</sup>

# Pathophysiology

**Accumulated evidence indicates that primary dysmenorrhea is caused by myometrial ischemia due to frequent and prolonged uterine contractions.** Studies of uterine blood flow using Doppler ultrasonography have revealed that uterine and arcuate artery resistance on the first day of menses is significantly higher in women with primary dysmenorrhea than in women without dysmenorrhea, suggesting that constriction of uterine vessels is the proximate cause for pain.<sup>183</sup>

The secretory endometrium contains substantial stores of arachidonic acid, which is converted to prostaglandin  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ), prostaglandin  $E_2$  ( $PGE_2$ ), and leukotrienes during menses.  $PGF_{2\alpha}$  always stimulates uterine contractions and is the primary mediator of dysmenorrhea.<sup>184</sup> Endometrial concentrations of  $PGF_{2\alpha}$  and  $PGE_2$  correlate with the severity of dysmenorrhea.<sup>185</sup> Treatment with cyclooxygenase (COX) inhibitors decreases prostaglandin levels in menstrual fluid and uterine contractile activity; response curves correlate closely with serum drug levels.<sup>186,187</sup>

Uterine smooth muscle contractions cause the crampy, spasmodic lower abdominal and low back pain typical of dysmenorrhea and of prostaglandin-induced labor or abortion. In women with primary dysmenorrhea, uterine contractions during menses begin from an elevated level of basal tone ( $>10$  mm Hg), generate higher intrauterine pressures that frequently reach 150–180 mm Hg and can exceed 400 mm Hg, occur more frequently ( $>4$ – $5/10$  minutes), and are not rhythmic or coordinated.<sup>187</sup> When intrauterine pressure exceeds arterial pressure for a sustained period of time, ischemia results in the production of anaerobic metabolites that stimulate small type C pain neurons, which contributes to the pain of dysmenorrhea. Moreover,  $PGF_{2\alpha}$  and  $PGE_2$  can stimulate bronchial, bowel, and vascular smooth muscle contractions, causing bronchoconstriction, nausea, vomiting, diarrhea, and hypertension.

Classically, primary dysmenorrhea begins just before or coincident with the onset of menses and declines gradually over the subsequent 72 hours. The menstrual cramps are intermittent, vary in intensity, and usually are centered in the suprapubic region, although some women also experience pain in their thighs and lower back. Typically, the pattern is consistent across cycles. In contrast, women with secondary dysmenorrhea related to pelvic pathology, such as endometriosis, frequently report increasingly severe pain that often occurs at midcycle and during the week preceding menses, in addition to symptoms of deep dyspareunia and dyschezia (painful bowel movements). In those with secondary dysmenorrhea related to uterine myomas, pain results primarily from menorrhagia, with an intensity that correlates with the volume of menstrual flow.

# Diagnosis

**Primary dysmenorrhea is a clinical diagnosis, based primarily on a history of characteristic symptoms and a physical examination yielding no evidence or suspicion of specific pelvic pathology such as endometriosis, adenomyosis, uterine myomas, or chronic pelvic inflammatory disease.** In general, laboratory tests, imaging, and laparoscopy are not necessary for diagnosis.

A careful menstrual history should include the age at menarche and at onset of dysmenorrhea, intermenstrual interval, and volume and duration of flow: note any symptoms of intermenstrual or premenstrual spotting or staining. The relationship between the onset of pain and the onset of flow, the severity and location of pain, and the presence of any associated nausea, vomiting, diarrhea, back pain, or headache should be determined. The extent to which the pain interferes with daily activities (work, school, or exercise), the use of medications and their effectiveness, any progression in severity over time, and the presence of pain at times other than during menses also should be defined. These historical features generally can distinguish reliably women with primary dysmenorrhea from those with secondary dysmenorrhea.

Whereas women with primary dysmenorrhea typically report the onset of menstrual pain before the age of 25, those with adenomyosis tend to present later, generally after age 35, and often also report noncyclic chronic pelvic pain. Women with endometriosis typically have pain at times other than during menses and frequently also report premenstrual spotting, dyspareunia, dyschezia, limited relief from treatment with non-steroidal anti-inflammatory drugs (NSAIDs), and increasing severity over time. Because NSAIDs generally are highly effective in relieving the pain of primary dysmenorrhea, pain that proves refractory to such treatment suggests pelvic pathology.

Women with primary dysmenorrhea usually have a normal pelvic examination. In those with secondary dysmenorrhea related to pelvic pathology, the pelvic examination can be normal but often is not, providing clues to the underlying cause. Adenomyosis often is associated with a bulky, globular, and tender uterus, whereas those with myomas frequently have an enlarged uterus with irregular contours. Women with secondary dysmenorrhea related to endometriosis often have abnormal physical examination findings, which can include thickening, nodularity, or focally tender uterosacral ligaments, lateral cervical displacement due to shortening of one uterosacral ligament, cervical stenosis, or an enlarged ovary due to an endometrioma.<sup>188,189</sup> Interestingly, red hair, scoliosis, and dysplastic nevi also are observed more frequently in women with endometriosis.<sup>190,191,192</sup>

The diagnosis of primary dysmenorrhea does not require laboratory tests or imaging. However, transvaginal ultrasonography can be very helpful in identifying

uterine myomas, endometriomas, and adenomyosis in women with secondary dysmenorrhea.<sup>193</sup> Although numerous studies have demonstrated that serum CA 125 often is elevated in women with endometriosis, the test has limited clinical utility due to its low negative predictive value.<sup>194,195</sup>

# Treatment

A wide variety of therapies has been proposed for the treatment of dysmenorrhea. These include the application of heat, dietary and vitamin or herbal therapies, exercise, and behavioral interventions, as well as more traditional medications such as NSAIDs and oral contraceptives.

Data from two clinical trials suggest that application of a heated abdominal patch or wrap for 8–12 hours daily is more effective than placebo and can be as effective as treatment with an NSAID.<sup>196,197</sup> Results from a few small clinical studies have suggested that a vegetarian diet,<sup>198</sup> vitamin E,<sup>199,200</sup> combinations of vitamins (B<sub>1</sub>, B<sub>6</sub>, E), and Asian herbal remedies are more effective than placebo, but two systematic reviews have concluded that evidence is insufficient to justify recommending dietary and herbal therapies for the treatment of dysmenorrhea.<sup>201,202</sup> Studies of the effects of exercise on dysmenorrhea have yielded mixed results, with some reporting improvement and others finding that regular exercise worsened symptoms.<sup>203,204</sup> Although behavioral interventions aimed at changing the way women think about or respond to pain appear to help some women with dysmenorrhea, evidence for their effectiveness derives from small studies in heterogeneous populations and is not compelling.<sup>205</sup>

**For both adolescent girls and women with primary dysmenorrhea, NSAIDs are the first treatment of choice.**<sup>206,207,208</sup> There are numerous NSAIDs to choose from, including the propionic acid derivatives (e.g., naproxen, ibuprofen, and ketoprofen) and fenamates (e.g., mefenamic acid, tolfenamic acid, flufenamic acid, and meclofenamate); all are very effective (Table 14.4). Numerous clinical trials have demonstrated that NSAIDs provide effective relief in 70–90% of patients.<sup>209,210,211,212,213,214</sup> Their efficacy derives from both a decrease in endometrial prostaglandin production and from decreased menstrual flow. The fenamates also block prostaglandin actions.<sup>215</sup> Although some selective COX-2 inhibitors have been approved for treatment of primary dysmenorrhea, their higher cost and greater potential risks suggest their use should be limited to women at high risk for serious gastrointestinal side effects.

## TABLE 14.4 Common NSAID Treatment Regimens for Dysmenorrhea

<b>Drug</b>	<b>Initial Dose (mg)</b>	<b>Maintenance Dose (mg)</b>
<i>Propionic acid derivatives</i>		
Ibuprofen	400	400 q6h
Naproxen	500	250 q6–8h
Naproxen sodium	550	275 q6–8h
Ketoprofen	75	75 q8h
<i>Fenamates</i>		
Mefenamic acid	500	250 q4h
Meclofenamate	100	50–100 q6h

NSAID treatment can be started at the onset of menses and continued for the usual duration of pain. Women with severe dysmenorrhea might benefit from starting treatment 1–2 days before menstrual bleeding begins. NSAIDs should be taken with food to minimize common gastrointestinal side effects. The propionic acid derivatives are a good initial choice because they are inexpensive and available over the counter without a prescription. Patients do exhibit variations in response to different NSAIDs. Consequently, if one fails, substituting another in a different drug class is reasonable and appropriate (e.g., changing from ibuprofen to mefenamic acid). Because prostaglandins play a role in ovulation, treatment with NSAIDs has the potential to delay or prevent ovulation.<sup>214,215,216</sup> However, given that NSAID treatment for dysmenorrhea is remote from ovulation, women attempting to conceive generally can be reassured that treatment will not adversely affect their fertility.<sup>219</sup>

**Combined hormonal contraceptives also are effective treatment for dysmenorrhea. They can be considered a first-line agent in sexually active women**

**who require contraception and are a logical alternative for those who do not tolerate or gain sufficient relief from NSAID treatment.**<sup>220</sup> The efficacy of hormonal contraceptives derives from their inhibition of ovulation, thereby decreasing endometrial prostaglandin production, and from the decrease in the volume and duration of flow that results from endometrial attenuation after months of use.<sup>220,221,222,223</sup> Oral combined hormonal contraceptives can be used in the standard cyclic fashion (21–24 active pills followed by 4–7 inactive pills for oral) or in an “extended” cyclic manner that aims at reducing the frequency of withdrawal bleeding to every 3 months by either utilizing one of the newer oral formulations that contain 12 weeks of active pills, followed by 7 pills that are inactive or contain a low dose of estrogen only.<sup>224,225</sup> Alternatively, extended regimens can be achieved using the traditional 28-day pill packets by discarding placebo pills and starting a new set of 21 active pills until the 3rd pill packet, when placebo or hormone-free period will result in withdrawal bleeding. All regimens are effective. Extended cycles offer the added advantage of fewer menses, but also are associated with a higher prevalence of unscheduled spotting or bleeding.<sup>226</sup>

The contraceptive ring is as effective as oral contraceptives for the treatment of dysmenorrhea.<sup>227</sup> Similar to the pills, an extended regimen can be achieved when using a vaginal ring by postponing the hormone-free week to every 3rd month of use. Although no studies have focused on the use of depot medroxyprogesterone acetate for dysmenorrhea, a small study in adolescents found that two-thirds of subjects reported decreased dysmenorrhea during treatment.<sup>228</sup> Efficacy of contraceptive patch against dysmenorrhea remains less clear.

The levonorgestrel intrauterine system (device) has emerged as an effective and well tolerated approach for the management of both primary dysmenorrhea and secondary dysmenorrhea.<sup>229,230,231,232</sup> Hormonal contraceptive implants, such as the single-rod implantable hormonal contraceptive containing etonogestrel (Implanon), have also shown benefit.<sup>233</sup>

Women who fail to respond to treatment with NSAIDs and/or hormonal contraceptives and those having recurrent or worsening pain merit re-evaluation to exclude causes of secondary dysmenorrhea, such as endometriosis.<sup>208</sup> In a study of women with pelvic pain who failed to obtain adequate relief from treatment with NSAIDs, the large majority had demonstrable endometriosis at laparoscopy.<sup>234</sup> These observations suggest that women with severe dysmenorrhea who fail to respond adequately to treatment with NSAIDs or oral contraceptives are candidates for diagnostic laparoscopy. Women with endometriosis should have their disease ablated, to the extent possible. Postoperative treatment with a GnRH agonist (e.g., leuprolide acetate depot 3.75 mg every 4 weeks) is effective for the management of those (with or without endometriosis) who have persistent dysmenorrhea. Although empirical

treatment with GnRH agonists, based on clinical criteria,<sup>234</sup> has been promoted as an alternative to surgery in women having a high likelihood of endometriosis, surgical treatment offers the advantages of a specific diagnosis, immediate pain relief, and better informed longer-term management.

# MENSTRUAL MIGRAINE

Headaches are very common, but the cause is rarely serious. Most headaches result from vasodilation, muscle contraction, or psychological stress. Menstrual headaches include all headaches that are temporally related to menses, beginning before or during menstruation (Figure 14.6).<sup>235</sup> For many women with PMS, headache is part of their cyclic symptom complex. The focus here is on pure menstrual migraine, describing headaches that occur exclusively in association with menses, and on “menstrually related migraine,” describing patients who have migraines with menses but also at other times in the cycle, such as in the middle of cycle, soon after ovulation.<sup>236</sup>

FIGURE 14.6

# Pathophysiology

The traditional “vascular theory,” holding that migraine and cluster headaches result from vasodilation and the preceding aura from vasoconstriction, is no longer considered viable.<sup>237</sup> Instead, vasodilation is probably an epiphenomenon that results from instability in central neurovascular control. **Current concepts of the pathophysiology of migraine center on the trigeminovascular system.** The large cerebral vessels, those of the pia and dura mater, and the large venous sinuses are innervated by sensory afferents originating from the trigeminal ganglion and upper cervical dorsal roots.<sup>238</sup> The two converge at the trigeminal nucleus caudalis, explaining the distribution of migraine pain, which typically involves the front and back of the head and upper neck. When the trigeminal ganglion is stimulated, vasoactive neuropeptides (substance P, calcitonin gene-related peptide, neurokinin) are released,<sup>239</sup> causing neurogenic inflammation, which results in vasodilation, extravasation of plasma proteins, and pain. In turn, neurogenic inflammation may cause sensitization, describing a process in which neuronal response thresholds decrease, the magnitude of response increases, and receptive fields expand.<sup>240,241,242</sup> The sensitization phenomenon helps to explain some of the clinical symptoms of migraine, which include a worsening with coughing or bending, hyperalgesia (increased sensitivity to painful stimuli), and allodynia (pain caused by normally nonpainful stimuli). The classical aura associated with migraine headaches (visual or auditory symptoms, nausea or vomiting, paresthesias) is attributed to “cortical spreading depression,” describing a self-propagating wave of neuronal and glial depolarization that spreads across the cerebral cortex.<sup>237</sup> Migraine without aura may involve areas of the brain where depolarization is not consciously perceived.<sup>243</sup>

The incidence of migraine headache increases significantly between the ages of 15 and 19 years, peaks in women in their late 30s to early 40s, and falls after menopause.<sup>244,245,246,247</sup> Up to 70% of women with migraine headaches observe an association with menses; 7–21% have pure menstrual migraine and the remainder has menstrually related migraines.<sup>248</sup> Compared with headaches that occur at other times of the month, menstrual migraines usually are more resistant to treatment, generally not associated with aura, of longer duration, and associated with more functional disability.<sup>249,250,251,252</sup>

The association between changes in the clinical course of migraine headaches and reproductive milestones, such as menarche, pregnancy, and menopause, suggests that ovarian steroid hormones are involved in their pathophysiology. Migraine appears to be associated with declining hormone levels, as occurs at the end of the normal menstrual cycle, postpartum, and during scheduled pill-free weeks in women using oral contraceptives.<sup>253,254</sup> **Biochemical and genetic evidence suggests that menstrual**

**migraine is triggered primarily by declining estrogen levels.** Estrogen has a number of actions within the central nervous system. Its effects on the serotonergic neurotransmitter system, in particular, may explain its association with migraine.<sup>248</sup> In women, serotonergic tone correlates with estrogen levels; when estrogen levels decline, serotonin concentrations also fall, due both to a decrease in production and to an increase in clearance. Estrogen also may modulate the balance between excitatory and inhibitory neurotransmission via its effects on other chemical mediators, such as nitric oxide, magnesium, or prostaglandins.<sup>248,255</sup>

# Evaluation

Although headaches are common, they also can be an indication of a serious condition, such as an intracranial space-occupying mass, vascular lesion, infection, or a metabolic disease. Chronic headaches should be characterized according to their location, quality, changes over time, and associated symptoms and signs.

Common tension-type headaches are classified as episodic (<15 per month) or chronic ( $\geq 15$  per month).<sup>256</sup> Tension-type headaches were named originally for their suspected cause, excessive stress or tension, resulting in muscle contraction, but that traditional explanation is no longer considered viable.<sup>257</sup> Although their pathogenesis remains unclear, current models center on heightened sensitivity of pain pathways in the central nervous system and possibly in the peripheral nervous system,<sup>258,259,260</sup> nitric oxide,<sup>261</sup> and genetic factors.<sup>262,263</sup> Tension-type headaches generally are mild to moderate in intensity, are bilateral, and usually are described as “dull,” “pressure,” “a tight cap,” “band-like,” or a sense of weight on the head and shoulders. They can vary in intensity and frequency, but generally do not exhibit progression over time.

When headaches are cyclic, completely absent for periods of time, and exhibit characteristic features, they generally can be ascribed comfortably to migraine. **Migraines are characteristically throbbing in nature, frequently but not always are preceded by a prodrome, and typically begin slowly, rising to a crescendo over 1–2 hours. Most patients with migraines have had numerous similar headaches in the past.** Migraines can be precipitated by stress, alcohol, or tyramine- and tryptophan-rich foods (e.g., red wine, chocolate, ripe cheeses). Classic migraine is now known as “migraine with aura” and common migraine as “migraine without aura.” **Menstrual migraine headaches typically are migraines without aura.**<sup>247</sup>

**Headaches that are sudden in onset, persistent headaches that worsen over time, and those that become severe shortly after their onset or are associated with changes in mental status warrant careful and thorough evaluation.** Focal neurologic symptoms, other than a typical visual or sensory aura, suggest a mass lesion, arteriovenous malformation, or collagen vascular disease. Fever is not a characteristic of migraine headache and suggests an intracranial, systemic, or local infection (e.g., paranasal or mastoid sinusitis). New headaches in women over 50 or in patients with cancer or human immunodeficiency virus (HIV) infection suggest pathology. Chronic nasal congestion suggests sinusitis. Blurred vision, headaches upon waking in the morning that improve after sitting or standing, double vision or loss of balance, and worsening headaches associated with chronic nausea suggest increased intracranial pressure. Sudden unilateral loss of vision suggests optic neuritis. **Brain imaging generally is indicated for patients having a recent significant change in the pattern,**

**frequency, or severity of headaches, worsening headaches despite treatment, focal neurologic symptoms or signs, or an onset of headaches with exertion or after the age of 40 years.**<sup>264</sup>

# Treatment

The treatment for acute menstrual migraine is similar to that for common migraine; serotonin agonists (known as triptans), such as sumatriptan (50–100 mg), rizatriptan (10 mg), and frovatriptan (2.5 mg), are effective in aborting migraine headaches.<sup>265,266,267</sup> Triptans inhibit the release of vasoactive peptides, promote vasoconstriction, and inhibit neurotransmission in the trigeminal nucleus, which blocks afferent input to second-order neurons. They also help in relieving associated nausea and photophobia. When acute abortive therapy is required repeatedly or proves inadequate, prevention strategies, both hormonal and nonhormonal, merit consideration.

Hormonal prevention therapies are aimed at minimizing or eliminating the premenstrual decline in serum estrogen levels.<sup>268</sup> They are a logical choice for patients with other menstrual pathology, such as irregular cycles, dysmenorrhea, or menorrhagia, and generally are preferred over nonhormonal prevention therapies. If menstrual migraines represent a reaction to cyclic changes in circulating levels of sex steroid hormones, it's logical to try to minimize or eliminate cyclicality, which can be achieved with continuous, daily oral contraceptives. For women who prefer to have menses, extended cycle oral contraceptives containing 9–12 consecutive weeks of active pills greatly reduce their frequency; standard formulations also can be used, but in either case, estrogen supplementation should be provided during any scheduled placebo week to prevent the estrogen withdrawal migraine.<sup>269</sup> The use of oral contraceptives in women who have migraine with aura has been controversial due to concerns about a potential increase in the risk for stroke. Whereas European studies have suggested that oral contraceptives may increase the risk,<sup>270,271,272</sup> American studies have not,<sup>273,274</sup> probably because low-dose pills are more prevalent and smoking over age 35 has been regarded as a relatively strong contraindication to use of oral contraceptives in the United States (discussed in detail in [Chapter 22](#)). Nonetheless, both the World Health Organization and the American College of Obstetricians and Gynecologists currently discourage the use of oral contraceptives in women over age 35 whose migraines are associated with focal neurologic symptoms or signs.

In women with contraindications to use of oral contraceptives, estrogen supplementation still can be used to buffer the decline in estrogen levels at the end of the cycle, beginning just before the onset of menses and continuing for a total of approximately 7 days. In clinical trials, a transdermal estradiol patch (0.1 mg/day) or gel (1.5 mg/day) was effective<sup>275,276</sup> but must be continued until endogenous estrogen levels rise again or treatment merely postpones estrogen withdrawal and related migraine.<sup>276</sup> A long-acting GnRH agonist is another alternative. Clinical studies in women with menstrual migraine indicate that treatment with leuprolide acetate can

decrease markedly the frequency of headaches, even when add-back estrogen/progestin treatment is provided.<sup>277,278</sup>

The prevalence of migraine is relatively high during the perimenopause, especially in women with a history of menstrual migraine.<sup>279</sup> In the Women's Health Study, 11% of more than 17,000 postmenopausal female health professionals reported migraine; current users of hormone therapy were more often affected than never users (OR = 1.42; 95% CI = 1.24–1.62) and prevalence correlated with the dose of estrogen therapy.<sup>280</sup> **The treatment of migraine in menopausal women is not different from that in premenopausal women.** Again, hormone regimens that minimize changes in circulating estrogen levels are preferable; therefore, continuous treatment is a better choice than cyclic therapy. Addition of a progestin, when needed, does not affect the frequency of migraines.<sup>280</sup>

Nonhormonal therapies for menstrual migraines include treatment with an NSAID or a triptan. Treatment with NSAIDs, beginning 7 days before onset and continuing through the end of menses, can help to decrease the frequency, duration, and severity of menstrual migraine.<sup>281</sup> Triptan treatment, beginning 2–3 days before menses and continuing for a total of 5–6 days, effectively prevents or decreases the severity of headaches in the majority of patients. Proven regimens include sumatriptan 25 mg 3 times daily,<sup>282</sup> naratriptan 1 mg twice daily,<sup>283</sup> and frovatriptan 2.5 mg daily or twice daily.<sup>284</sup>

The newest class of agents for preventive treatment of migraine target calcitonin gene-related peptide (CGRP) signaling. Erenumab is a monoclonal antibody to CGRP receptor that has recently been approved in the United States for the preventive treatment of migraine in adults<sup>285</sup>; efficacy of this class of drugs against menstrual migraines is, however, yet to be demonstrated.

# CATAMENIAL EPILEPSY

---

In ancient times, catamenial epilepsy was attributed to the moon, giving rise to the word, “lunatic.”<sup>286</sup> The word, “catamenial,” derives from the Greek word katomenios, meaning “monthly.” Catamenial epilepsy describes seizures that are clustered around specific points in the menstrual cycle, usually during the perimenstrual or periovulatory intervals. **The diagnosis of catamenial epilepsy is based on demonstrating the temporal relationship between menstruation and seizure activity; a twofold or greater increase in seizure frequency during a particular phase of the menstrual cycle generally is considered as evidence of catamenial epilepsy.**<sup>287,288</sup> Based on that definition, catamenial epilepsy affects from 30% to 60% of women with epilepsy.<sup>289,290,291</sup> Given that epilepsy affects an estimated 1.3 million women in the United States,<sup>292,293</sup> approximately 400,000 women with epilepsy experience catamenial seizures, which often are quite resistant to treatment.<sup>294</sup>

# Pathophysiology

Catamenial seizures are associated with every type of epilepsy but are more common among women with focal epilepsy (e.g., temporal lobe epilepsy) than in those with generalized epilepsy.<sup>295</sup> Their specific cause is still unclear. Hypotheses include fluctuations in antiepileptic drug levels, changes in water and electrolyte balance, and variations in ovarian steroid hormone secretion.<sup>288</sup> Cyclic changes in estrogen and progesterone across the menstrual cycle are widely regarded as playing a central role. There are three recognized patterns that relate to timing of occurrence of seizures in the menstrual cycle: perimenstrual, periovulatory, and inadequate luteal (in anovulatory cycles).<sup>296</sup>

**Estrogens generally are considered as proconvulsant, although their effects depend on the duration of treatment, dosage, the mode of administration, and the seizure model.** Estrogens affect neuronal excitability via modulation of gene expression, regulation of neurotransmitter release, and direct interaction with neurotransmitter receptors. Estrogen acts on neurons within the limbic system, cerebral cortex, and other regions important for seizure susceptibility.<sup>297</sup> Estrogen also interacts with neurotrophins, which enhance hippocampal excitability. In women with epilepsy, seizure susceptibility correlates with the estrogen/progesterone ratio, which peaks in the premenstrual and preovulatory intervals. Although serum estradiol concentrations in women with catamenial epilepsy are similar to those in normal controls across the menstrual cycle, evidence suggests that progesterone levels are lower and estrogen/progesterone ratios are higher.<sup>291,298</sup> Seizure frequency decreases during the midluteal phase when progesterone levels are highest and increases in the premenstrual phase when progesterone levels fall and the estrogen/progesterone ratio increases.

**Progesterone generally is considered to have an anticonvulsant action, by lowering seizure susceptibility.** Changes in serum progesterone levels have been correlated directly with catamenial seizures,<sup>291,298</sup> and evidence from studies in mice supports the concept that 5 $\alpha$ -reduced metabolites of progesterone, particularly allopregnanolone, are responsible for its antiseizure activity.<sup>288,299</sup> Neurosteroids like allopregnanolone are synthesized locally within the brain, both de novo and from circulating steroid precursors, and modulate neural excitability. Allopregnanolone potentiates the action of GABA, the major inhibitory neurotransmitter in the brain, via modulation and direct interaction with GABA-A receptors.<sup>300</sup>

The interactions between gonadal steroid hormones, seizures, and antiepileptic drugs are complex. Whereas gonadal steroid hormones can affect seizure susceptibility, seizures may disrupt patterns of steroid hormone secretion, and antiepileptic drugs can affect sex steroid hormone levels by altering their metabolism. In adolescents with

epilepsy, the incidence of generalized tonic-clonic seizures often increases during puberty,<sup>301</sup> when the levels of steroid hormones increase and menses begin. At menopause, seizure activity increases in some women but decreases or remains unchanged in others.<sup>302,303,304</sup> Hormone therapy can increase seizure activity in postmenopausal women, particularly in those having a history of catamenial epilepsy.<sup>305,306</sup> On the other hand, the prevalence of menstrual disorders such as polycystic ovary syndrome is increased,<sup>307</sup> and fertility is decreased among women with epilepsy,<sup>308</sup> suggesting that seizures may predispose to reproductive dysfunction, possibly by altering the pattern of hypothalamic GnRH release. The association between epilepsy and reproductive dysfunction also might reflect the effects of antiepileptic drugs on steroid hormone metabolism. Some, such as phenytoin, carbamazepine, and phenobarbital, induce hepatic cytochrome P450 enzymes, which can accelerate the metabolism of steroid hormones that share common metabolic pathways.<sup>309,310</sup> They also can increase serum SHBG concentrations, thereby further decreasing the concentrations of free or biologically active steroids. Other antiepileptic drugs, such as sodium valproate, inhibit hepatic enzymes, which may increase bioactive steroid hormone levels. However, there is no direct evidence linking catamenial epilepsy with specific antiepileptic drugs. The extent to which all of these competing mechanisms contribute to catamenial epilepsy remains to be determined.

Some studies have suggested that oral contraceptives might increase seizure activity, but most have observed no effect<sup>305,311,312</sup> or a decrease in seizure frequency.<sup>313,314</sup> Although certain antiepileptic drugs have the potential to reduce the efficacy of oral contraceptives by accelerating their metabolism,<sup>305,315</sup> there is no evidence the effect is clinically important.<sup>316,317,318,319</sup> Conversely, oral contraceptives can decrease circulating concentrations of some antiepileptic drugs via the same mechanism, which may increase the risk of seizures<sup>320</sup>; evidence indicates that women receiving treatment with lamotrigine or valproic acid may need dosage adjustments if also using oral contraceptives.<sup>319,321,322</sup>

# Treatment

Antiepileptic drugs are the mainstay in the management of catamenial epilepsy. However, approximately one-third of women with catamenial seizures require treatment with more than one drug, partly because catamenial epilepsy often proves refractory to conventional medications. At least in theory, gabapentin, levetiracetam, tiagabine, zonisamide, and pregabalin are attractive choices, because they do not induce hepatic enzymes. Acetazolamide, a potent inhibitor of carbonic anhydrase, has been used empirically for years in the treatment of catamenial epilepsy, but there are few direct studies attesting to its effectiveness<sup>324</sup>; drug tolerance, requiring progressive dosage escalation, is a common problem. Benzodiazepines, such as clonazepam and clobazam, increase GABA-A receptor activity and have broad-spectrum antiseizure activity. Clobazam (20–30 mg daily), administered intermittently from 2 to 4 days before menses through the first 3 days of bleeding, has proven effective for the treatment of catamenial epilepsy; intermittent treatment helps to avoid problems with tolerance, which otherwise is common.<sup>325</sup> Limited evidence suggests that treatment with lamotrigine (25–200 mg daily) can decrease or eliminate catamenial seizures, at least in some women.<sup>326</sup> Ganaxolone, a synthetic neurosteroid (a 3 $\beta$ -methyl analog of allopregnanolone) that has shown promise in preclinical models of catamenial epilepsy and preliminary investigations in women,<sup>327</sup> is now in clinical trials.<sup>328</sup>

Hormonal therapies for the management of catamenial seizures also deserve consideration, particularly for women who prove resistant to antiepileptic drugs. Treatment with depot medroxyprogesterone acetate in doses that typically eliminate menses (e.g., 150 mg intramuscularly every 3 months) can improve seizure control in many women.<sup>329</sup> Cyclic natural progesterone also has been demonstrated effective for the treatment of catamenial seizures; 100–200 mg, administered orally or vaginally 3 times daily between days 15 and 28 of the cycle, decreased seizure frequency by approximately 50–75%.<sup>330,331</sup> A randomized controlled trial that was sponsored by the National Institute of Health in the United States compared bioidentical progesterone with placebo in the treatment of focal onset epilepsy. While progesterone was no better than placebo against seizures, subgroup analyses identified benefit of progesterone in women specifically experiencing perimenstrual exacerbation of seizure activity.<sup>332,333</sup> Evidence from studies in animal models and clinical data suggest the antiseizure effects of progesterone derive from its metabolic conversion to neurosteroids, primarily allopregnanolone.<sup>334,335</sup> Continuous oral contraceptives, the progestin-only minipill,<sup>336</sup> and GnRH agonists with add-back estrogen/progestin therapy also have demonstrated some effectiveness in small numbers of women with catamenial epilepsy.<sup>337,338,339</sup>

In sum, catamenial epilepsy is a complex and multifaceted condition. Ovarian

hormones play a central role but the exact cause is unknown. Evidence indicates that estrogen, progesterone, and endogenous neurosteroids are involved in its pathophysiology, but no specific hormonal dynamic predisposing to seizures has been identified. Neurosteroid withdrawal may be the critical factor that increases seizure susceptibility during the perimenstrual interval, acting via changes in central GABA-A receptors. Conventional antiepileptic drugs are not effective in most patients with catamenial seizures, possibly because they can alter sex steroid concentrations and metabolism. Hormonal therapies, such as progesterone, oral contraceptives, and GnRH agonists, have proven efficacy. Finally, newly developed synthetic neurosteroids have shown considerable promise in animal studies of catamenial epilepsy and may offer a specific treatment in the future.

# PREMENSTRUAL ASTHMA

---

Approximately 20–40% of women with asthma have an increase in symptoms associated with menstruation.<sup>340,341,342</sup> Even asthmatics not aware of a link to menses demonstrate a worsening of pulmonary function during menstruation.<sup>343,344</sup> Women with hormonally triggered asthma generally tend to have more severe asthma than those whose asthma is not affected by changes in hormones. The mechanism is unknown, but prostaglandin release, changes in the immune system, and a direct effect of declining estrogen and progesterone levels on bronchial smooth muscle all have been suggested.

The best method for treating premenstrual asthma has not been established. Treatment with estrogen (micronized estradiol, 2 mg orally daily) has been reported to improve symptoms and measures of pulmonary function.<sup>344</sup> A randomized clinical trial found no difference between the effects of estrogen and placebo, although the subjects all had mild asthma generally under good control.<sup>345</sup> Another study found that administration of intramuscular progesterone helped to ameliorate premenstrual asthma.<sup>346</sup> The logic of eliminating menstrual periods by daily treatment with oral contraceptives, intramuscular depot medroxyprogesterone acetate, or treatment with a long-acting GnRH agonist is tempting, but there are no available data demonstrating their efficacy. Alternatives include a rescue inhaler, when necessary, or a leukotriene modifier, such as montelukast, zafirlukast, or zileuton.

# CATAMENIAL PNEUMOTHORAX, HEMOTHORAX, AND HEMOPTYSIS

---

Thoracic endometriosis syndromes are closely linked to the presence of pelvic endometriosis. In a retrospective analysis of 110 cases, the mean age at presentation of thoracic endometriosis was  $35 \pm 0.6$  years, with a range from 15 to 54 years.<sup>347</sup> Catamenial pneumothorax was the most common presentation, occurring in 80/110 patients (73%); catamenial hemothorax occurred in 15 (14%), catamenial hemoptysis occurred in 8 (7%), and lung nodules were observed in 7 (6%). Fifty-one of sixty-one patients who underwent laparoscopy or laparotomy had evidence of pelvic endometriosis. Pleural implants were observed in less than 15% of those who had thoracostomy or thoracotomy, and diaphragmatic defects, parenchymal cysts, or blebs were observed in approximately 25% of cases.<sup>347</sup>

The most plausible explanations for catamenial pneumothorax, hemothorax, and hemoptysis are peritoneal to pleural transfer of endometrial tissue through diaphragmatic defects<sup>348,349</sup> and microembolization through pelvic veins.<sup>347</sup> A review of 154 cases of catamenial pneumothorax treated surgically found that 16% of patients had demonstrable diaphragmatic perforations in the absence of thoracic endometriosis and 12% had visible diaphragmatic endometriosis associated with one or more perforations.<sup>350</sup>

In affected women, symptoms of thoracic endometriosis typically arise within 24–48 hours after the onset of menses. Chest pain is the most common symptom, occurring in 90% of patients, and one-third have dyspnea. Pneumothorax occurs most commonly on the right side and usually is small to moderate in size; hemothorax also usually is right sided.<sup>351,352</sup> Women with endobronchial or pulmonary parenchymal endometriosis usually present with catamenial hemoptysis.

The diagnosis of thoracic endometriosis should be suspected in reproductive-aged women presenting with recurrent chest pain, pneumothorax, or hemoptysis during menses. Although not required, diagnosis can be established by pleural fluid cytology,<sup>353</sup> needle aspiration of lung masses,<sup>354</sup> cytology performed on bronchoscopic aspirations,<sup>355</sup> or video thoracoscopy.<sup>356</sup> In a systematic review of 182 women with catamenial pneumothorax who underwent video-assisted thoracoscopic surgery, endometrial implants were noted in 59% and 57% had evidence of diaphragmatic perforations. Pelvic endometriosis was reported in 39.5%. Notably, those with diagnosed pelvic endometriosis showed a significantly higher rate of thoracic endometrial implants and histologically confirmed endometriosis lesions than patients without pelvic endometriosis.<sup>355</sup> In women with catamenial pneumothorax, chest

computerized tomography (CT) can reveal bullae, cavities, or fibrosis and, in those with hemoptysis, can demonstrate small parenchymal nodules, which may be visible only during the menstrual phase of the cycle.<sup>358,359</sup>

The initial treatment of patients with symptomatic thoracic endometriosis is the same as for others with pneumothorax, hemothorax, or hemoptysis. Longer-term, successful treatment requires suppression or excision of thoracic endometrial implants, prevention of re-seeding from the pelvis, and prevention of air leakage across diaphragmatic perforations. Although hormonal suppressive treatments (e.g., oral contraceptives, progestins, danazol, GnRH analogs) generally are considered first-line therapy, the recurrence rate is greater than 50%.<sup>347</sup> When they fail, surgical treatment is indicated. Direct inspection of the pleura via video thoracoscopy or thoracotomy can identify diaphragmatic endometrial implants or perforations, which can be excised or closed, usually followed by chemical pleurodesis using talc poudrage (blowing powder or an aerosol into the pleural cavity) or pleural abrasion.<sup>350,352</sup> Surgical treatments generally are very effective for preventing recurrent catamenial pneumothorax or hemothorax, but some who continue to have cyclic chest pain due to pleuropulmonary implants may require longer-term medical suppressive therapy.<sup>360</sup>

# VASOVAGAL SYNCOPE

---

Vasovagal syncope (VVS) is a disorder of autonomic regulation, in which sudden postural changes contribute to transient global cerebral hypoperfusion that results in brief loss of consciousness.<sup>361,362</sup> VVS is much more common in women than men, and in some women, the frequency of episodes is higher in the menstrual phase.<sup>363</sup> In a prospective study, the occurrence of syncope induction by head-up tilt test (HUTT) differed by the phase of menstrual cycle (follicular and luteal), among premenopausal women; a vasodepressive type of vasovagal syndrome occurred more often in follicular than in luteal phase.<sup>364</sup> Others have failed to identify any relevance of timing of menstrual cycles on results of tilt table test.<sup>365</sup> Notably, provoked responses did not differ between pre and postmenopausal women.<sup>364</sup>

---

# Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) is the single most common complaint that reproductive-age women bring to their clinicians. All clinicians who provide primary care for women must therefore be familiar with its causes and have an organized, logical approach to the evaluation and treatment of the problem.

Management of AUB requires familiarity with the reproductive endocrinology and functioning of the hypothalamo-pituitary-ovarian (HPO) axis and determinants of ovulatory response, awareness of mechanisms that underlie both onset as well as cessation of menstruation, and knowledge of the various common and uncommon gynecologic and systemic disorders that can contribute to AUB. Dysfunctions of endocrinology, disorders of physiology of ovulation, and disturbances of hematologic factors as well as local uterine anatomical structures that are important for cessation of menses can all present as AUB. A careful menstrual as well as medical history and physical examination usually provide most of the information needed to distinguish functional causes (such as anovulation) from structural causes (such as endometrial polyps, fibroids) of abnormal bleeding.

# TERMINOLOGY (OLD AND NEW)

---

Historically, clinicians have used a wide variety of terms to describe abnormal patterns of menstrual bleeding that do not always mean or communicate the same thing to others. Traditional terms ([Table 15.1](#)) having Greek or Latin roots have long been used to describe different abnormalities relating to the frequency, regularity, duration, and volume of menstrual bleeding.

## **TABLE 15.1 Traditional Terms Describing Abnormalities of Menstrual Bleeding (Old Nomenclature)**

Term	Description
Amenorrhea	Absent menses
Oligomenorrhea	Menses less frequent than every 35 days
Polymenorrhea	Menses more frequent than every 21 days
Metrorrhagia	Menses at irregular intervals
Menorrhagia	Abnormally long or heavy menses, lasting >7 d
<i>or</i>	<i>or</i>
Hypermenorrhea	Involving blood loss >80 mL

Although these definitions are reasonably well established, the terms are not always used or understood accurately.<sup>1,2</sup> For example, in the United States, the term **abnormal uterine bleeding** generally describes all abnormal patterns of bleeding that may result from a wide variety of causes, including anovulation, pregnancy, uterine pathology, and coagulopathies.<sup>3</sup> The older term **dysfunctional uterine bleeding** has been used as synonymous with anovulatory bleeding, in the absence of pregnancy or any demonstrable pathology (a diagnosis of exclusion), and the term **menorrhagia** describes regular, but heavy or prolonged, bleeding. However, in other countries, dysfunctional uterine bleeding and menorrhagia often are used to describe both ovulatory (regular) and anovulatory (irregular) bleeding that is heavy or prolonged.<sup>1</sup> The confusion surrounding the exact meaning of the traditional terms has spurred a call to abandon them, in favor of simple terms that can be understood by patients and translated easily into languages other than English, with the ultimate goal of improving communication among health care providers, investigators, and patients. To that end, recommendations arising from an international consensus conference proposed terms to describe the most important features of menstrual bleeding during the reproductive years, as shown in [Table 15.2](#).<sup>1</sup>

**TABLE 15.2 Descriptive Terms for Menstrual Abnormalities**

<b>Characteristic</b>	<b>Descriptive Terms</b>	<b>Normal Limits</b>
Frequency of menses	Frequent	<24 d
	Normal	24–38 d
	Infrequent	>38 d
Regularity (cycle to cycle variation)	Absent	—
	Regular	±2–20 d
	Irregular	>20 d
Duration of flow	Prolonged	>8 d
	Normal	4–8 d
	Shortened	<4 d
Volume of monthly blood loss	Heavy	>80 mL
	Normal	5–80 mL
	Light	<5 mL

The suggested normal limits for frequency, regularity, and duration of menstrual flow were based on the 5th and 95th percentiles for data drawn from population studies.<sup>4,5,6</sup> As such, they are influenced by the prevalence of common anovulatory disorders, such

as the polycystic ovary syndrome (PCOS), in a given population. Consequently, the population-based norms are wider than the generally accepted norms for menstrual frequency (24–35 days), regularity ( $\pm 5$  days variation), and duration (2–7 days) among ovulatory women. The normal limits for the volume of menstrual blood loss were based primarily on measurements of hemoglobin loss in a Swedish community.<sup>4</sup> It is important to note that, while heavy menstrual bleeding is officially defined by a volume measurement, it is more meaningful and clinically recommended to define heavy menstrual bleeding based upon its impact on a woman’s quality of life, with consideration to both objective and subjective measures. The expectation is that a structured menstrual history can clarify the details needed to categorize a patient’s complaint in clear and simple terms (e.g., irregular, heavy menstrual bleeding).<sup>7,8</sup>

### International Federation of Gynecology and Obstetrics (FIGO) Classification System for AUB: New Nomenclature

In the early 2000s, there was a global push to move away from the traditional terminology that focused on descriptives with little guidance on interpretability across regions and populations, toward a more standardized nomenclature.<sup>9,10,11,12</sup> The proposed system leaves little room for misinterpretation while allowing an appreciation of the underlying mechanisms for the clinical presentation of AUB. The differential diagnoses for AUB are comprehensively encapsulated in the acronym PALM-COEIN, as shown in **Figure 15.1**. This new classification scheme for AUB was developed by the FIGO with input from clinicians across the globe to maximize its applicability in a variety of contexts.

**FIGURE 15.1**

# NORMAL MENSTRUAL BLEEDING

---

It is ovulation (or, more specifically, the organized sequence of endocrine signals that characterizes the ovulatory cycle) that gives menses regularity, predictability, and consistency. The endocrinology of the normal menstrual cycle is discussed in detail in [Chapter 5](#). Only the most basic concepts and characteristics are summarized here, with a focus on the major events and mechanisms that control the endometrial cycle and the volume and duration of menstrual flow.

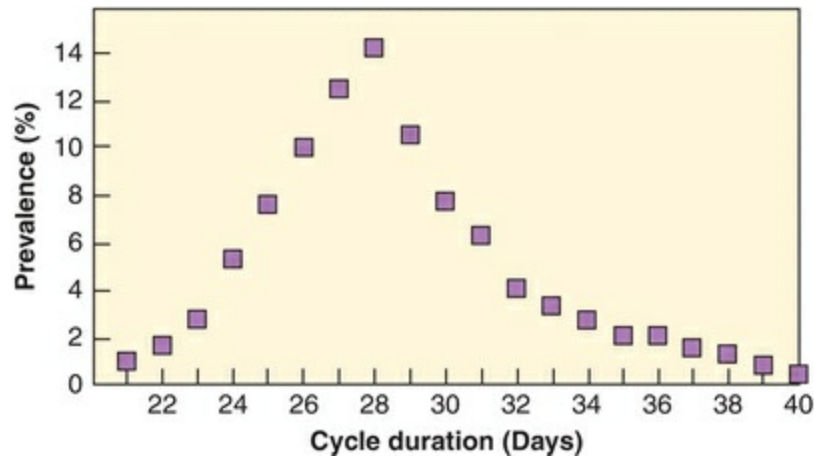

During the follicular phase of the normal ovarian cycle (corresponding to the proliferative phase of the endometrial cycle), estrogen levels rise, slowly at first and then more rapidly, as the dominant ovarian follicle emerges, grows, and matures. In response to that estrogen, the functional layer of the endometrium regrows, after having been shed during the preceding menses. After ovulation, the corpus luteum derived from the ovulatory follicle continues to produce estrogen but now (and more importantly) also progesterone. During the luteal phase of the ovarian cycle (corresponding to the secretory phase of the endometrial cycle), estrogen and progesterone levels rise together as the corpus luteum grows to maturity. In response to the combined actions of estrogen and progesterone, the endometrium transforms and organizes in preparation for the anticipated arrival and implantation of a conceptus. If pregnancy and rapidly rising levels of human chorionic gonadotropin (hCG) do not come to its “rescue,” the corpus luteum regresses spontaneously in a form of preprogrammed cell death. As it does, estrogen and progesterone levels fall steadily, eventually withdrawing the functional support for the endometrium. Menses begin, marking the end of one endometrial cycle and the beginning of another.

From the endometrial perspective, the endocrine features of the ovarian cycle are quite simple; the quantities of hormones produced are not nearly as important as the sequence in which they appear: estrogen, followed by estrogen and progesterone, followed by withdrawal of both hormones. Of all the different hormone effects on the endometrium, estrogen-progesterone stimulation produces the most stable endometrium, and their combined withdrawal yields the most consistent menstrual characteristics. **The sequence is so controlling that most ovulatory women have a pattern, volume, and duration of menstrual flow they recognize as their own and come to expect, very often accompanied by an equally consistent and predictable pattern of premenstrual molimina (such as bloating, breast tenderness, and mood swings).** Even slight deviations from the usual pattern in the timing, amount, or length of flow can cause concern. Careful attention to the finer details of the menstrual history can be very helpful in distinguishing anovulatory bleeding from other causes.

Variations in menstrual flow and cycle length are common at the extremes of

reproductive age (i.e., during the early teenage years and those preceding the menopause). Menstrual cycles often are irregular for the first 12–18 months after menarche, due to immaturity of the HPO axis.<sup>13,14</sup> In a study conducted by the World Health Organization, the median length of the first cycle after menarche was 34 days; almost 40% of cycles were longer than 40 days and fewer than 10% were less than 20 days.<sup>15</sup> Cycles remain relatively long for the first 5–7 years after menarche, thereafter decreasing gradually in length and becoming more regular.<sup>15</sup> The prevalence of anovulatory cycles is higher in women under age 20 and over age 40.<sup>16,17</sup> Menstrual cycle characteristics generally do not change appreciably during the reproductive years,<sup>6</sup> although overall cycle length and variability slowly decrease. On average, mean cycle length and range reach their lows at about age 40–42.<sup>6,18</sup> Over the subsequent 8–10 years before the menopause, the trend is reversed; both average cycle length and variability increase steadily as ovulation becomes less regular and frequent.<sup>5,18,19,20</sup> Mean cycle length is greater in women at the extremes of body mass and composition; both high and low body mass index (BMI), body fat mass, and body lean mass are associated with an increased mean cycle length.<sup>21,22</sup>

In general, variations in cycle length reflect differences in the length of the follicular phase of the ovarian cycle (**Figure 15.2**). Women who have a 25-day cycle ovulate on or about cycle day 10–12, and those with a 35-day cycle ovulate approximately 10 days later. Within a few years after menarche, the luteal phase becomes extremely consistent (13–15 days in duration) and remains so until the perimenopause.<sup>5,18</sup> At age 25, over 40% of cycles are between 25 and 28 days in length, and between age 25 and 35, over 60% are. **Although 28 days is the most commonly reported intermenstrual interval, only approximately 15% of cycles among reproductive-aged women actually are 28 days in length.** Less than 1% of women have a regular cycle lasting less than 24 days or more than 35 days.<sup>23</sup> Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles.<sup>6</sup>

**FIGURE 15.2**

The usual duration of menstrual flow is 4–6 days, but for some women (approximately 3%), menses may last as few as 2 days or as many as 7 days.<sup>24</sup> The average volume of menstrual blood loss is approximately 30 mL<sup>4</sup>; greater than 80 mL is abnormal. Flow can be excessive without being abnormally long because most of the menstrual blood loss occurs during the first 3 days.<sup>25,26</sup>

**Women who menstruate more often than every 24 days or less often than every 35 days deserve evaluation,<sup>5,6</sup> as do those who consistently flow for more than 7 days and women with monthly menstrual blood loss exceeding 80 mL.** Any of these abnormal patterns can result in anemia that also requires treatment.<sup>27,28</sup> The intermenstrual interval and duration of menses are relatively easy to determine, but the volume of menstrual blood loss is difficult to measure. The correlation between perceived and actual blood loss is relatively poor.<sup>29</sup> In population-based studies, one-fourth to one-third of women with normal periods considered their menstrual blood loss excessive, and 40% of those with documented menorrhagia (blood loss >80 mL) described their menses as light or moderate.<sup>4,30</sup> Complaints of heavy menstrual bleeding appear to relate more to perceived interference with daily function than to actual blood loss,<sup>31</sup> and evidence indicates that psychosocial factors may have significant influence on those perceptions; the incidence of depression and anxiety is increased among women with complaints of heavy menstrual bleeding.<sup>32,33,34</sup>

# Mechanisms Controlling Onset and Cessation of Normal Menstruation

A conceptual understanding of the mechanisms involved in the onset and cessation of normal menstrual bleeding provides both the foundation and the context for understanding the pathophysiology of anovulatory bleeding.

The classic concepts of normal menstruation derived primarily from direct observations of the cyclic changes in endometrium transplanted from the uterus to the anterior chamber of the eye in nonhuman primates; vascular events played the key role in the explanation of how menses both began and ended.<sup>35,36</sup> Basically, menstruation was envisioned as ischemic necrosis of the endometrium caused by vasoconstriction of the spiral arterioles in the basal layer, triggered by withdrawal of estrogen and progesterone. Similarly, the end of menses was explained by longer and more intense waves of vasoconstriction, combined with coagulation mechanisms activated by vascular stasis and endometrial collapse, aided by rapid reepithelialization mediated by estrogen derived from the emerging new follicular cohort.

The results of more contemporary investigations do not support the classic hypoxia theory of menstruation. Perfusion studies in women have failed to demonstrate reduced endometrial blood flow just before menses.<sup>37</sup> Hypoxia-inducible factor (HIF)-1, a nuclear protein that activates gene transcription in response to reduced cellular oxygen (the earliest known marker of response to hypoxia), is barely detectable and not widely distributed in human premenstrual endometrium cultured under hypoxic conditions.<sup>38</sup> Histologically, early menstrual endometrium exhibits focal necrosis, inflammation, and coagulation rather than the diffuse hyalinization or coagulation necrosis that would be expected to result from vasoconstriction and hypoxia.<sup>39</sup> Thus, the operational paradigm for menstruation has shifted. **Instead of vascular events, the central theme of the current model of the initiation of menstruation is an enzymatic autodigestion of the functional layer of the endometrium and its subsurface capillary plexus, possibly extending to the spiral arteriolar system in the basal layer.**<sup>39</sup> **The classic concept of the mechanisms that end normal menstruation is essentially unchanged; coagulation mechanisms, local vasoconstriction, and reepithelialization all contribute to hemostasis in the menstrual endometrium with vascular events playing the key role.**

The enzymatic degradation of the endometrium triggered by estrogen-progesterone withdrawal involves a number of different but interrelated mechanisms including the release of intracellular lysosomal enzymes, proteases from infiltrating inflammatory cells, and the actions of matrix metalloproteinases (MMPs). In the first half of the

secretory phase, acid phosphatase and other potent lytic enzymes are confined to intracellular lysosomes, their release inhibited by progesterone via stabilization of lysosomal membranes. As estrogen and progesterone levels fall in the days preceding menses, lysosomal membranes destabilize, and the enzymes within are released into the cytoplasm of epithelial, stromal, and endothelial cells and, eventually, into the intercellular space. These proteolytic enzymes digest their cellular constraints as well as surface membranes and desmosomes (intercellular bridges). In the vascular endothelium, their actions result in platelet deposition, prostaglandin release, vascular thrombosis, extravasation of red blood cells, and tissue necrosis.<sup>39,40</sup>

Progesterone withdrawal also stimulates an inflammatory response in the endometrium. Just before menstruation, the total number of leukocytes in the endometrium increases markedly to as much as 40% of the stroma.<sup>41,42</sup> The inflammatory infiltrate (including neutrophils, eosinophils, and macrophages or monocytes) is drawn by chemoattractive molecules (chemokines) synthesized by endometrial cells, some of which are down-regulated by progesterone (such as IL-8 and MCP-1).<sup>41</sup> When activated, the leukocytes produce a wide assortment of regulatory molecules including cytokines, chemokines, and a range of enzymes (including MMPs) that contribute to degradation of the extracellular matrix, directly or indirectly, via activation of other proteases.

Matrix metalloproteinases are a family of proteolytic enzymes that degrade components of the extracellular matrix and basement membrane.<sup>43</sup> The metalloproteinases include collagenases that degrade interstitial and basement membrane collagens, gelatinases that further digest collagens, and stromelysins that attack fibronectin, laminin, and glycoproteins. Each member of the family is substrate specific and secreted as an inactive zymogen that requires activation by plasmin, leukocyte proteases, or other metalloproteinases. The expression, secretion, and activation of endometrial MMPs are cycle dependent and increases markedly in the late secretory phase just before menstruation.<sup>44,45</sup> Overall, progesterone inhibits endometrial metalloproteinase expression, an action mediated by transforming growth factor beta (TGF- $\beta$ ).<sup>46</sup> Progesterone withdrawal has the opposite effect—increased metalloproteinase secretion and activation, followed by dissolution of the extracellular matrix.<sup>47</sup> Local modulators (predominantly cytokines), derived from endometrial epithelial, stromal, and endothelial cells, and natural tissue inhibitors of MMPs (which bind the active form of the enzymes) also play an important role in their regulation.<sup>48</sup> In cycles of conception wherein elevated progesterone levels are sustained, MMP activity remains effectively suppressed. In the normal menstrual cycle, metalloproteinase expression is suppressed again after menses, presumably by increasing estrogen levels.

Progressive enzymatic degradation of the endometrium eventually disrupts the

subsurface capillary and venous vascular system, causing interstitial hemorrhage; dissolution of the surface membrane allows blood to escape into the endometrial cavity. Ultimately, degeneration extends to the deepest extent of the functional layer where rupture of the basal arterioles contributes to bleeding. A natural cleavage plane develops at the junction of the loose, vascular, edematous stroma with the basal layer. Desquamation begins in the fundus and gradually extends toward the isthmus. The end result is the typical deflated and shallow but dense menstrual endometrium.<sup>49,50</sup>

The menstrual fluid is comprised of an autolyzed endometrium rich in inflammatory exudates, red blood cells, and proteolytic enzymes.<sup>39,50</sup> One of those enzymes, plasmin (formed by activation of its inactive precursor, plasminogen), has potent fibrinolytic actions that help to prevent clotting of menstrual fluid and to facilitate the expulsion of degenerated tissue. Plasminogen activators that mediate the conversion of plasminogen to plasmin are found in late secretory and menstrual endometrium and are released from degenerated endometrial vascular endothelium.<sup>39,50</sup> The volume of menstrual bleeding is controlled, at least to some extent, by the local balance between fibrinolysis and clotting. Endometrial stromal cell tissue factor and plasminogen activator inhibitor (PAI)-1 promote clotting and help to balance fibrinolytic processes.<sup>51,52,53</sup> Early in menstruation, intravascular platelet plugs (and, later, thrombi) form at the shedding surface, helping to limit blood loss. Their importance to hemostasis in the menstrual endometrium can be inferred from the increased volumes of menstrual blood loss observed in women with thrombocytopenia and von Willebrand disease. Ultimately, however, the cessation of menstrual bleeding depends on vasoconstriction in the denuded spiral arterioles in the basal layer of the endometrium and also possibly in the radial arteries of the superficial myometrium. Endothelins are potent long-acting vasoconstrictors of vascular smooth muscle produced by endometrial glandular, stromal, and endothelial cells. Menstrual endometrium contains high concentrations of endothelins and prostaglandins, which together cause intense vasoconstriction in the spiral arterioles.<sup>39</sup> The myometrial contractions associated with menstrual events very likely reflect the actions of prostaglandin  $F_{2\alpha}$ ; however, in contrast to postpartum bleeding, myometrial contractions are not important for control of menstrual bleeding.

Surface reepithelialization also contributes to hemostasis in the menstrual endometrium. The process occurs very rapidly, beginning at the mouth of the basal portions of residual glands in areas otherwise completely denuded and spreading outward. The peripheral regions of the cavity at the isthmus and near the tubal ostia (which do not shed during menses) also contribute to its resurfacing.<sup>42,50</sup> Generally, by cycle day 5, these scattered areas of epithelial proliferation converge and fuse; bleeding stops completely only when the new epithelial surface is complete. The mechanisms that govern this initial phase of tissue repair and the role that estrogen has, if any, are

uncertain. In the first few days of the new cycle, circulating estrogen levels and endometrial estrogen and progesterone receptor concentrations are low and unchanged from premenstrual levels.<sup>54,55</sup> Moreover, even after oophorectomy and vigorous endometrial denudation, the endometrium heals, suggesting that the initial phase of tissue repair is largely independent of estrogen.<sup>42,50</sup>

The stroma regenerates from stem cells located in the basal layer of the endometrium but only after a confluent surface epithelium has been restored. Damaged endometrial vessels are quickly repaired. New vessel growth and mitotic activity in all parts of the regenerated human endometrium coincide with increasing serum estrogen levels and rising endometrial estrogen and progesterone receptor concentrations.<sup>42,50</sup> MMPs present in the menstrual endometrium and other proteases may be important mediators of the release and activation of growth factors needed for endometrial repair. Vascular endothelial growth factor (VEGF) is an important promoter of endometrial mitosis and can be induced by tumor necrosis factor (TNF)- $\alpha$ , TGF- $\beta$ , and insulin-like growth factor-1.<sup>39,56,57</sup> Experimental evidence derived from model systems suggests that activins and other members of the TGF- $\beta$  superfamily also may play a role.<sup>42,58</sup>

**There are two basic reasons why normal menstrual bleeding is self-limited.**

1. In response to a simultaneous estrogen-progesterone withdrawal, endometrial shedding is universal. Because the onset and end of menses relate to organized cyclic hormonal events, menstrual changes occur uniformly, throughout the endometrial cavity. Shedding of the functional layer and exposure of the basal regenerative layer of the endometrium stimulate coagulation, vasoconstriction, and epithelial reconstruction mechanisms that effectively limit the volume and duration of bleeding.
2. In response to cyclic sequential estrogen-progesterone stimulation, growth and development of the endometrial epithelium, stroma, and microvasculature is structurally stable and random breakdown is avoided. The sequence of events leading to the enzymatic disintegration of the endometrium proceeds in an orderly and synchronous fashion. The endometrium is not just repaired, but is completely remodeled, at regular intervals.

# **ENDOMETRIAL RESPONSES TO STEROID HORMONES: PHYSIOLOGIC AND PHARMACOLOGIC**

---

The normal menstrual bleeding that occurs at the end of an ovulatory cycle results from estrogen-progesterone withdrawal. The same mechanism operates when the corpus luteum is removed or when its gonadotropin support is suddenly interrupted during the luteal phase, such as by treatment with a gonadotropin-releasing hormone (GnRH) antagonist. Other examples include the bleeding that follows discontinuation of both estrogen and progesterone in women receiving cyclic postmenopausal hormone therapy and the bleeding that comes at the end of a standard cycle of treatment with an estrogen-progestin contraceptive. The bleeding that follows estrogen-progesterone withdrawal generally is regular, predictable, and consistent in volume and duration. However, estrogen-progesterone withdrawal is not the only pattern of steroid hormone signals that can provoke endometrial bleeding. Bleeding also can result from estrogen withdrawal, estrogen breakthrough, progestogen withdrawal, and progestogen breakthrough.

# **Estrogen Withdrawal Bleeding**

One clinical example of estrogen withdrawal bleeding is that which may follow bilateral oophorectomy during the follicular phase of the cycle. The bleeding that occurs after removal of the ovaries can be delayed by exogenous estrogen therapy but will occur when treatment stops. Other examples include cyclic estrogen-only hormone therapy in castrate or postmenopausal women and the midcycle bleeding that can accompany the transient but abrupt fall in estrogen levels immediately preceding and following ovulation.

# Estrogen Breakthrough Bleeding

The best clinical examples of estrogen breakthrough bleeding are the different patterns of bleeding observed in women with chronic anovulation. The amount and duration of estrogen breakthrough bleeding can vary widely, depending on the amount and duration of unopposed estrogen stimulation that the endometrium has received. **Relatively low levels of chronic estrogen exposure typically result in intermittent spotting or staining that is generally light in volume but may be prolonged. In contrast, sustained high-level estrogen stimulation commonly results in long intervals of amenorrhea punctuated by acute episodes of often profuse bleeding that vary in duration and can be severe enough to necessitate emergent care.**

# Progestogen Withdrawal Bleeding

Progestogen withdrawal bleeding is observed when treatment with exogenous progesterone or a synthetic progestin is discontinued. **Progestogen withdrawal bleeding occurs only when the endometrium has first been primed with estrogen (endogenous or exogenous).** The amount and duration of bleeding can vary widely and generally correlate with the level and duration of previous estrogen-stimulated endometrial proliferation. In women with marginal to frankly low estrogen levels or short intervals of amenorrhea, bleeding is generally light to scant and may not occur at all. In those with sustained high estrogen levels or long intervals of amenorrhea, bleeding can be heavy and somewhat prolonged but still is self-limited. Between the extremes, the amount and duration of bleeding induced by progestogen withdrawal are typically similar to that observed at the end of a normal ovulatory cycle. In women receiving cyclic hormone therapy with exogenous estrogen and progestin, bleeding follows withdrawal of progestin even if estrogen treatment continues; progestin withdrawal bleeding can be delayed but only if estrogen levels are increased by 10- to 20-fold.<sup>59</sup>

# Progestogen Breakthrough Bleeding

Progestogen breakthrough bleeding occurs when the ratio of progestogen to estrogen is unfavorably high. Unless there is sufficient estrogen to balance its action, continuous treatment with exogenous progesterone or synthetic progestins will result in intermittent bleeding of varying duration that is generally light, a pattern very similar to low-level estrogen breakthrough bleeding described above. Clinical examples of progestogen breakthrough bleeding are the bleeding observed in women using the progestin-only contraceptive “minipill” or other long-acting progestin-only contraceptive methods (such as progestin implants or depot medroxyprogesterone acetate).<sup>60</sup> The breakthrough bleeding observed in women using combination estrogen-progestin contraceptives also is a form of progestogen breakthrough bleeding. Such breakthrough bleeding is more common with contraceptives containing a lower estradiol dose but can be seen with any combination hormonal formulation.<sup>61</sup> **Although all estrogen-progestin contraceptive regimens contain pharmacologic quantities of both estrogen and progestin, the progestin component is always the dominant hormone, and the net effect on the endometrium is profoundly progestational.**

# PATHOPHYSIOLOGY OF ANOVULATORY BLEEDING

---

Anovulatory bleeding can result from estrogen withdrawal bleeding, reflecting the transient fall in estrogen levels that accompanies spontaneous regression of a follicular cohort. More commonly, however, AUB in anovulatory women reflects estrogen breakthrough bleeding, due to focal breakdown of an overgrown and structurally fragile endometrium under continuous estrogen stimulation. The heaviest episodes of anovulatory bleeding tend to occur in women following prolonged periods of exposure to estrogen, unopposed by progesterone, such as in women with PCOS, obese women, postmenarcheal adolescents, and perimenopausal women. The clinical presentation spans the spectrum from the pale frightened teenager who has bled for weeks to the older woman who is deeply concerned that she may have cancer.

In contrast to the organized predictable pattern of sequential estrogen-progesterone stimulation and withdrawal that characterizes the normal ovulatory menstrual cycle, the patterns of ovarian steroid hormone production and endometrial stimulation in anovulatory women are disorganized and unpredictable. By definition, the anovulatory woman is always in the follicular phase of the ovarian cycle and in the proliferative phase of the endometrial cycle. There is no luteal or secretory phase because there is no ovulation or cycle. The only ovarian steroid signal the endometrium receives is estrogen, levels of which constantly fluctuate, rising and falling as each new cohort of follicles begins to grow, but ultimately loses its developmental momentum and, sooner or later, lapses into atresia. Although the amplitude of the signal (estrogen contributed by inefficient follicular growth) may vary, the message for endometrial growth stays the same.

Over a period of time, an unrelenting, uninterrupted estrogen signal can stimulate the endometrium to proliferate to achieve abnormal degrees of thickness where the tissue outgrows its own blood supply and becomes fragile. Without the growth-limiting and growth-organizing effects of progesterone, the endometrium lacks the stromal support structure to maintain stability. Focal areas break down and bleed; as those areas heal under the influence of continued estrogen stimulation, others break down and bleed. Persistent proliferative and hyperplastic endometrium characteristically exhibits numerous discrete foci of stromal breakdown near the epithelial surface, associated with pools of extravasated red blood cells, capillary platelet/fibrin thrombi, and repair-related changes recognized as ball-like aggregates of tightly packed stromal cells beneath a cap of intact but hypertrophied epithelium.<sup>39</sup> The cause for the focal breakdowns in persistent proliferative endometrium is not entirely clear.

Abnormal endometrial growth involves not only epithelial and stromal cells but

also the microvasculature. Venous capillaries in persistent proliferative and hyperplastic endometrium are increased, dilated, and often form abnormal irregular channels; ultrastructural studies have revealed a number of abnormal structural elements that predispose to fragility.<sup>62,63</sup> The abnormal microvasculature could be the result, but is more likely the proximate cause, of abnormal bleeding. **The weight of available evidence from histologic and molecular studies indicates that anovulatory bleeding results from an increased density of abnormal vessels having a fragile structure prone to focal rupture, followed by release of lysosomal proteolytic enzymes from surrounding epithelial and stromal cells and migratory leukocytes and macrophages.** Once initiated, the process is further aggravated by local release of prostaglandins, with greater sensitivity to those that vasodilate (PGE<sub>2</sub>) than to those that vasoconstrict (PGF<sub>2α</sub>).<sup>64</sup> Other molecules (perforins) inhibit capillary plug formation and further degrade the capillary venous network. Vasoconstriction of basal endometrial and superficial myometrial vessels does not occur because tissue loss is only focal and superficial and does not typically reach the basal layer where denudation triggers an intense vasoconstrictive response. The final mechanism that normally controls menstrual bleeding, surface epithelial reconstruction, operates in persistent proliferative endometrium, but not in a normal way. Epithelial repair is focal, in the areas of breakdown, and not universal; the result is a constantly changing patchwork of small repairs instead of an organized and well-structured remodeling as what follows after the endometrial shedding of normal menstruation.<sup>39</sup>

# DIFFERENTIAL DIAGNOSIS OF ABNORMAL UTERINE BLEEDING

---

The differential diagnoses for AUB include a wide spectrum of possibilities that range from pregnancy to ovulation disorders, uterine/vaginal/cervical abnormalities (benign and malignant), trauma, infection, coagulopathies, endocrine disorders, foreign bodies, systemic disease, to bleeding relating to medications. **The prevalent causes of AUB vary with age.** In premenarcheal girls, foreign bodies, trauma, and infection are the most common. In postmenarcheal adolescents, anovulatory bleeding, coagulopathies, infections, and complications of pregnancy head the list. During the reproductive years, most abnormal bleeding results from anovulation, hormonal contraception, complications of pregnancy, infections, endocrine disorders, and polyps and myomas. In perimenopausal women, anovulation, benign uterine neoplasia, and endometrial hyperplasia cause the majority of problems, and in postmenopausal women, vaginal/endometrial atrophy and hormone therapy are the most common causes of abnormal bleeding; only about 10% of postmenopausal bleeding results from endometrial cancer.

**Complications of pregnancy** always should be considered and excluded, particularly in adolescents who may be reluctant to reveal their sexual history. **It is important to emphasize that the most common cause of a sudden departure from a well-established pattern of regular and predictable menses is a complication of pregnancy; threatened or spontaneous abortion and ectopic pregnancy are the most common, but possibilities also include retained products of conception and gestational trophoblastic disease.**

The PALM portion of the FIGO classification acronym encompasses structural causes for AUB: **polyps, adenomyosis, leiomyomata, and malignancy/hyperplasia (Figure 15.1).** Two-thirds of women with endometrial polyps will experience AUB, with intermenstrual bleeding and heavy menses as the most common patterns. Women with adenomyosis are more likely to experience heavy menses but may instead have intermenstrual bleeding (or dysmenorrhea alone). Myomas generally cause heavy menstrual bleeding, which is mediated by alteration to the usual hemostatic mechanisms of the uterus through changes in vascular compression and the release of vasoactive growth factors. Women with malignancy or hyperplasia may have a variety of abnormal bleeding patterns, including intermenstrual bleeding, frequent menses, or heavy or prolonged bleeding. **Nonstructural causes of AUB are represented in the “COEIN” portion of the PALM-COEIN acronym, where COEIN stands for coagulopathy, ovulatory dysfunction, endometrial factors, iatrogenic, and “not yet classified.”**

## AUB-P (Polyps) (Figure 15.3)

Modified from **Anatomical Chart Company**, Common Gynecological Disorders Anatomical Chart, Wolters Kluwer, Philadelphia, 2007.

Endometrial polyps often cause abnormal bleeding, most likely due to vascular fragility, chronic inflammation, and surface erosions. Larger pedunculated polyps may develop ischemic necrosis at their apex that extends to the subsurface capillaries as a consequence of intermittent torsion and related thrombosis.

## AUB-A (Adenomyosis) (Figure 15.4)

Modified from **Anatomical Chart Company**, Common Gynecological Disorders Anatomical Chart, Wolters Kluwer, Philadelphia, 2007.

Adenomyosis is a disorder characterized by the extension of endometrial glands and stroma into the myometrium, a relatively common finding in hysterectomy specimens from women with menorrhagia unrelated to uterine myomas or endometrial pathology. Hypertrophy and hyperplasia in the surrounding myometrium generally result in diffuse uterine enlargement.<sup>65</sup> However, some women develop focal nodular lesions called adenomyomas (exaggerated myometrial proliferation around foci of ectopic endometrium), which resemble leiomyomas clinically. The pathogenesis of adenomyosis and associated menorrhagia is unknown. The disease may develop from endomyometrial invagination of the endometrium or develop de novo from müllerian rests.<sup>66,67,68</sup>

In symptomatic women, transvaginal ultrasonography can suggest the diagnosis; while asymmetric thickening and heterogeneity of the myometrium are suggestive features, myometrial cysts are the most specific diagnostic criterion.<sup>69</sup> A meta-analysis including 14 studies involving women who had ultrasonography performed before hysterectomy found that sonography has 83% sensitivity and 85% specificity for diagnosis of adenomyosis.<sup>70</sup> Magnetic resonance imaging (MRI) is a more sensitive diagnostic technique,<sup>71</sup> particularly in the presence of uterine myomas; thickening of the junctional zone on T2-weighted imaging is characteristic.<sup>65,69,72</sup> However, the costs of MRI are difficult to justify if the results do not affect clinical management. In recent years, a role of hysteroscopy in diagnosing adenomyosis has also emerged; irregular appearance of the endometrium and evidence of hemorrhagic foci are suspicious for

underlying adenomyosis, and use of a resectoscope also allows an opportunity for confirming a histologic diagnosis in appropriately selected cases.<sup>73,74,75</sup>

## AUB-L (Leiomyoma)

Uterine leiomyomas are extremely common (Figure 15.5). Heavy menstrual bleeding is the most common form of AUB encountered in women with fibroids, although most women with uterine fibroids do not experience abnormal bleeding. The high prevalence of uterine myomas guarantees that they will often be identified in women who are undergoing gynecologic evaluation for any form of AUB or even reasons other gynecologic disorders. **Myomas cannot, therefore, be regarded as the cause of abnormal bleeding before other obvious possibilities have been excluded, particularly when they do not protrude into or displace the uterine cavity.** Fibroids may be the cause of heavy or prolonged bleeding in ovulatory women; they may aggravate the bleeding that results from anovulation or other causes. Many times, uterine fibroids represent only an incidental finding. Transvaginal ultrasonography generally provides accurate information regarding the size, number, and location of myomas, but images can be difficult to interpret when fibroids are multiple and large. Sonohysterography more clearly defines the proximity of myomas to the uterine cavity and can thus help to differentiate clinically relevant myomas from those that are not.<sup>76</sup>

**FIGURE 15.5**

The mechanisms by which uterine myomas may cause abnormal bleeding are not entirely clear but seem closely related to their location. Histologic studies suggest that submucous and large deep intramural myomas cause the overlying endometrium to stretch. Compression from below and trauma from intracavitary friction at the epithelial surface combine to cause focal chronic inflammation or even ulceration, resulting in bleeding.<sup>77</sup> In compressed or damaged endometrium, other hemostatic mechanisms like platelet plug formation also may be impaired. Erosion and rupture of the larger caliber surface vessels observed on some myomas can further contribute to prolonged or heavy bleeding.<sup>39,78</sup> The greater surface area of a grossly enlarged uterine cavity probably explains menorrhagia in women with fibroids that are numerous and large but distant from the endometrium.

## AUB-M (Malignancy or Hyperplasia)

Endometrial hyperplasia is a histologic diagnosis based on findings of proliferating glands of varying size and shape and a greater gland-to-stroma ratio than is observed in normal endometrium.<sup>79</sup> Endometrial hyperplasia results almost exclusively from unopposed chronic estrogen stimulation.

Historically, endometrial hyperplasia was classified as simple or complex (reflecting the architectural pattern), with or without nuclear atypia (enlargement, rounding, pleomorphism, and aneuploidy). The simple and complex designations, based upon the gland-to-stroma ratio in the endometrium, were abandoned by the World Health Organization in 2014,<sup>80</sup> both to simplify terminology and to reflect the molecular understanding that only the presence of atypia is reflective of the genetic changes seen in the development of invasive endometrial cancer. Lesions without atypia basically represent only exaggerated forms of persistent proliferative endometrium; they regress spontaneously, after curettage or with progestin treatment, and are associated with little risk (1–3%) for progression to adenocarcinoma.<sup>81,82,83,84</sup> In contrast, atypical endometrial hyperplasia exhibits an entirely different behavior; it does not often spontaneously regress and can be quite resistant to even repeated curettage or prolonged high-dose progestational therapy. **Endometrial hyperplasia with atypia has significant risk (10–30%) of progression to adenocarcinoma if left untreated and must therefore be regarded as a precancerous lesion.**<sup>81,82,83,84</sup> Atypical lesions are distinguished from invasive carcinomas by the absence of stromal invasion. It is important to note that, despite concerted efforts to standardize classification criteria, there is significant interobserver variability in the classification assigned by pathologists, even within the same institution.<sup>85,86</sup> Other classification systems have been proposed,<sup>87,88</sup> but none has gained wide acceptance.

**When an office biopsy (discussed under evaluation) reveals endometrial hyperplasia, further evaluation is required to exclude atypia or a coexisting cancer that was not represented in the tissue specimen, and if subsequent curettage reveals atypical endometrial hyperplasia, there is significant risk of an unrecognized adenocarcinoma.** In a retrospective study involving 824 women with a diagnosis of complex atypical hyperplasia after office sampling, 100 were diagnosed with cancer after further evaluation with curettage, but 298 of the remaining 724 (41%) had unexpected cancer in a hysterectomy specimen obtained within 6 months of the original diagnosis; among those having an occult cancer, 30% had been further evaluated with curettage and 45% had not.<sup>89</sup>

## AUB-C (Coagulation or Bleeding Disorders)

The possibility of a coagulopathy should be particularly kept in mind, particularly for adolescents whose menstrual history is short and not yet well defined. The most common cause of AUB in adolescents is anovulation, but up to a third may have a coagulation defect,<sup>90,91,92,93</sup> including von Willebrand disease, Glanzmann thrombasthenia, and idiopathic thrombocytopenic purpura. In patients diagnosed with malignancy, platelet dysfunction and thrombocytopenia may be related to the underlying cancer or result from treatment of malignancy. Bleeding disorders usually are associated with cyclic, regular, heavy, or prolonged bleeding (older terminology, menorrhagia). The same pattern may be observed in women receiving treatment with anticoagulants.<sup>94</sup> **Previous history of postpartum hemorrhage or excessive bleeding with surgery, dental procedures, or trauma should raise suspicion, but heavy menstrual bleeding since menarche may be the only clue.**<sup>95</sup> **Coagulation defects are not as rare as is generally perceived and may be found in 10–20% of women with unexplained heavy menses.**<sup>95,96,97,98</sup> Numerous studies have documented the association between heavy menstrual bleeding and inherited coagulation defects.<sup>95,96,97,99,100,101</sup> Combined, they provide ample justification for performing screening coagulation studies in women with long-standing and unexplained heavy menstrual flow.

**Von Willebrand disease is the most common inherited bleeding abnormality affecting women.** The disease is the consequence of quantitative or qualitative defects of von Willebrand factor, a protein that plays an important role in primary hemostasis by binding to both platelets and the vascular endothelium, forming a bridge between them and adjacent platelets at the site of injury.<sup>102,103</sup> By serving as a carrier protein for factor VIII and thereby prolonging its half-life in the circulation, von Willebrand factor also contributes to fibrin clot formation. There are three types of inherited von Willebrand disease.<sup>104,105,106</sup> The tendency of excess bleeding can vary widely, even within individuals and their families. There are also acquired forms of von Willebrand disease associated with a variety of different diseases ([Table 15.3](#)).

### TABLE 15.3 Types of von Willebrand Disease

Type	Inheritance	Characteristics
I	Autosomal dominant	Most common variant (85%) Results from <i>quantitative</i> deficiency of von Willebrand factor
II	Autosomal dominant	Has four subtypes ALL of which involve <i>qualitative</i> abnormalities of von Willebrand factor
III	Autosomal recessive	Rare Total deficiency of von Willebrand factor—this results in the most severe form of coagulopathy

## **AUB-O (Ovulatory Dysfunction)**

Anovulatory bleeding (previously referred to as “dysfunctional uterine bleeding”) describes the spectrum of abnormal bleeding patterns that can occur in anovulatory women. The mechanisms involved in anovulatory bleeding reflect an abnormal pattern of steroid hormone stimulation that deviates from the sequence characterizing the normal ovulatory menstrual cycle. Anovulation and oligoovulation can result from a variety of endocrinologic disturbances either directly involving or influencing the functioning of the HPO axis, including thyroid disease (hyper- and hypothyroidism), hyperprolactinemia, PCOS, and hypothalamic dysfunction from nutritional deficiency, systemic illness, or stress. In the case of **systemic illnesses** that predispose to anovulation, the abnormal bleeding can be compounded by concomitant coagulation abnormalities; for example, chronic renal disease is associated with both ovulatory and platelet dysfunction, while liver disease can adversely affect estrogen metabolism (predisposing to anovulation) and impair the synthesis of clotting factors. Many of the endocrinopathies predisposing to or characterized by anovulation are discussed in further detail in other chapters of this textbook.

## **AUB-E (Endometrial)**

Endometrial causes of AUB other than the polyps and the fibroids discussed earlier (particularly the submucous myomas that distort the endometrium) are less common. Chronic endometritis is a poorly understood entity that can be categorized under endometrial cause as much as under the “not otherwise specified” category, as discussed below. Acute endometritis in the postpartum or postabortal period is a well-defined entity that can cause heavy menstrual bleeding. Abnormal bleeding has also been described in patients with subclinical *Chlamydia trachomatis* infections, pelvic tuberculosis, and pelvic inflammatory disease. Bleeding abnormalities associated with placental site nodule belong under this category.<sup>107</sup>

## AUB-I (Iatrogenic)

A variety of different **medications** can predispose to abnormal bleeding, by interfering with hemostasis (usually resulting in menorrhagia), by affecting the concentrations of endogenous or exogenous hormones (causing fluctuations in circulating levels), or by disrupting the HPO axis. Drugs associated with abnormal menstrual bleeding include hormonal contraceptives, those used for postmenopausal hormone therapy, digitalis, anticonvulsants, anticoagulants, and psychopharmacologic medications. Some common herbs have estrogenic activity (e.g., ginseng) and may be associated with abnormal bleeding.<sup>108</sup> Use of various forms of **hormonal contraceptives is probably the most common iatrogenic cause of abnormal bleeding in reproductive-age women. Similarly**, abnormal bleeding is well described in users of **menopausal hormone therapy**. When assessing women experiencing AUB who are on hormone regimens, the possibility of issues of compliance as well as of underlying pathology must be given consideration. Abnormal bleeding patterns are commonly reported in association with both copper (Cu) and levonorgestrel (LNG)-containing intrauterine contraceptive device (IUD) use; whereas heavy menstrual bleeding is often encountered with use of Cu-containing IUDs, erratic spotting is more common in the initial few months following placement of LNG-IUD, followed by eventual development of amenorrhea.

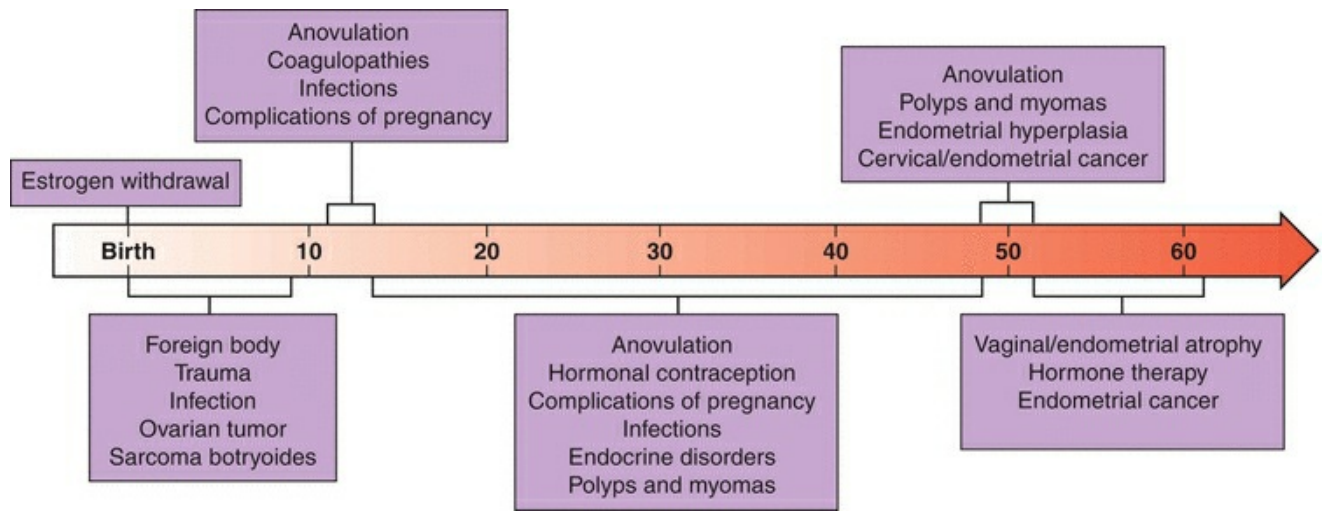

## AUB-N (Not Otherwise Classified)

This remains the vaguest category of the new classification system. Chronic endometritis can be placed under this heading given that the exact mechanism contributing to nor clinical implications of this histologic entity are entirely clear. Chronic endometritis is a histologic diagnosis, based on the finding of plasma cells in the endometrial stroma. The condition can result from infections (chlamydia, tuberculosis, mycoplasma), intrauterine foreign bodies or growths (IUD, submucous myoma), and radiation exposure, but no cause can be identified in about one-third of cases.<sup>109</sup> **Women with symptomatic chronic endometritis typically present with AUB, which can vary from intermenstrual spotting and postcoital bleeding to heavy menstrual bleeding.** Some may have vague, crampy lower abdominal pain, although many or most have no symptoms at all.

Chronic endometritis is seldom the direct cause but often may be an indirect or contributing cause of abnormal bleeding. Inflammatory cells release proteolytic enzymes that damage the subepithelial capillary plexus and surface epithelium, rendering them fragile and prone to breaks and microerosions. Proteases also interfere with both repair processes and new vessel formation. In addition, leukocytes and macrophages release platelet-activating factor and prostaglandins, which are potent vasodilators. Histologic studies suggest that chronic endometritis also contributes to abnormal bleeding relating to submucous and deep intramural myomas and endometrial polyps.<sup>77</sup>

Abnormal bleeding associated with arteriovenous malformations can also be categorized in this section.<sup>110</sup>

**Although the effort by FIGO to simplify and standardize the terminology used to describe menstrual abnormalities is reasoned and laudable, the adoption of this new nomenclature has been slow because the traditional terms, however ambiguous, still remain entrenched (Figure 15.6).**

**FIGURE 15.6**

# DIAGNOSTIC EVALUATION OF ABNORMAL UTERINE BLEEDING

---

A careful history and physical examination narrow the number of possibilities meriting serious consideration and define the scope and content of the evaluation required to establish a definitive diagnosis.

The history should seek to define each of the following characteristics:

- **Onset of abnormal menses (perimenarcheal, sudden, gradual)**
- **Duration (normal or prolonged, consistent or variable)**
- **Intermenstrual interval (number of days, regularity)**
- **Volume (heavy, light, or variable)**
- **Temporal associations (postcoital, postpartum, postpill, weight gain or loss)**
- **Associated symptoms (premenstrual molimina, dysmenorrhea, dyspareunia, galactorrhea, hirsutism)**
- **Underlying systemic illness (renal, hepatic, hematopoietic, thyroid)**
- **Medications (hormones, anticoagulants, antipsychotics, antidepressants, antiseizure)**

**In the majority of women with true anovulatory bleeding, the menstrual history alone can establish the diagnosis with sufficient confidence that treatment can begin without extensive laboratory evaluation or expensive imaging.** Infrequent, irregular, unpredictable menstrual bleeding that varies in amount, duration, and character and is not preceded by any recognizable or consistent pattern of premenstrual molimina or accompanied by any visible or palpable genital tract abnormality is not difficult to interpret. **Conversely, regular monthly periods that are heavy or prolonged are more likely related to an anatomical lesion or a bleeding disorder than to anovulation.** Objective methods for measuring menstrual blood loss include the photometric alkaline hematin test (the historical gold standard for research purposes but clinically impractical)<sup>111,112</sup> and menstrual pictograms (illustrations of blood stains of different sizes on feminine hygiene products),<sup>113,114</sup> both of which provide objective means of quantifying menstrual blood loss.<sup>115</sup> However, the most practical approach is the menstrual history. Although subjective, a history of changing pads or tampons more often than every 3 hours, use of more than 20 over single menses, the need to change protection during the night, frequent episodes of accidental soiling of clothing and bedsheets, the passage of clots larger than an inch in diameter, menses lasting longer than 7 days, and diagnosis of anemia should all raise concerns about abnormally heavy menstrual bleeding.<sup>30</sup> **Regardless of the actual amount of blood loss, menstrual**

**bleeding that interferes with daily activities or causes anxiety and concern merits evaluation.**

During the physical examination, attention should be given to the general well-being of the patient. Clinicians must be vigilant for signs that could reflect an underlying disorder as a cause of ovulatory dysfunction, such as signs of hyperandrogenism (discussed in [Chapter 11](#)), or features suggesting thyroid disorder (discussed in [Chapter 20](#)), or prolactin excess ([Chapter 4](#)). Gynecologic examination should systematically evaluate for potential anatomical contributors to AUB. Extrauterine sources for abnormal bleeding include the urethra (urethritis or caruncle), bladder (urinary tract infections and cancers), vagina (vaginitis, trauma, and ulcerative lesions), cervix (ectropion, cervicitis, polyps, focal lesions), vulva (trauma, skin lesions), and anorectal region (anal fissures, hemorrhoids, inflammatory bowel disease, cancers). During pelvic examination, attention should be paid to uterine size (normal or enlarged), contour (smooth and symmetrical or irregular), consistency (firm or soft), mobility and tenderness, and presence of adnexal masses.

# Laboratory Evaluation

Laboratory tests can be very helpful but are not always necessary. A sensitive urine or serum **pregnancy test** can quickly exclude the possibility that abnormal bleeding relates to a complication of pregnancy; a positive test leaves only a few diagnostic possibilities, which generally are not difficult to distinguish. A **complete blood count** to exclude anemia and thrombocytopenia is prudent in all women with complaints of abnormal bleeding. Iron studies should be considered especially when bleeding is heavy.

After excluding pregnancy, the most important question to answer is whether the patient is ovulating, because the causes and clinical management of ovulatory and anovulatory uterine bleeding are quite different. When the menstrual history alone does not allow a confident conclusion, a well-timed **serum progesterone** assessment during the putative luteal phase of the cycle can help to document ovulation or anovulation. A logical strategy is to obtain the test between cycle day 22 and 24 in women reporting a 28-day cycle, after ovulation in the longest normal cycle and before the end of the shortest normal cycle; any value greater than 3 ng/mL provides reliable evidence that ovulation has occurred recently.<sup>116</sup> However, when bleeding episodes are frequent or poorly documented, proper timing for a progesterone measurement can be difficult to determine. It also is important to remember that many women with abnormal bleeding, especially perimenarcheal and perimenopausal women, ovulate at least occasionally. Although most commonly applied to assess ovulatory function in women with infertility (and now seldom used even for that purpose), basal body temperature recordings can be quite informative in women with a confusing pattern of bleeding. Attainment of a dominant ovarian follicle can be followed and evidence of rupture ascertained by serial pelvic ultrasound imaging. Endometrial biopsy also can be used to assess ovulatory function (by identifying proliferative vs. secretory endometrium) but cannot be justified for that purpose alone when a less costly and less invasive serum progesterone measurement provides the same qualitative information. Thus, endometrial sampling should be reserved for those at risk for endometrial pathology, such as hyperplasia or neoplasia, as discussed below.

In sexually active women, a nucleic acid–based test for **chlamydia and gonorrhea** and a **wet prep** to exclude trichomonas infection merit consideration, particularly in those with evidence of vaginitis and/or cervicitis. In presumed or proven anovulatory women, a **serum thyroid-stimulating hormone (TSH)** level evaluates for an associated thyroid disorder, and prolactin level should be similarly checked to assess for hyperprolactinemia. **Liver or renal function tests** are indicated only for those with known or strongly suspected disease.

Adolescents, women with a suspicious personal or family history of bleeding symptoms (such as easy bruising, frequent gum bleeding when flossing or brushing teeth, epistaxis), and women with unexplained and protracted history of heavy menses warrant evaluation with **coagulation studies** to exclude coagulopathies, such as von Willebrand disease, factor deficiencies, and platelet function abnormalities.<sup>95,97,117,118</sup> **In addition to a platelet count, screening should include both a prothrombin (PT), which evaluates the extrinsic and final common clotting pathways, and an activated partial thromboplastin time (aPTT), which tests the intrinsic and common pathways of coagulation.** Although the PT and aPTT have relatively low positive and negative predictive value for detecting underlying bleeding disorders,<sup>119</sup> they are adequate screens for severe factor deficiencies.<sup>120</sup> **The high prevalence of von Willebrand disease among women with AUB (approximately 13%) warrants specific exclusion of the diagnosis and justifies measurement of von Willebrand factor, ristocetin cofactor activity (von Willebrand factor activity), the factor VIII level, and blood typing.**<sup>99,118,121</sup> It is important to note that test results can fluctuate over time<sup>122</sup> and also may vary across the menstrual cycle; repeated testing, ideally during the first few days of the cycle, may be required to establish the diagnosis of von Willebrand disease.<sup>99,123</sup> The blood type is helpful because von Willebrand factor and factor VIII levels are 25% lower in patients with type O blood than in those with other blood types.<sup>124</sup> For patients with abnormal coagulation studies, consultation with a hematologist is recommended.<sup>100,125</sup>

# Endometrial Sampling

An endometrial biopsy can exclude endometrial hyperplasia or cancer. Age over 35 or 40 years is widely considered a risk factor for endometrial disease and cited as an indication for biopsy in women with abnormal bleeding. **Endometrial hyperplasia and cancer are more commonly detected in older than in younger women, but the duration of exposure to unopposed estrogen stimulation is the more critical risk factor.** Long-term exposure is more likely in older than in younger women, but women under age 30, and even teenagers, can develop endometrial cancer.<sup>126,127,128,129</sup> In premenopausal women, the likelihood of abnormal endometrial histology is relatively high (14%) when menses are irregular but very low (<1%) when cycles are regular.<sup>130</sup> Thus, the prolonged unopposed estrogen exposure seen in obesity or anovulatory conditions like PCOS also merits endometrial sampling. Such sampling should also be pursued in a woman of any age who has persistent AUB despite reasonable attempts of medical management.

The small flexible suction cannulas now widely available (e.g., Pipelle suction curette) for endometrial biopsy cause less discomfort than older traditional biopsy instruments and yield comparable results.<sup>131,132,133</sup> Unfortunately, hospital-based curettage without hysteroscopy is still commonly performed, even though it is no longer the gold standard. Current indications for dilation and curettage (D&C) include a nondiagnostic office biopsy (for instance, in the setting of insufficient tissue for diagnosis or persistent AUB despite normal histology) or when the office biopsy cannot be completed, due to such factors as cervical stenosis or patient discomfort. When D&C is pursued, however, it is recommended that hysteroscopy be done beforehand to obtain targeted biopsies, if needed; this is warranted because of the significant likelihood of missing focal pathology with a diagnostic D&C.

In addition to revealing any intrinsic endometrial disease, such as hyperplasia, adenocarcinoma, or chronic endometritis, biopsy can help to direct further evaluation or to guide the choice of treatment in women with a confusing history of abnormal bleeding. An inactive or atrophic endometrium identifies women unlikely to respond to progestational therapy. **In women with no recent exposure to exogenous progestins, a secretory endometrium provides reliable evidence of recent ovulation and signals the need to search for an anatomical cause.**

# Imaging

Pelvic ultrasonography, preferably utilizing a transvaginal approach, can provide reliable information about the size and location of any uterine fibroids and raise suspicion for endometrial pathology or even adenomyosis as mechanisms for abnormal bleeding.<sup>134,135</sup>

Ultrasonography may reveal an obvious intracavitary lesion or an abnormally thin or thick endometrium. A very thin endometrial “stripe” (<5 mm), similar to a biopsy that yields minimal tissue, suggests an attenuated or denuded endometrium that is best treated first with estrogen rather than with a progestin or an estrogen-progestin combination (discussed below). **In perimenopausal and postmenopausal women with abnormal bleeding, endometrial biopsy generally is considered unnecessary when the endometrial thickness is less than 4 mm because the risk of endometrial hyperplasia or cancer is remote.**<sup>136,137,138</sup> It seems logical to apply the same criterion for the same reason in premenopausal women with abnormal bleeding, although there is no substantial direct evidence to support the extrapolation. Otherwise, the decision to biopsy or not should be based primarily on clinical suspicion and risk factors rather than on ultrasonographic measurements of endometrial thickness. That does not mean that endometrial thickness has no bearing on the decision whether to perform a biopsy; a grossly increased endometrial thickness (>12 mm) increases the risk of disease and is an indication for sampling, even when clinical suspicion of pathology is otherwise low.<sup>139</sup> **In summary, we believe that biopsy is unnecessary when the endometrial thickness is less than 4 mm and that biopsy is indicated when the clinical history suggests long-term unopposed estrogen exposure even when the endometrial thickness is “normal” (5–12 mm).**

Sonohysterography utilizes introduction of sterile saline via a catheter into the uterine cavity, while transvaginal ultrasound is being performed (the procedure is also known as hydrosalpingography and saline infusion sonography). The saline sharply defines the uterine cavity contours and readily demonstrates even small intrauterine lesions. The sensitivity and specificity of sonohysterography exceed that of standard transvaginal ultrasonography and compare favorably with hysteroscopy.<sup>76,140,141,142</sup> **The combination of sonohysterography and endometrial biopsy offers a high sensitivity and high negative predictive value for detection of endometrial and uterine pathology in women with abnormal bleeding.**<sup>143</sup> One disadvantage of the technique is that minor cavity contour abnormalities or blood clots may be misinterpreted as polyps; in this case, hysteroscopy and/or tissue sampling is often needed to clarify the true nature of the structural finding.

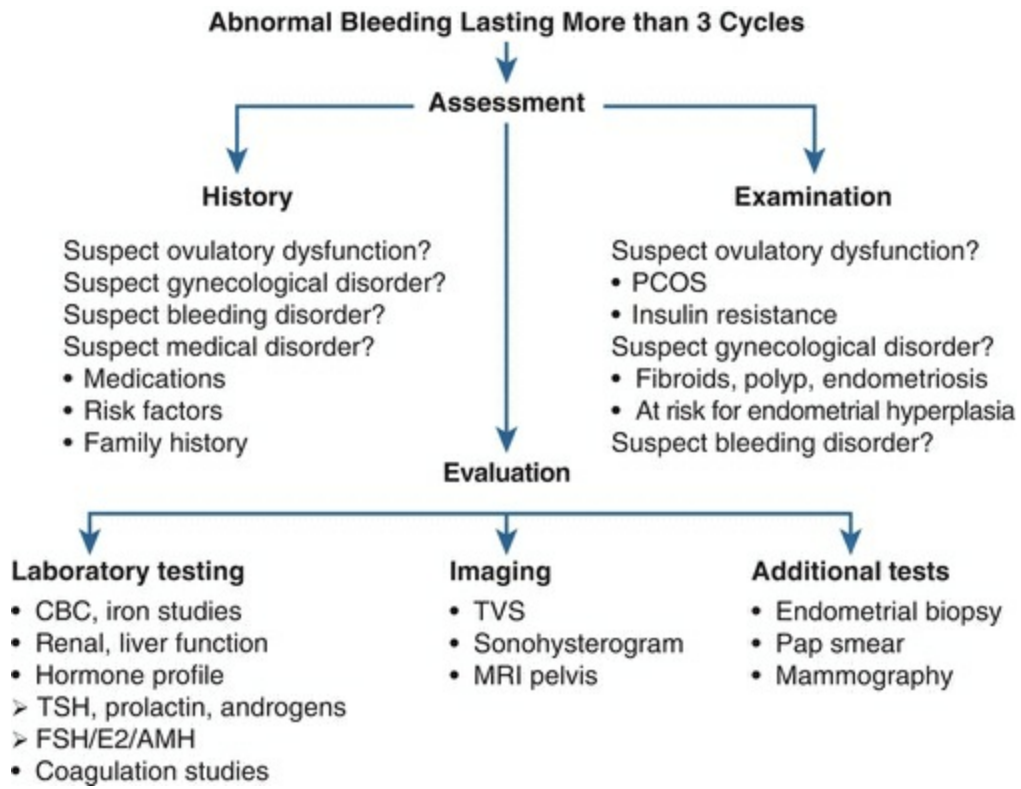

**Magnetic resonance imaging** is gaining acceptance in the evaluation of AUB. It

can reliably define uterine anatomy, distinguish between adenomyosis and leiomyomata, and demonstrate the proximity of myomas to the uterine cavity.<sup>144</sup> Although costly, MRI can be helpful in women who cannot be imaged adequately with ultrasonography or when surgical planning is needed.

**Hysteroscopy** is the definitive method for both diagnosis and treatment of symptomatic intrauterine pathology, particularly submucosal myomas and endometrial polyps; additionally, with technologic advances and better magnification, classic hysteroscopic findings attributable to adenomyosis and chronic endometritis are also recognized.<sup>75,145</sup> Traditionally, hysteroscopy has been reserved for treatment of disease identified by other less invasive methods, but modern hysteroscopes having an outer diameter of 2–5.5 mm now permit diagnostic and minor operative procedures to be performed in the office setting with minimal anesthesia.<sup>146</sup> For clinicians having the necessary training and experience, office hysteroscopy has a very low incidence of complications, which may include uterine perforation, infections, and excessive bleeding. Major intrauterine pathology generally requires more traditional operative hysteroscopy using instruments having a larger caliber and greater capabilities.

**In general, diagnostic uterine imaging can be reserved for women in whom the menstrual history or the results of other evaluations provide strong evidence for an anatomical cause of abnormal bleeding, including any of the following:**

- **Regular monthly cycles with increasing volume or duration of bleeding**
- **Regular monthly cycles complicated by intermenstrual bleeding in the absence of a vaginal or cervical lesion.**
- **Abnormal bleeding despite objective evidence of ovulation from measurement of serum progesterone (>3 ng/mL) or from endometrial sampling (secretory endometrium)**
- **Failed empirical medical management ([Figure 15.7](#))**

**FIGURE 15.7**

# MANAGING ABNORMAL UTERINE BLEEDING

---

As in all aspects of clinical medicine, the success of treatment hinges on an accurate diagnosis. When there is good reason to suspect a coagulopathy or uterine pathology as the cause of abnormal bleeding, diagnostic laboratory tests, endometrial biopsy, or uterine imaging should be considered carefully before beginning empiric medical management. **However, when there is every reason to believe that anovulation is the cause, empiric medical management based on that premise is entirely reasonable; a prompt resolution of the problem also should be expected. When bleeding persists despite appropriate empiric medical management, further diagnostic evaluation is more productive than a higher dose or otherwise different medical treatment regimen.**

# TREATMENT OF ANOVULATORY BLEEDING

---

The primary objective of treatment in women with anovulatory bleeding is to induce or restore the natural control mechanisms that are not operating—orderly, synchronous growth, development, and shedding of a structurally stable endometrium. Without treatment or correction of the cause of chronic anovulation, recurrent episodes of heavy or prolonged bleeding can be expected.

Although most women with anovulatory bleeding can be managed effectively on an outpatient basis, acute bleeding occasionally may be severe enough to require hospitalization and emergency treatment. **Hospitalization is indicated for women with active hemorrhage who are hemodynamically unstable and those with symptomatic anemia or a serious underlying medical illness.** The most effective initial strategy in emergent circumstances is to insert a Foley catheter with a 30-mL balloon into the uterus to **tamponade** the bleeding while establishing intravenous access for fluid administration and, if necessary, transfusion.<sup>147</sup> Once the patient is stabilized, the diagnostic evaluation can proceed to determine the cause of the bleeding and the most appropriate treatment strategy. Acute anovulatory bleeding can be treated with estrogen, estrogen-progestin, or progestin alone. The best choice in a given patient depends primarily on the condition of the endometrium at the time. **It is important to emphasize that progestin treatment (remembering that the net effect of all estrogen-progestin contraceptives is progestational) is unlikely to be effective in patients with a thin, attenuated, or denuded endometrium.** Ideally, given the importance of making the correct choice in women with acute bleeding, transvaginal ultrasonography should be performed before treatment begins, to identify any obvious pathology that may dictate management and to assess the endometrial thickness.<sup>134</sup> **Possibility of pregnancy complications must be excluded in any patient presenting with AUB.**

# Progestin Therapy

Just as progesterone is the dominant and controlling influence in normal menstrual cycles, progestins are the mainstay of treatment for anovulatory bleeding. Progestins are powerful antiestrogens. Progestins stimulate  $17\beta$ -hydroxysteroid dehydrogenase and sulfotransferase activity, the enzymes that work in concert to convert estradiol to estrone sulfate (which is rapidly cleared from the body).<sup>148</sup> Progestins further antagonize estrogen action by inhibiting estrogen's induction of its own receptor (estrogen receptor replenishment). Progestins also suppress estrogen-mediated transcription of oncogenes.<sup>149</sup> Together, these actions explain the antimitotic, growth-limiting effects of progesterone and progestins on the endometrium (arrest of growth during the secretory phase of the cycle, prevention and reversal of hyperplasia, and marked attenuation during pregnancy or treatment with estrogen-progestin contraceptives).

In most circumstances, progestin therapy will control anovulatory bleeding once uterine pathology has been excluded. **In oligomenorrheic anovulatory women with episodic abnormal bleeding, orderly, predictable, self-limited progestogen withdrawal bleeding can be induced by cyclic treatment with an orally active progestin (e.g., medroxyprogesterone acetate 5–10 mg daily for 10–14 days each month).** Cyclic progestin therapy restores the normal sequence of endometrial steroid hormone stimulation—estrogen, followed by estrogen plus progestogen, followed by withdrawal. The interval of progestin therapy can be fixed to the calendar (beginning on the first of every month) or to the timing of menses (beginning 15–16 days after onset of the last progestin-induced menses); both regimens work well. **Failed progestin treatment suggests strongly that another pathology is causing or contributing to the problem and signals the need for additional diagnostic evaluation.**

**Although cyclic progestin therapy generally works well in women who are completely anovulatory and not sexually active, treatment with an estrogen-progestin contraceptive is a better choice for those who likely still ovulate (albeit infrequently) or want to avoid pregnancy.** Inevitably, programmed cyclic progestin treatment will not coincide with endogenous progesterone production in random ovulatory cycles like those that occur in aging women. When that happens, bleeding may deviate from the predicted pattern and be misinterpreted or cause alarm. **Moreover, standard cyclic progestin treatment regimens do not reliably suppress the HPO axis, so they will not prevent random ovulation and are not contraceptive.** In contrast, contraceptive doses of exogenous steroids effectively suppress endogenous function and prevent such confusion.

Acute severe anovulatory bleeding also can be treated effectively with high-dose progestin alone (medroxyprogesterone acetate 10–20 mg twice daily, megestrol acetate

20–40 mg twice daily, norethindrone 5 mg twice daily), provided that the endometrial thickness on ultrasound is in normal range or is thickened, suggestive of some degree of target tissue estrogen exposure.<sup>150,151,152</sup> Once initiated, progestin treatment should continue for approximately 3 weeks, decreasing frequency of dosing to once daily treatment after 7–10 days. High-dose progestin treatment induces stabilizing predecidual changes in a thickened, vascular, and fragile endometrium. However, a substantial amount of tissue remains to be shed upon progestin withdrawal, resulting in a so-called medical curettage. **If not warned to expect heavy menses and increased dysmenorrhea likely to arrive within 2–4 days after progestin treatment stops, most women will interpret this heavy bleeding experience as “treatment failure.”** Thereafter, standard cyclic progestin treatment or an estrogen-progestin contraceptive may be offered for longer-term management.

Depot-medroxyprogesterone acetate (150 mg intramuscularly every 3 months) can be a useful option for maintenance therapy in women who have difficulty with or cannot take estrogen-progestin contraceptives. **However, depot progestin treatment has no place in the acute management of abnormal bleeding. Once given, it cannot be withdrawn, and resulting intolerable side effects can be difficult to overcome.** Episodic breakthrough bleeding is relatively common and can be treated with estrogen as discussed below.

The levonorgestrel-releasing intrauterine system (LNG-IUS) is an effective progestin-based strategy for the long-term management of anovulatory bleeding in women who do not actively desire pregnancy. Beyond the first few months following insertion of a LNG-IUS during which time irregular spotting is not uncommon, almost two-thirds of users develop scant to absent menses. LNG-IUS is an ideal approach for managing AUB in women deemed at risk for endometrial pathology (such as those with chronic anovulation and who are obese), in those experiencing poor tolerance of systemic progestin regimens, and in those in whom estrogen use may be contraindicated.<sup>153</sup>

# Estrogen-Progestin Therapy

**Women with anovulatory bleeding who are sexually active and not planning on pursuing pregnancy are often effectively managed by treatment with an estrogen-progestin contraceptive.** A gradual but progressive decrease in the volume and duration of flow and improvement in associated dysmenorrhea can be expected and are reassuring. In women with normal uteri, estrogen-progestin contraceptives reduce menstrual flow by at least 60% from that in natural cycles.<sup>154</sup> Longer cycle regimens (discussed in [Chapter 22](#)) offer the advantage of fewer and lighter menses but increase the incidence of episodic breakthrough bleeding.

**Acute prolonged episodes of heavy anovulatory bleeding also can be treated effectively with high-dose estrogen-progestin therapy, provided that the endometrium is or normal or increased thickness.** Ideally, transvaginal ultrasonography should be performed before treatment begins to minimize the risk of unsuccessful treatment with continued heavy blood loss, as will occur in women with a denuded endometrium when either progestin alone or a low estrogen dose combined hormone regimen is chosen for managing heavy bleeding. In women with a thickened, vascular, and fragile endometrium, estrogen-progestin treatment inhibits further growth and induces structural changes that organize and stabilize the endometrium, thereby preventing further random breakdown. **Any monophasic combination oral contraceptive can be used in a multidose regimen as first-line approach to managing heavy abnormal bleeding in hemodynamically stable individuals** ([Table 15.4](#)).<sup>155,156,157</sup>

## **TABLE 15.4 High-Dose Oral Contraceptive Regimens for Control of Heavy Abnormal Bleeding**

Ethinyl Estradiol Dose in Combined Oral Contraceptive	Regimen	Anticipated effect
30–35 µg	1 pill 3 times daily × 48–72 h 2 pills daily × 1 wk 1 pill daily × 1 wk Stop Consider restarting at 1 pill daily	Reduction anticipated within 48 h. If nausea, consider adding an antiemetic Withdrawal bleeding Cycle control
20–25 µg	1 pill 4 times daily 3 pills daily × 1 wk 2 pills daily × 1 wk 1 pill daily × 1 wk Stop Consider restarting at 1 pill daily	Reduction anticipated within 48 h. If nausea, consider adding an antiemetic Withdrawal bleeding Cycle control

30–35 µg	Day#1—5 pills Day#2—4 pills Day#3—3 pills Day#4—2 pills Days#5 to days 14–21—1 pill daily Stop Consider restarting at 1 pill daily	Reduction anticipated within 48 h. If nausea, consider adding an antiemetic Withdrawal bleeding Cycle control

Data from Ely JW, Kennedy CM, Clark EC, Bowdler NC, Abnormal uterine bleeding: a management algorithm, J Am Board Fam Med 19(6):590, 2006.

**The dose of ethinyl estradiol in the contraceptive regimen should be considered when deciding on the multidose regimens as higher starting number of pills should be considered for pills containing 20–25 µg or lesser doses of ethinyl estradiol. These regimens achieve reduction in bleeding within 24–40 hours in most women. Once control of bleeding is achieved, a taper in hormone dosing should be planned over the next 1–2 weeks with the goal of continuing one pill daily for at least 1 week after the bleeding completely subsides. Patient should be informed that stopping the hormone regimen will be followed by withdrawal bleeding, following which starting a standard dose of oral contraceptives can be considered to prevent future episodes of abnormal bleeding and to allow the opportunity for hemoglobin levels to increase in anemic patients. Failed estrogen-progestin treatment indicates the need for additional diagnostic evaluation.**

# Estrogen Therapy

Intermittent vaginal spotting frequently is associated with marginal or frankly low levels of estrogen stimulation (estrogen breakthrough bleeding) and a very thin, unstable endometrium. In this setting, the usual beneficial effect of progestin treatment cannot be achieved because estrogen levels are insufficient to stimulate the growth that serves as the foundation for the actions of progestin; the growth-limiting effects of progestin are not helpful and may further aggravate the problem, as in women whose endometrium becomes denuded after prolonged heavy bleeding. Logically, estrogen therapy is the most effective initial treatment strategy.

Estrogen also is the obvious and best choice for management of episodic progestogen breakthrough bleeding, as commonly observed in women receiving low-dose estrogen-progestin contraceptives, depot medroxyprogesterone acetate, or other forms of continuous progestin treatment utilized for contraception (e.g., the progestin-only “minipill” or progestin implants) or in the management of endometriosis.<sup>158</sup> A common clinical story involves long-term use of estrogen-progestin contraception with reports of markedly decreased or absent menstrual flow during the pill-free week and episodes of breakthrough bleeding at other times. Over time, unless there is sufficient endogenous or exogenous estrogen to effectively balance its effects, progestin attenuates the endometrium, inducing pseudoatrophy. Histologically, the endometrium has little height and is composed almost entirely of pseudodecidualized stroma and blood vessels with relatively few glands. Although the mechanism is different, the light spotting, staining, or bleeding that may occur is in many ways similar to the type of estrogen breakthrough bleeding observed in women with marginal or very low levels of circulating estrogen. In all such scenarios, a short interval of added estrogen (e.g., conjugated estrogens 1.25 mg or micronized estradiol 2.0 mg daily for 7–10 days) is generally highly effective. In some women, the problem recurs frequently or persists. Higher doses, longer durations, or repeated courses of estrogen treatment are sometimes needed. When treatment fails, further evaluation with transvaginal ultrasound or sonohysterography can exclude the possibility of a previously unrecognized endometrial polyp or submucous myoma. Rarely, only a brief hiatus in estrogen-progestin or progestin alone treatment will resolve the problem.

**When acute, heavy bleeding results in a thin, denuded endometrium, high-dose estrogen therapy is the best initial treatment; progestin or estrogen-progestin therapy is unlikely to succeed and may aggravate the problem.** Estrogen stimulates endometrial re-epithelialization and proliferation and stabilizes lysosomal enzymes. Evidence suggests that high-dose estrogen therapy also stimulates clotting at the capillary level.<sup>159,160</sup> **In patients who are hemodynamically unstable, intravenous estrogen therapy (25 mg conjugated equine estrogens every 4 hours intravenously**

**until bleeding subsides, for up to 24 hours) is very effective.** Treatment with an antiemetic is recommended (e.g., promethazine, 12.5–25 mg intramuscularly or rectally), because high-dose estrogen results in nausea and vomiting in up to 40% of patients.<sup>161</sup> The regimen controls acute bleeding effectively in more than 70% of patients, usually within 4–8 hours.<sup>161</sup> Thereafter, high-dose estrogen therapy should continue orally (2.5 mg conjugated estrogens or 2.0 mg micronized estradiol every 6 hours), tapering to a once daily dose after bleeding is controlled and adding a progestin (e.g., medroxyprogesterone acetate 5–10 mg daily × 7–10 days) or changing to an estrogen-progestin contraceptive after 14–21 days to stabilize the estrogen-stimulated endometrial growth. In the hemodynamically stable patient with a denuded endometrium whose bleeding is less emergent but still acute and quite heavy, the same high-dose oral estrogen and antiemetic treatment regimen generally is effective.

**High-dose intravenous or oral estrogen treatment may increase the risk of thromboembolism. There are no data that quantify the risk, but venous and pulmonary embolism is a potential complication and has been reported.<sup>162</sup> As with any therapeutic decision, the benefits of treatment must be weighed against its potential risks and those of alternative methods for the management of AUB. In women with a personal or family history of thromboembolism, high-dose estrogen treatment should be avoided, if at all possible.**

# Curettage

In women with acute bleeding, **dilation and curettage** can be performed as both a therapeutic and diagnostic procedure. Curettage is an expeditious and effective way to stop acute uncontrollable uterine bleeding in the absence of any apparent pathology.<sup>163</sup> The mechanism responsible for the therapeutic effects of curettage is not entirely clear, but surgical denudation of the basal layer of the endometrium is presumed to acutely stimulate all of the normal processes involved in cessation of normal menstrual bleeding—local clotting mechanisms, vasoconstriction of basal arterioles, and re-epithelialization.<sup>39</sup> Blind curettage however can easily miss focal lesions and, in most cases, does not treat the underlying cause of bleeding.<sup>164</sup> Consequently, curettage ideally should be combined with hysteroscopy to improve diagnostic accuracy and the effectiveness of postoperative treatment, thereby minimizing the risk for recurrence.<sup>26,147</sup>

# TREATMENT OF ABNORMAL BLEEDING FROM SPECIFIC CAUSES

---

As reviewed above, not all irregular or abnormally heavy or prolonged menstrual bleeding relates to anovulation. History and physical examination generally are all that is needed to exclude trauma and foreign bodies. With few exceptions (retained nonviable products of conception), complications of pregnancy are easily excluded with a simple pregnancy test. Cervical biopsy of any suspicious lesion and endometrial biopsy in women with risk factors for endometrial cancer eliminate reproductive tract malignancies as a possibility. Otherwise, the differential diagnosis of abnormal bleeding in ovulatory women and in anovulatory women who fail appropriate hormonal treatment centers on a few major possibilities that are captured by the PALM-COEIN mnemonic and which require an individualized management approach.

# Endometrial Polyps

**When polyps are identified by transvaginal ultrasonography or sonohysterography, hysteroscopic surgery offers a simple and highly effective remedy.<sup>39</sup>** In premenopausal women, endometrial polyps have only a 1.7% chance of malignancy, but the risk is increased if the patient has AUB. Thus, for patients with AUB-P, polyp removal is recommended to both address the presenting symptom and assess for malignancy.

# Adenomyosis

Symptomatic adenomyosis can be particularly challenging. There have been no large or controlled studies of medical or limited surgical treatment for adenomyosis. In individual patients, continuous treatment with progestins, suppression by treatment with a GnRH agonist, and use of aromatase inhibitors can be effective, similar to their use in patients with endometriosis.<sup>165</sup> **Growing evidence indicates that insertion of a LNG-IUS can be very effective in providing relief from both menorrhagia and dysmenorrhea in women with adenomyosis.**<sup>166,167,168,169,170</sup> Conservative surgery can be technically challenging because, unlike the pseudocapsule that typically surrounds leiomyomas, there is no clear plane separating adenomyotic nodules from normal myometrium. Uterine artery embolization has proven effective in some women but is not appropriate for women who have not completed childbearing.<sup>171,172,173</sup>

# Leiomyomas

The nature and severity of symptoms; the size, location, and multiplicity of myomas; and desire for fertility are all relevant to the choice of management approach to symptomatic uterine myomas. In some women, medical treatment can be helpful in the management of abnormal bleeding directly related to uterine myomas. Estrogen-progestin contraceptives can decrease the volume and duration of blood loss in the same way they do in women without fibroids; benefits are less likely in women with submucous myomas. Nonsteroidal anti-inflammatory drugs (NSAIDs), GnRH agonists, and, most recently, GnRH antagonists all offer benefits and are individually discussed below.

**The surgical management of abnormal bleeding resulting from or aggravated by uterine myomas must be individualized after considering the size, number, and location of the fibroids; the relative risks, benefits, and consequences of different surgical treatments; age; and desire for future fertility.** In general, hysteroscopic myomectomy is a logical choice for a single symptomatic small submucous myoma, regardless of age and future reproductive goals. Hysteroscopic surgery for large and multiple submucous myomas requires greater technical expertise and poses greater risks, including sterility resulting from severe postoperative intrauterine adhesions—an important consideration in women who hope to preserve their fertility. Patients should be counseled that a hysteroscopic approach for resection of a large or numerous submucosal fibroids may require a staged or “two-step” surgery, if visibility is compromised due to poor distention of the cavity or attainment of maximal fluid deficit before complete resection is achieved. Submucous myomas that extend deeply into the myometrium (>50%) can be managed by subtotal hysteroscopic myomectomy, abdominal myomectomy, or hysterectomy, depending on the surgeon’s skills and the need to preserve fertility potential. For those experienced with the procedure, laparoscopic or robotic myomectomy approaches are options that are increasingly utilized by women who have not yet completed childbearing; while offering quicker postoperative recovery and cosmetic benefits from smaller size incisions, these minimally invasive approaches do not eliminate the risk of pelvic adhesions nor the need for cesarean delivery in a future pregnancy. Hysterectomy is certainly an option for women with AUB, multiple large fibroids, and no interest in future pregnancy.

# Endometrial Hyperplasia

Endometrial hyperplasia is a histologic diagnosis based on findings of proliferating glands of varying size and shape and a greater gland-to-stroma ratio than is observed in the normal endometrium.<sup>79</sup> Endometrial hyperplasia results almost exclusively from unopposed chronic estrogen stimulation.

Historically, endometrial hyperplasia was classified as simple or complex (reflecting the architectural pattern), with or without nuclear atypia (enlargement, rounding, pleomorphism, and aneuploidy). The simple and complex designations, based upon the gland-to-stroma ratio in the endometrium, were abandoned by the World Health Organization in 2014,<sup>80</sup> both to simplify the terminology and to better reflect the molecular understanding that only the presence of atypia is reflective of the genetic changes that are relevant to the risk of progression of hyperplasia to invasive endometrial cancer. Lesions without atypia basically represent only exaggerated forms of persistent proliferative endometrium; they regress spontaneously, after curettage or with progestin treatment, and are associated with little risk (1–3%) for progression to adenocarcinoma.<sup>81,82,83,84</sup> In contrast, atypical endometrial hyperplasia exhibits an entirely different behavior; it does not often spontaneously regress, can be quite resistant to even repeated curettage or prolonged high-dose progestational therapy, has significant risk (10–30%) of progression to adenocarcinoma if left untreated, and must therefore be regarded as a precancerous lesion.<sup>81,82,83,84</sup> Atypical lesions are distinguished from invasive carcinomas by the absence of stromal invasion. It is important to note that, despite concerted efforts to standardize classification criteria, there is significant interobserver variability in the classification assigned by pathologists, even within the same institution.<sup>85,86</sup> Other classification systems have been proposed,<sup>87,88</sup> but none has gained wide acceptance.

**When an office biopsy reveals endometrial hyperplasia, further evaluation is required to exclude atypia or a coexisting cancer that was not represented in the tissue specimen, and if subsequent curettage reveals atypical endometrial hyperplasia, there is significant risk of an unrecognized adenocarcinoma.** In a retrospective study involving 824 women with a diagnosis of complex atypical hyperplasia after office sampling, 100 were diagnosed with cancer after further evaluation with curettage, but 298 of the remaining 724 (41%) had unexpected cancer in a hysterectomy specimen obtained within 6 months of the original diagnosis; among those having an occult cancer, 30% had been further evaluated with curettage and 45% had not.<sup>89</sup>

Endometrial hyperplasia without atypia has a low risk for progression to endometrial cancer and can be corrected using progestin treatment regimens similar to

those recommended for the management of anovulatory bleeding. Cyclic progestin therapy (medroxyprogesterone acetate 5–10 mg daily or norethindrone acetate 5 mg daily for 14 days/month × 3–6 months) induces regression in at least 80–90% of patients<sup>82,174</sup>; alternatively, continuous progestin treatment for a similar interval is an effective option. Yet another option for women interested in longer-term contraception is LNG-IUS.<sup>175,176,177</sup> Repeat biopsy to confirm regression is recommended in 3 months following initiation of treatment, and in those with a LNG-IUS, it can be performed without removing the device.

**Hysterectomy should be considered in patients with persistent endometrial hyperplasia with atypia that is unresponsive to aggressive progestin regimens.** Women with intent on preserving their reproductive potential may be treated with progestins, but more potent and longer durations of treatment (megestrol acetate 80 mg twice daily for 3–6 months) are required and repeated biopsies to monitor response and confirm resolution of the lesion are essential. Insertion of an LNG-IUS is an effective treatment option<sup>178</sup>; in fact, multiple studies suggest it is more effective than oral progestins, with higher resolution and lower relapse rates. Most women with atypical hyperplasia will respond to medical treatment.<sup>179,180,181</sup> The median time to regression is approximately 9 months, and persistent disease after 7–9 months of treatment predicts failure.<sup>179,181</sup> Resistant lesions in women who remain adamantly opposed to surgery may require even higher and longer durations of progestational therapy. The resistance of atypical lesions to progestin therapy should not be surprising since nuclear atypia reflects a degree of cellular dedifferentiation. **Women who respond to medical management should be encouraged to pursue pregnancy at the earliest possible time and must be carefully monitored because recurrence is common. Once childbearing is completed, placement of LNG-IUS and periodic endometrial surveillance utilizing transvaginal ultrasound and endometrial sampling may be considered.**

# Coagulation Disorders

Desmopressin (DDAVP) is a synthetic analog of arginine vasopressin that has been used to treat AUB in women with coagulation disorders, especially those with von Willebrand disease.<sup>182,183,184</sup> The drug promotes the release of von Willebrand factor from endothelial cell storage sites and also may have other actions.<sup>185</sup> Desmopressin can be administered intravenously, subcutaneously, or by intranasal spray. The nasal spray formulation generally is recommended for home and prophylactic treatment of von Willebrand disease. Treatment induces a rapid increase in coagulation factor VIII and von Willebrand factor that lasts 6–12 hours. **Although its effects may be only modest, desmopressin has been used successfully in the management of heavy menstrual bleeding in women with von Willebrand disease, beginning treatment with the onset of menses.**<sup>183,184,186, 187,188</sup>

Antifibrinolytic therapy is an alternative to treatment with desmopressin in women with menorrhagia relating to von Willebrand disease. Tranexamic acid prevents clot dissolution, particularly in mucous membranes having naturally high fibrinolytic activity such as the endometrium.<sup>188,189</sup> Estrogen-progestin contraceptives or the LNG-IUS also help to reduce the volume and duration of menses in women with von Willebrand disease.<sup>190,191</sup>

# Chronic Endometritis

Although there is no single etiology that has been identified as a mechanism for chronic endometritis, a number of infectious etiologies have been suggested including gut bacteria, mycoplasma, ureaplasma, chlamydia, and even yeast. While there is no consensus on the choice of antimicrobial regimen nor on duration of therapy, a number of empiric regimens are in clinical use ([Table 15.5](#)).<sup>192,193,194,195</sup>

## **TABLE 15.5 Common Approaches to Managing Chronic Endometritis (CE) Chronic Endometritis**

Approach	Who for?	With what?	How long?
<b>Expectant</b>	If CE is an incidental finding	Vigilant Watching	—
<b>Antimicrobial treatment</b>	If evidence of CE is accompanied by: <ul style="list-style-type: none"> <li>• Abnormal bleeding</li> <li>• Pregnancy loss</li> <li>• Infertility</li> </ul>	<ol style="list-style-type: none"> <li>1. Doxycycline</li> <li>2. Metronidazole</li> <li>3. Levaquin</li> <li>4. Ciprofloxacin</li> <li>5. Combinations <ul style="list-style-type: none"> <li>• 1 + 2</li> <li>• 1 + 3 or 1 + 4</li> <li>• 1 + 2 + 3</li> </ul> </li> </ol>	7–21 d

If the abnormal bleeding does not improve with this treatment, efforts should be made to identify another explanation for the abnormal bleeding.

# OTHER TREATMENTS FOR HEAVY MENSTRUAL BLEEDING

---

A specific cause for heavy or prolonged menstrual bleeding in ovulatory women cannot always be identified; local defects in endometrial hemostasis are presumed responsible.<sup>196</sup> Nevertheless, the problem still can be effectively managed using a variety of nonspecific medical and surgical therapies.

# Nonsteroidal Anti-Inflammatory Drugs

There is little question that prostaglandins have important actions on the endometrial vasculature and in endometrial hemostasis. The concentrations of PGE<sub>2</sub> and PGF<sub>2α</sub> increase progressively in human endometrium during the menstrual cycle and are found in high concentrations in menstrual endometrium.<sup>39</sup> The NSAIDs inhibit prostaglandin synthesis and decrease menstrual blood loss and may also alter the balance between thromboxane A<sub>2</sub> (a vasoconstrictor and promoter of platelet aggregation) and prostacyclin (a vasodilator and inhibitor of platelet aggregation).<sup>197</sup>

Although the exact mechanism involved is unclear, NSAIDs decrease both normal menstrual bleeding and the increased bleeding associated with an intrauterine device.<sup>198,199</sup> **In general, NSAID treatment reduces menstrual blood loss by approximately 20–40% and to a greater extent in those with heavy menstrual bleeding.**<sup>200,201,202</sup> Ibuprofen (400 mg, taken 3 times daily) and mefenamic acid (500 mg, taken 3 times daily) have been studied most extensively, but no specific NSAID offers any clear advantage.<sup>202</sup> Treatment with NSAIDs might be considered the first-line therapy for ovulatory women with heavy menstrual bleeding and no demonstrable pathology. Side effects are few because treatment is limited, usually beginning with the onset of bleeding and continuing for 3–5 days as necessary. NSAIDs have the added advantage of providing relief from dysmenorrhea, even when menses are normal, and can be taken perimenstrually by women attempting to conceive.

# Estrogen-Progestin Contraceptives

In addition to their role in anovulatory women, estrogen-progestin contraceptives can be used to reduce menstrual blood loss in ovulatory women with heavy menstrual bleeding, regardless whether the bleeding is associated with pathology (e.g., myomas, adenomyosis) or is unexplained. **In women with unexplained menorrhagia, estrogen-progestin contraceptives can be expected to decrease bleeding by up to 40%.** <sup>203,204</sup>

# The Levonorgestrel-Releasing Intrauterine System

The LNG-IUS is available in multiple models with different doses and release rates of progestin, as well as different physical sizes and durations of efficacy. The best-studied model is LNg 52/5, marketed in the United States under the brand name Mirena. Mirena has a reservoir containing 52-mg levonorgestrel mixed with polydimethylsiloxane, which controls the rate of hormone release. For contraceptive purposes, the device is approved for 5 years but lasts for 7 years and perhaps up to 10 years. **Menstrual blood loss in women with heavy menstrual bleeding can be reduced by 75–95%, due to progestin-induced decidualization of the endometrium.**<sup>205,206</sup> Data from randomized trials indicate that the decrease in menstrual blood loss achieved with the LNg 52/5 is greater than with cyclic administration of norethindrone (5 mg 3 times daily, cycle days 5–26),<sup>206,207</sup> NSAIDs,<sup>208,209</sup> or tranexamic acid<sup>210</sup> and approaches or even equals that achieved with endometrial ablation.<sup>211,212</sup> Patient satisfaction with the LNG-IUS also compares favorably to that with ablation or hysterectomy.<sup>211</sup> **The LNG-IUS is an attractive option for ovulatory women with heavy menstrual bleeding and for women with intractable bleeding associated with chronic illnesses (renal failure).**

# Gonadotropin-Releasing Hormone Agonists

Treatment with a long-acting gonadotropin-releasing hormone agonist (GnRHa) can achieve short-term relief from a bleeding problem and has been used effectively as a preoperative adjunct in women awaiting conservative (myomectomy, endometrial ablation) or definitive surgery (hysterectomy) for abnormal bleeding.

**In women with severe anemia resulting from menorrhagia, preoperative GnRHa-induced amenorrhea can provide temporary relief from further bleeding, allow hemoglobin levels to return to normal, and decrease the probability of transfusion with surgery.** GnRHa treatment also will often decrease the size of myomas and overall uterine mass. In women with large fibroids awaiting hysterectomy, the effect can provide an added benefit by allowing a minimally invasive surgical approach when an abdominal operation might otherwise have been required. While the same benefit can be obtained for women with plans for myomectomy (along with a small decrease in intraoperative blood loss), GnRHa can decrease the size and firmness of myomas, making their identification and removal more difficult. This can result in both an increase in surgical difficulty and an increased chance of persistent myomas that remain after the surgery. As a method for thinning the endometrium before an ablation procedure (particularly using a resectoscope), GnRHa treatment improves operating conditions and outcomes.<sup>213</sup>

GnRHa treatment is also useful in the management of abnormal menstrual bleeding that may follow organ transplantation where the toxicity of immunosuppressive drugs makes use of sex steroids less desirable. However, the expense and side effects resulting from estrogen deficiency (hot flashes, bone mineral depletion) make GnRHa an unattractive long-term strategy for treatment of abnormal bleeding.

# **Gonadotropin-Releasing Hormone Antagonists**

An oral formulation of a GnRH antagonist was recently approved in the United States (Elagolix) for the management of moderate to severe pain associated with endometriosis but also offers a potential for benefit for the management of heavy uterine bleeding related to uterine fibroids.<sup>214</sup>

# Selective Progesterone Receptor Modulators

This class of agents includes mifepristone and ulipristal acetate (UPA), which in the past decade has emerged as an effective strategy against heavy menstrual bleeding related to uterine fibroids. Selective progesterone receptor modulators (SPRMs) are highly effective in improving fibroid-related menstrual loss and health-related quality of life.<sup>215</sup> In clinical studies, repeated doses of UPA reduced the median fibroid volume by 45% with nearly 90% of patients reporting a significant reduction in menstrual bleeding.<sup>216</sup> Long-term use of SPRMs however has been associated with unique endometrial effects described as progesterone receptor modulator–associated endometrial changes (PAEC), which are considered as both benign and reversible.<sup>217</sup>

# Tranexamic Acid

Tranexamic acid is an antifibrinolytic agent that has been used widely in Europe for the treatment of menorrhagia. The drug reversibly blocks lysine binding sites on plasminogen, thereby preventing fibrin degradation. An oral form of the drug was approved by the U.S. Food and Drug Administration in 2009 for the treatment of heavy menstrual bleeding. The drug is administered for 4–7 days during menses (1000–1500 mg 3–4 times daily; the FDA-approved formulation sold in the United States is taken as 1300 mg 3 times daily for 5 days during menstruation) and decreases menstrual blood loss by 35–60%.<sup>218,219</sup> The risk for thrombosis associated with tranexamic acid is controversial.<sup>220,221</sup> Consequently, it has limited value in women with contraindications to hormone therapy, because most relate to the risk of thrombosis.

# Endometrial Ablation

Persistent bleeding despite treatment is both frustrating and concerning. Myomas and polyps usually can be removed, with improvement or resolution of abnormal bleeding. Hysterectomy is an appropriate choice for some, but many prefer to avoid a major operation if possible, and still others have conditions that make them poor candidates for major surgery. Endometrial ablation is another option for the management of unexplained heavy menstrual bleeding when medical treatments are rejected, unsuccessful, or poorly tolerated.<sup>222</sup>

A wide variety of methods have been developed for endometrial ablation. The first method described was hysteroscopic Nd:YAG (neodymium-doped yttrium aluminum garnet) laser photovaporization, almost 40 years ago.<sup>223</sup> Soon thereafter, less costly techniques were developed using electro-surgical instruments (resectoscopic loop, roller ball).<sup>224,225</sup> A number of randomized controlled trials have compared hysteroscopic electro-surgical endometrial ablation to hysterectomy as treatment for heavy menstrual bleeding. Overall, hysterectomy involves longer operating and recovery time, a higher risk for complications, and greater expense but provides a permanent solution; the need for retreatment of many women after ablation narrows the cost difference over time. Satisfaction rates with both procedures are high.<sup>226</sup>

Several additional techniques for endometrial ablation have been developed.<sup>227</sup> Hysteroscopic approaches include a bipolar vaporizing electrode<sup>228</sup> and a hydrothermal technique.<sup>229</sup> There are also balloon devices that contain heated water ( $87^{\circ}\text{C} \pm 5^{\circ}\text{C}$ )<sup>230,231</sup> and another method that uses a gold-plated mesh electrode that conforms to the uterine cavity and ablates with bipolar radiofrequency.<sup>232,233</sup> Still, others employ microwave<sup>234</sup> or cryosurgical technologies.<sup>235</sup> **Compared to traditional hysteroscopic methods, the “blind” techniques for ablation are technically easier to perform, take less time, are more likely to require only local anesthesia, and achieve similar results, but equipment problems are more common.**<sup>196,236</sup>

Although all methods are effective, there are reasons for choosing one method over another in individual women. Cryoablation and thermal balloon ablative devices are available for office use for women who prefer an office-based procedure using minimal or no anesthesia.<sup>236</sup> Radiofrequency electro-surgical ablation is another excellent office-based method and does not require medical pretreatment to thin the endometrium. Hydrothermal ablation is the procedure of choice for women having an abnormally shaped uterine cavity, unrelated to uterine myomas. For women with submucous fibroids smaller than 3 cm, microwave ablation may be ideal, although hysteroscopic myomectomy and roller ball electro-surgical ablation also is appropriate and is

preferred for women with larger submucous myomas ([Table 15.6](#)).

## **TABLE 15.6**

Method	Advantages	Disadvantages
Cryoablation	Not completely blind Less pain than methods using heat energy Requires minimal or no anesthesia	No outcomes data for women with intracavitary lesions
Thermal balloon ablation	First global technique approved for use Easy to learn	Not recommended for women with an abnormal uterine cavity (anomaly, enlarged, polyps, myomas, adhesions)
Hydrothermal ablation	Circulating hot water contacts all endometrial surfaces, regardless of shape Direct visualization of uterine cavity	Not recommended for women with a uterus >10 cm Requires 8 mm hysteroscope Hot water stimulates pain Risk for burns to vagina and perineum
Bipolar radiofrequency ablation	Short procedure time Easy to perform Requires no endometrial pretreatment	Not recommended for women with an enlarged or abnormal uterine cavity
Microwave ablation	Applicable in women with large cavity or small myomas (<3 cm)	Requires pretreatment ultrasonography to document minimum 1 cm myometrial thickness in all areas Contraindicated for women with previous transmural myomectomy or classical cesarean section

Preoperative evaluation before ablation should include thorough examination of the uterine cavity by saline sonography or office hysteroscopy to exclude focal lesions such as polyps and myomas that can be resected and to identify women not having a normally shaped uterine cavity who may not be appropriate candidates for some global ablation methods like the thermal balloon. Best results with ablation can be achieved if the endometrium also is first rendered thin and inactive, to increase the likelihood that ablation will include the basal layer of the endometrium, which is 4–6 mm beneath the surface, depending on the phase of the cycle. Several methods to achieve that purpose have been described, including curettage immediately prior to performing the ablation and preoperative treatment with progestins, estrogen-progestin contraceptives, danazol, or GnRH agonists.<sup>213,237</sup> Bipolar radiofrequency ablation is an exception, in that the technique is equally effective with and without endometrial pretreatment.

**Among women with menorrhagia who undergo an endometrial ablation procedure, 80–90% report reduced bleeding, 25–50% develop amenorrhea, 70–80% report less menstrual pain, 75–90% are satisfied with the surgical outcome, and 80% require no additional surgery up to 5 years after ablation.**<sup>229,231,232,234,235,236,238,239,240</sup> Approximately 15–24% of women who have an endometrial ablation will later have a hysterectomy. Overall, despite the lower risks, fewer complications, and more rapid recovery associated with endometrial ablation, women treated with hysterectomy tend to be more satisfied with the outcome.<sup>241,242,243,244</sup>

For obvious reasons, endometrial ablation is not an appropriate treatment for women who have not completed childbearing. Conversely, endometrial ablation is not a sterilization procedure. Although uncommon, pregnancy is still possible after ablation and is associated with an increased risk for complications, including miscarriage, antepartum hemorrhage, preterm delivery, and abnormal placentation.<sup>245,246</sup> Consequently, sexually active women still require contraception after endometrial ablation.

There are legitimate concerns that endometrial carcinomas might be inadvertently managed by endometrial ablation<sup>247,248</sup> or that the procedure might obliterate portions of the uterine cavity leaving isolated, residual islands of endometrium in which adenocarcinoma could develop and go unrecognized in the absence of bleeding.<sup>249,250</sup> These observations emphasize the importance of thorough preoperative evaluation, to include endometrial biopsy, and proper patient selection for ablation procedures. **Although the risk can never be completely avoided, endometrial ablation is not recommended for women at increased risk for endometrial cancer (obesity, diabetes, hypertension, smoking, family history, chronic anovulation).**<sup>251</sup> **Importantly, in women who have had an endometrial ablation and receive postmenopausal hormone therapy, treatment must include a progestin to minimize the induction of endometrial hyperplasia or cancer from long-term use of estrogen alone.**

Other complications of endometrial ablation include hematometra, cervical stenosis, and uterine perforation. Hematometra develops when active islands of endometrium remain above ablated areas that adhere. Thorough ablation of the upper limits of the cavity, including the cornua and tubal ostia but excluding the cervix and cervical-uterine junction, decreases the risk for complication. Uterine perforation complicates 1% or less of endometrial ablation procedures.

Endometrial ablation can be an effective treatment for women with acute or prolonged bleeding who are hemodynamically stable when medical treatment fails or is contraindicated.<sup>252,253,254,255</sup> In one reported series of 26 women with acute severe bleeding treated by hysteroscopic endometrial resection, no further medical or surgical treatment was required for 24 of the women over 19 months of follow-up; 1 with endometrial cancer detected in the surgical specimen and another with uterine myomas required hysterectomy.<sup>252</sup>

## Key Point: Clinical Principles

Considering that abnormal menstrual bleeding is the single most common complaint

that reproductive-age women bring to their physician, all clinicians who provide primary care for women must have an organized, logical approach to the evaluation and treatment of the problem. The following summarizes the key elements of the clinical evaluation and treatment of abnormal menstrual bleeding in premenopausal women.

# DIAGNOSTIC EVALUATION SUMMARY

---

- Anovulatory bleeding is usually irregular, infrequent, and unpredictable; variable in amount, duration, and character; and most often observed in adolescents and aging women, the obese, and women with the clinical features of PCOS.
- Regular and predictable but increasingly heavy or prolonged periods or new onset of episodic intermenstrual bleeding more often results from a structural abnormality than from anovulation.
- Recurrent episodes of intermenstrual bleeding often result from intrauterine pathology and warrant evaluation.
- The most common cause of a sudden departure from a well-established pattern of predictable menses is a complication of pregnancy.
- The evaluation of women with a complaint of AUB should include a pregnancy test and complete blood count to exclude the possibility of pregnancy and to identify those with anemia and thrombocytopenia.
- When the clinical history and examination clearly point to anovulatory bleeding, empiric medical treatment can be offered without additional laboratory evaluation or imaging.
- A well-timed serum progesterone determination can help to confirm the diagnosis of anovulatory bleeding when doubt exists. A serum TSH can exclude thyroid disorders in anovulatory women. Liver or renal function tests are indicated only for those with known or strongly suspected disease.
- Bleeding disorders are more common than is generally perceived. Coagulation tests are indicated for adolescents with heavy menstrual bleeding from menarche, women with past episodes of excessive bleeding from trauma or surgery, and those with unexplained heavy or prolonged menstrual bleeding.
- Endometrial biopsy should be seriously considered before treatment begins when the clinical history suggests long-term unopposed estrogen exposure, regardless of age, but is unnecessary when the endometrium is very thin (<5 mm). Endometrial biopsy should be considered when the endometrium is abnormally thick (>12 mm), even when clinical suspicion of disease is low.
- Uterine imaging with ultrasound or sonohysterography should be performed when examination reveals abnormal uterine size or contours, when history (regular cycles of increasing volume or duration, new-onset intermenstrual bleeding), laboratory tests (serum progesterone >3 ng/mL), or biopsy results (secretory endometrium) provide objective evidence of ovulation, and when empiric medical treatment fails.
- The combination of sonohysterography and endometrial biopsy has high sensitivity and high negative predictive value for detection of endometrial and uterine

pathology in women with abnormal bleeding.

# TREATMENT SUMMARY

---

- Cyclic progestin therapy is an appropriate treatment for oligomenorrheic anovulatory women with episodic abnormal bleeding who do not need contraception; choice of an estrogen-progestin contraceptive or the LNG-IUS may be preferable in those seeking contraception. Standard cyclic progestin treatments do not reliably suppress the HPO axis, will not prevent random ovulation, and are not contraceptive.
- Estrogen therapy is the best initial treatment when a denuded or attenuated endometrium is strongly suspected or demonstrated. Clinical examples include women in whom optimally performed endometrial biopsy yields minimal tissue, women receiving chronic progestin treatment, and women with prolonged heavy bleeding. Progestin or estrogen-progestin therapy is unlikely to succeed in these situations and may even aggravate the problem.
- Failed medical management for presumed anovulatory bleeding suggests strongly that another pathology is causing or contributing to the bleeding and signals the need for additional diagnostic evaluation.
- In women with acute heavy bleeding, imaging with transvaginal ultrasonography helps to guide the choice of treatment by defining the endometrial thickness and revealing structural abnormalities not otherwise suspected.
- Acute prolonged episodes of heavy anovulatory bleeding can be treated effectively with high-dose estrogen-progestin therapy or with high-dose progestin alone (when estrogen is contraindicated), provided that the endometrium is normal or increased in thickness.
- Treatment with depot medroxyprogesterone acetate has no place in the acute management of abnormal bleeding. Once administered, it cannot be withdrawn, and if unsuccessful, its effects can be difficult to overcome.
- Endometrial curettage should be considered when bleeding is acute and demands immediate action or fails to respond promptly to intensive medical therapy. Hysteroscopy at time of curettage helps to ensure an accurate diagnosis.
- Endometrial hyperplasia without cytologic atypia is an exaggerated form of persistent proliferative endometrium resulting from long-term unopposed estrogen stimulation in women with chronic anovulation. With few exceptions, the lesion can be treated effectively with cyclic or continuous progestin therapy or by insertion of a LNG-IUS.
- Endometrial hyperplasia with cytologic atypia is a precancerous lesion best treated surgically except in women with intent on preserving reproductive potential. Medical management of atypical endometrial hyperplasia requires high doses and longer durations of progestin treatment or insertion of a LNG-IUS, serial

endometrial biopsies to monitor response, and longer-term close surveillance.

- Uterine myomas are extremely common and cannot be regarded as the cause of abnormal bleeding before other possibilities have been excluded, particularly when they do not protrude into or displace the uterine cavity. Sonohysterography clearly defines the proximity of myomas to the uterine cavity and helps to differentiate clinically relevant myomas from those that are not.
- Desmopressin is very effective for the management of heavy menstrual bleeding in women with von Willebrand disease, beginning treatment with the onset of menses. Tranexamic acid, estrogen-progestin contraceptives, or insertion of a LNG-IUS also helps to reduce the volume and duration of menses in women with coagulation disorders.
- Nonsteroidal anti-inflammatory drugs, estrogen-progestin contraceptives, LNG-IUS, and tranexamic acid are effective medical treatment options for the management of heavy menstrual bleeding in ovulatory women with adenomyosis, global cavity enlargement related to multiple intramural leiomyomata, and otherwise unexplained menorrhagia. SPRMs are the newest class of agents available for managing abnormal bleeding in patients with uterine fibroids. LNG-IUS and GnRH $\alpha$  are effective options for managing adenomyosis-related abnormal bleeding.
- Endometrial ablation using hysteroscopic or nonhysteroscopic techniques is an effective alternative to hysterectomy for management of abnormally heavy menstrual bleeding when medical treatments are rejected, unsuccessful, or poorly tolerated.

# The Breast

The form, function, and pathology of the human female breast are major concerns of medicine and society. Mammals define our biologic class by the ability of the breast to nourish our young. As obstetricians, we seek to enhance or diminish function, and as gynecologists, the appearance of inappropriate lactation (galactorrhea), breast masses, breast pain, or changes in breast contour may signify serious disease. Cancer of the breast is the most prevalent cancer in women.

This chapter reviews the factors involved in normal growth and development of the breast, including the physiology of normal lactation, describes the numerous factors leading to inappropriate lactation, and, finally, discusses the endocrine aspects of breast cancer.

# GROWTH AND DEVELOPMENT

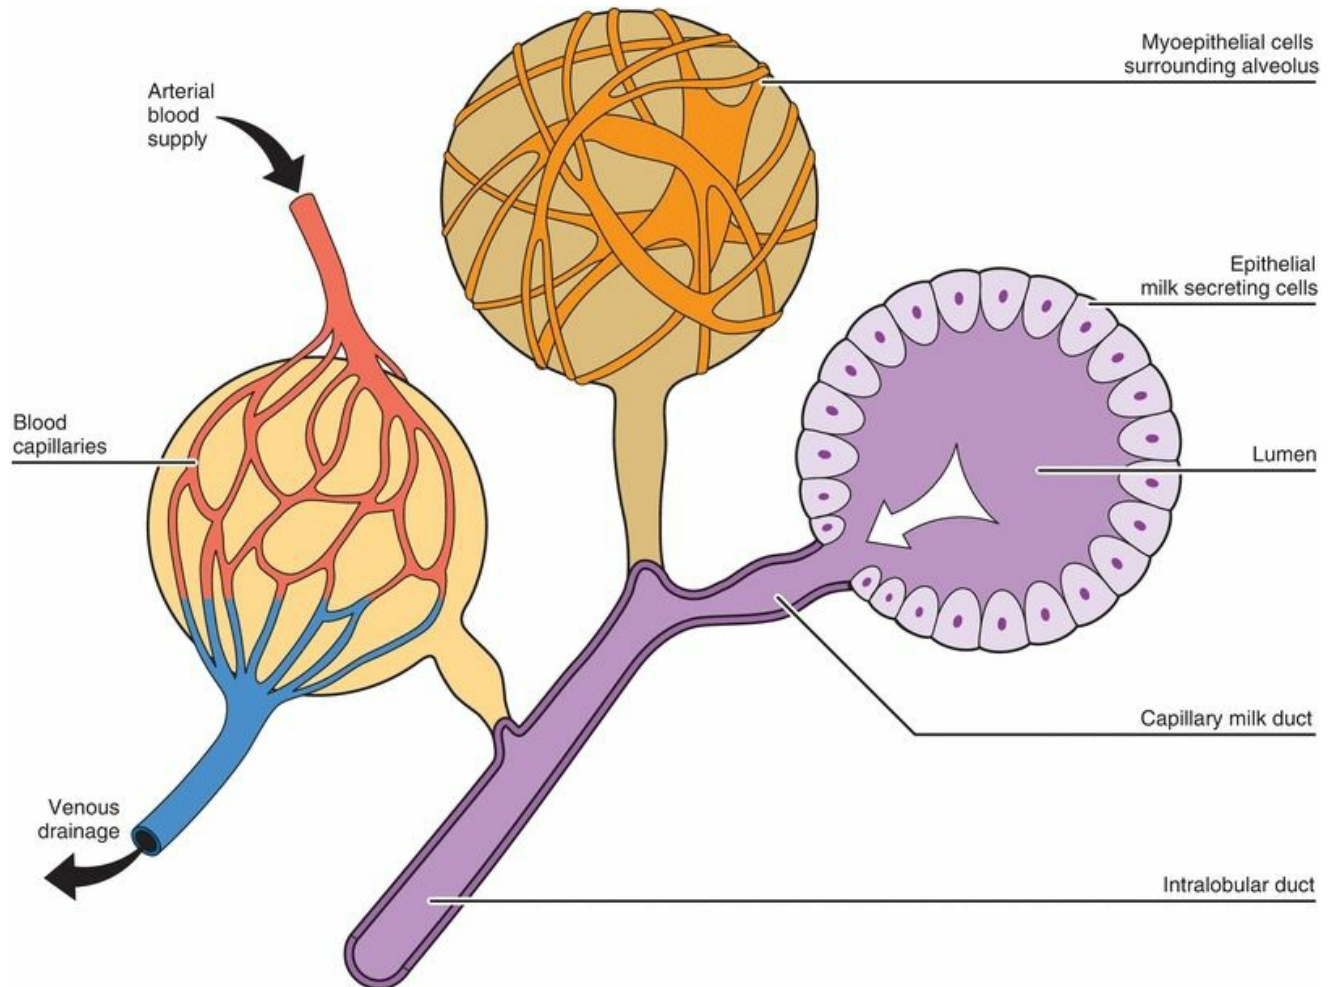

---

The basic component of the breast lobule is the hollow alveolus or milk gland lined by a single layer of milk-secreting epithelial cells, derived from an ingrowth of epidermis into the underlying mesenchyme at 10–12 weeks of gestation. Each alveolus is encased in a crisscrossing mantle of contractile myoepithelial strands and a rich capillary network.

The lumen of the alveolus connects to a collecting intralobular duct by means of a thin nonmuscular duct. There are 15–20 of these collecting intralobular ducts per breast, which are arranged radially into mammary lobules. The collecting intralobular ducts reach the exterior of the breast and are also lined by contractile muscle cells.

Growth of this milk-producing system is dependent on numerous hormonal factors that occur during embryologic development, at puberty, and then in pregnancy. Although there is considerable overlapping of hormonal influences, the differences in quantities of the stimuli in each circumstance and the availability of entirely unique inciting factors (human placental lactogen [hPL] and prolactin) during pregnancy permit this chronologic distinction. The strength of the hormonal stimulus to breast tissue during pregnancy is responsible for the fact that nearly half of the male and female newborns have breast secretions ([Figure 16.1](#)).

**FIGURE 16.1**

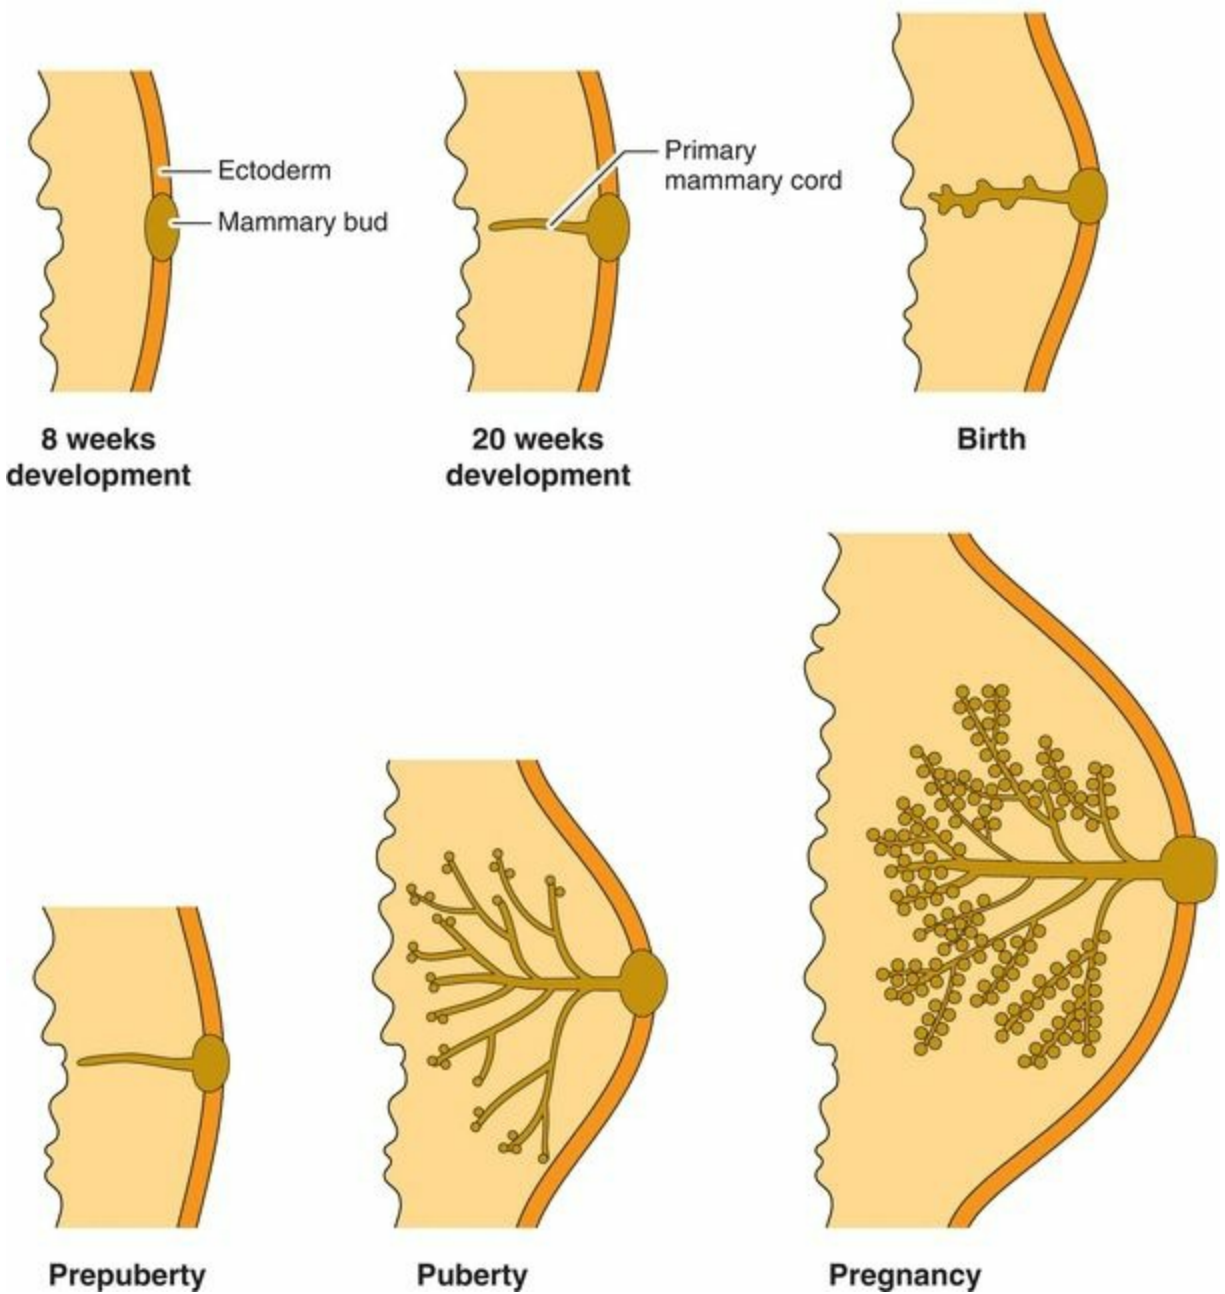

In embryologic development, the ectoderm gives rise to the epithelial component of the mammary gland and the mesoderm gives rise to the stroma. These initially form as mammary lines down the ventral surface of the embryo, resolving to one pair of placodes of mammary tissue in most humans due to complex signaling cascades from TBX3, BMP4, FGF10, Lef1, and Wnt10b.<sup>1,2</sup> These placodes descend from the surface epithelium into the underlying mesenchyme, leaving stalks of epithelium.<sup>3</sup> Once the mammary placode reaches the fat pad, the epithelium branches and lumenizes to form the rudimentary intralobular ducts. Nipple generation occurs by thickening of the epidermis and suppression of hair follicle growth, and this is regulated by parathyroid hormone–related protein.<sup>4</sup> In humans, these processes are similar in males and females.

Gender-specific breast differentiation in humans occurs at puberty. The major influences on breast growth at puberty are growth hormone as mediated by insulin-like growth factor 1 (IGF-1) and estrogen.<sup>5</sup> In most girls, the first response to the increasing levels of IGF-1, growth hormone, and estrogen is an increase in size and pigmentation

of the areola and the formation of a mass of breast tissue just underneath the areola. Breast tissue binds estrogen in a manner similar to the uterus and vagina. The human breast expresses both estrogen receptors, ER-alpha and ER-beta.<sup>6</sup> The development of estrogen receptors in the breast does not occur in the absence of prolactin. The primary effect of estrogen in subprimate mammals is to stimulate growth of the ductal portion of the gland system. Progesterone in these animals, in the presence of estrogen, influences growth of the alveolar components of the lobule that later become the milk-producing structures.<sup>7</sup> However, no hormone alone is capable of yielding optimal breast growth and development. Full differentiation of the gland requires insulin, cortisol, thyroxine, and prolactin.<sup>8</sup> Experimental evidence in mice knockout models supports the combined actions of estrogen and progesterone, mediated primarily by ER-alpha and progesterone receptor-B but dependent on epidermal growth factor and IGF-1.<sup>9,10,11,12</sup> Estrogen and progesterone receptors in normal breast tissue are located in nondividing epithelial cells and in stromal cells adjacent to proliferating epithelial cells, indicating the importance of paracrine communication using growth factors. Growth hormone–induced IGF-1 is essential in both mammary development and function.<sup>9</sup>

The pubertal response is a manifestation of closely synchronized central (hypothalamus-pituitary) and peripheral (ovary-breast) events. For example, gonadotropin-releasing hormone (GnRH) is known to stimulate prolactin release, and this action is potentiated by estrogen.<sup>13</sup> This suggests a paracrine interaction between gonadotrophs and lactotrophs, linked by estrogen, ultimately with an impact on the breast.

Changes occur routinely in response to the estrogen-progesterone sequence of a normal menstrual cycle. Maximal size of the breast occurs late in the luteal phase. Fluid secretion (**Figure 16.2**), mitotic activity, and DNA production of nonglandular tissue and glandular epithelium peak during the luteal phase.<sup>14,15,16</sup> This accounts for cystic and tender premenstrual changes.

**FIGURE 16.2**

During the normal menstrual cycle, estrogen receptors in mammary gland epithelium decrease in number during the luteal phase, whereas progesterone receptors remain at a high level throughout the cycle.<sup>17</sup> Studies using tissue from reduction mammoplasties or from breast tissue near a benign or malignant lesion have demonstrated a peak in mitotic activity during the luteal phase.<sup>15,18,19</sup> Using fine-needle biopsy tissue, an immunocytochemical marker of proliferation was higher in the luteal phase than in the proliferative phase.<sup>17</sup> And in this study, there was a direct correlation with serum progesterone levels. However, important studies indicate that with increasing duration

of exposure, progesterone imposes a limitation on breast cell proliferation.<sup>20,21,22</sup>

Final differentiation of the alveolar epithelial cell into a mature milk cell is accomplished by the gestational increase in estrogen and progesterone, combined with the presence of prolactin, but only after prior exposure to cortisol and insulin. The complete reaction depends on the availability of minimal quantities of thyroid hormone. Thus, the endocrinologically intact individual in whom estrogen, progesterone, thyroxine, cortisol, insulin, prolactin, hPL, and growth hormone are available can have appropriate breast growth and function. During the first trimester of pregnancy, growth and proliferation are maximal, changing to differentiation and secretory activity as pregnancy progresses.

Breast tissue changes with aging. During teenage years, the breasts are dense and predominantly glandular. As the years go by, the breasts contain progressively more fat, but after menopause, this process accelerates so that soon into the postmenopausal years, the breast glandular tissue is mostly replaced by fat.

# Abnormal Shape and Size

Early differentiation of the mammary gland anlage is under genetic and fetal hormonal control. Abnormalities in adult size or shape may reflect the impact of hormones (especially the presence or absence of testosterone) during this early period of development. This prenatal hormonal influence programs the breast development that will occur in response to the increase in hormones at puberty. Occasionally, the breast bud begins to develop on one side first. Similarly, one breast may grow faster than the other. These inequalities usually disappear by the time development is complete. However, exact equivalence in size may not be attained. Significant asymmetry is correctable only by a plastic surgeon. Likewise, hypoplasia and hypertrophy can be treated only by corrective surgery. Hormone therapy is ineffective in producing a permanent change in breast shape or size, with one exception, in patients with primary amenorrhea due to deficient ovarian function; estrogen treatment induces significant and gratifying breast growth. Breast size can be temporarily increased in current users of oral contraceptives, but there is no lasting effect associated with past use.<sup>23</sup>

**Accessory nipples** (almost always without underlying breast tissue) can be found anywhere from the groin to the neck, remnants of the mammary line that extends early in embryonic life (6th week) along the ventral, lateral body wall. They occur in approximately 1% of women (sporadic or familial) and require no therapy. Whether or not **polythelia** is associated with renal and urinary tract malformations is controversial.<sup>24,25,26,27,28</sup> It is recommended to investigate the renal-urinary tract by renal ultrasound in the presence of polythelia.<sup>29</sup>

**Accessory breast tissue** occurs because of incomplete embryologic regression of the mammary ridges, and for this reason, the location is along the mammary line that extends from the axilla to the pubic area. Ectopic breast tissue is usually detected during puberty, pregnancy, or lactation, a consequence of hormonally induced enlargement. Accessory breasts are commonly bilateral and occasionally are found in unusual locations such as the axilla, scapula, thigh, or labia majora, and when nipple and areola are absent, the mass can be a diagnostic dilemma.<sup>30</sup> Even when the diagnosis is obvious, surgical excision is indicated for cosmetic and comfort reasons.<sup>31</sup> Accessory breast tissue is subject to the same risk of cancer as normal breasts.

# **PREGNANCY AND LACTATION**

---

# Prolactin Secretion

In most mammalian species, prolactin is a single-chain polypeptide of 199 amino acids, 40% similar in structure to growth hormone and placental lactogen. All three hormones are believed to have originated from a common ancestral protein about 400 million years ago.

Prolactin is encoded by a single gene on chromosome 6, producing a molecule that in its major form is maintained in three loops by disulfide bonds.<sup>32</sup> Prolactin variants are the result of posttranslational modifications. Little prolactin represents a splicing variant resulting from the proteolytic deletion of amino acids. Big prolactin can result from the failure to remove introns; it has little biologic activity and does not cross-react with antibodies to the major form of prolactin. The so-called big variants of prolactin are due to separate molecules of prolactin binding to each other, either noncovalently or by interchain disulfide bonding. Some of the apparently larger forms of prolactin are prolactin molecules complexed to binding proteins. High levels of relatively inactive prolactin in the absence of a tumor can be due to the creation of macromolecules of prolactin by antiprolactin autoantibodies.<sup>33,34</sup> Overall, big prolactins account for somewhere between 10% and 25% of the hyperprolactinemia reported by commercial assays.<sup>35</sup>

Other modifications of prolactin exist, including glycosylation, phosphorylation, deamidation, and sulfation. Prolactin that has been glycosylated continues to exert activity, and other enzymatic cleavages of the prolactin molecule yield fragments that may be capable of biologic activity. Differences in the carbohydrate moieties can produce differences in biologic activity and immunoreactivity. However, the nonglycosylated form of prolactin is the predominant form of prolactin secreted into the circulation.<sup>36</sup>

**At any one point of time, the bioactivity (e.g., galactorrhea) and the immunoreactivity (circulating levels by immunoassay) of prolactin represent the cumulative effect of the family of structural variants. Remember, immunoassays do not always reflect the biologic situation (e.g., a normal prolactin level in a woman with galactorrhea). The routine radioimmunoassay of prolactin is generally clinically reliable, especially at extremely high levels associated with prolactin-secreting pituitary tumors.**

The anterior pituitary cells that produce prolactin, growth hormone, and thyroid-stimulating hormone (TSH; lactotrophs, somatotrophs, and thyrotrophs) require the presence of Pit-1, a transcription factor, for transactivation. Pit-1 binds to the prolactin gene in multiple sites in both the promoter region and in an adjacent region, designated as a distal enhancer; Pit-1 binding is a requirement for prolactin promoter activity and

gene transcription. Many hormones, neurotransmitters, and growth factors influence the prolactin gene, involved in a level of function beyond that allowed by Pit-1. Fundamental modulation of prolactin secretion is exerted by estrogen, producing both differentiation of lactotrophs and direct stimulation of prolactin production.<sup>37,38</sup> An estrogen response element is adjacent to one of the Pit-1 binding sites in the distal enhancer region, and estrogen stimulation of the prolactin gene involves interaction with this Pit-1 binding site. Estrogen additionally influences prolactin production by suppressing dopamine secretion.<sup>39</sup> Prolactin is also synthesized in extrapituitary tissues, including breast tissue and endometrial decidua.<sup>40</sup> In extrapituitary sites, the active promoter site is upstream of the pituitary initiation site and is not regulated by Pit-1, estrogens, or dopamine. Progesterone increases prolactin secretion in the decidua but has no effect in the pituitary (**Figure 16.3**).

**FIGURE 16.3**

Prolactin is involved in many biochemical events during pregnancy. Surfactant synthesis in the fetal lung is influenced by prolactin, and decidual prolactin modulates prostaglandin-mediated uterine muscle contractility.<sup>41,42</sup> Prolactin also contributes to the prevention of the immunologic rejection of the conceptus by suppressing the maternal immune response. Prolactin is both produced and processed in breast cells. The mechanisms and purpose for mammary production of prolactin remain to be determined, but prolactin in milk is believed to be derived from local synthesis. Transmission of this prolactin to the newborn may be important for immune functions.

# Prolactin-Inhibiting Dopamine

The basal hypothalamus maintains suppression of pituitary prolactin secretion by delivering dopamine, a prolactin-inhibiting factor (PIF), to the anterior pituitary via the portal circulation. Suckling suppresses the formation of dopamine.<sup>43</sup> Dopamine binds specifically to lactotroph cells and suppresses the secretion of prolactin into the general circulation; in its absence, prolactin is secreted. Dopamine binds to a G-protein-coupled receptor ([Chapter 2](#)) that exists in a long form and a short form, but only the D<sub>2</sub> (long form) is present on lactotrophs. There are several other PIFs, but a specific role has been established only for dopamine.

# Prolactin-Releasing Factor

Prolactin secretion may also be influenced by a positive hypothalamic factor, prolactin-releasing factor (PRF). PRF does exist in various birds. The identity of this material has not been elucidated or its function substantiated in normal human physiology. It is believed that most prolactin secretagogues work by inhibiting dopamine secretion, including thyrotropin-releasing hormone (TRH), growth factors, vasopressin, and oxytocin.<sup>44</sup> TRH stimulation of prolactin release involves calcium mechanisms (both internal release and influx via calcium channels) in response to the TRH receptor, also a member of the G-protein family. However, except in hypothyroidism, normal physiologic changes as well as abnormal prolactin secretion are easily explained and understood in terms of variations in the PIF, dopamine.

# The Prolactin Receptor

The prolactin receptor is encoded by a gene on chromosome 5p13–14 that is near the gene for the growth hormone receptor. The prolactin receptor belongs to a receptor family that includes many cytokines and some growth factors, supporting a dual role for prolactin as a classic hormone and as a cytokine.<sup>32</sup>

Prolactin receptors exist in more than one form, all containing an extracellular region, a single transmembrane region, and a relatively long cytoplasmic domain. There is evidence for more than one receptor, depending on the site of action (e.g., decidua and placenta).<sup>45</sup> The similar amino acid identity between prolactin and growth hormone receptors is approximately 30%, with certain regions having up to 70% homology.<sup>46</sup> Prolactin receptors are expressed in many tissues throughout the body. Because of the various forms and functions of prolactin, it is likely that multiple signal mechanisms are involved, and for that reason, no single second messenger for prolactin's intracellular action has been identified. A protein also exists that functions as a receptor/transporter, translocating prolactin from the blood into the cerebrospinal fluid, the amniotic fluid, and milk.

# Amniotic Fluid Prolactin

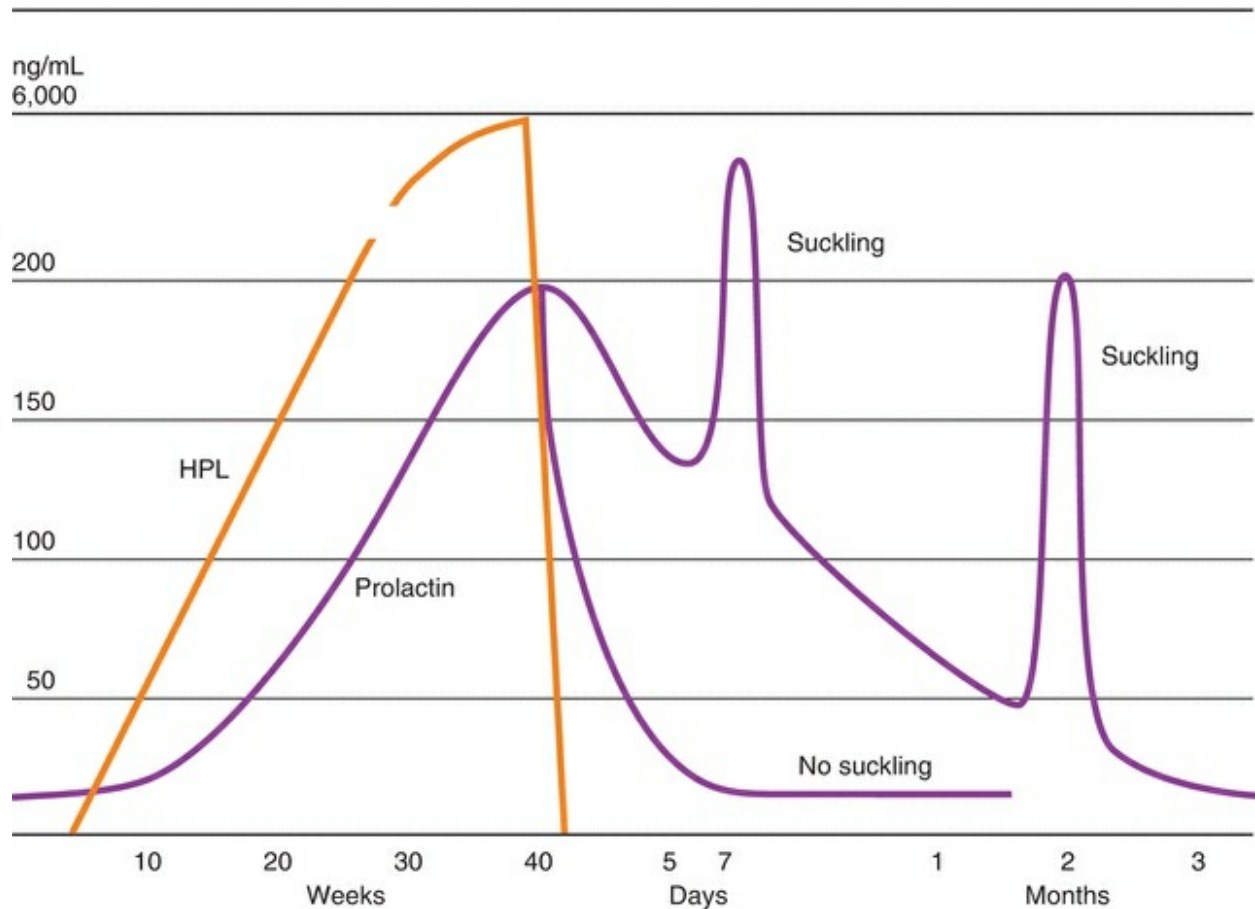

Amniotic fluid concentrations of prolactin parallel maternal serum concentrations until the 10th week of pregnancy, rise markedly until the 20th week, and then decrease. Maternal prolactin does not pass to the fetus in significant amounts. Indeed, the source of amniotic fluid prolactin is neither the maternal pituitary nor the fetal pituitary. The failure of dopamine agonist treatment to suppress amniotic fluid prolactin levels, and studies with in vitro culture systems indicate a primary decidual source with transfer via amnion receptors to the amniotic fluid, requiring the intactness of amnion, chorion, and adherent decidua. This decidual synthesis of prolactin is initiated by progesterone, but once decidualization is established, prolactin secretion continues in the absence of both progesterone and estradiol.<sup>47</sup> Various decidual factors regulate prolactin synthesis and release, including relaxin, insulin, and IGF-1. Prolactin produced in extrapituitary sites involves an alternative exon upstream of the pituitary start site, generating a slightly larger RNA transcript compared with the pituitary product. However, the amino acid sequence and the chemical and biologic properties of decidual prolactin are identical to those of pituitary prolactin. It is hypothesized that amniotic fluid prolactin plays a role in modulating electrolyte economy not unlike its ability to regulate sodium transport and water movement across the gills in fish (allowing the ocean-dwelling salmon and steelhead to return to freshwater streams for reproduction). Thus, prolactin would protect the human fetus from dehydration by control of salt and water transport across the amnion. Prolactin reduces the permeability of the human amnion in the fetal to maternal direction by a receptor-mediated action on the epithelium lining the fetal surface.<sup>48</sup> Decidual and amniotic fluid prolactin levels are lower in hypertensive pregnancies and in patients with polyhydramnios.<sup>49,50</sup> Prolactin receptors are present in the chorion laeve, and their concentration is lower in patients with polyhydramnios.<sup>51</sup> Thus, idiopathic polyhydramnios may be a consequence of impaired prolactin regulation of amniotic fluid.

# Lactation

During pregnancy, prolactin levels rise from the normal level of 10–25 ng/mL to high concentrations, beginning about 8 weeks and reaching a peak of 200–400 ng/mL at term.<sup>52,53</sup> The increase in prolactin parallels the increase in estrogen beginning at 7–8 weeks' gestation, and the mechanism for increasing prolactin secretion (discussed in [Chapter 7](#)) is believed to be estrogen suppression of the hypothalamic dopamine, as well as direct stimulation of prolactin gene transcription in the pituitary.<sup>54,55</sup> There is marked variability in maternal prolactin levels in pregnancy, with pulsatile secretion and a diurnal variation similar to that found in nonpregnant subjects. The peak level occurs 4–5 hours after the onset of sleep.<sup>56</sup>

Made by the placenta and actively secreted into the maternal circulation from the 6th week of pregnancy, hPL rises progressively, reaching a level of approximately 6,000 ng/mL at term. hPL, though displaying less activity than prolactin, is produced in such large amounts that it may exert a lactogenic effect.

Although prolactin stimulates significant breast growth, and is available for lactation, only colostrum (composed of desquamated epithelial cells and transudate) is produced during gestation. Full lactation is inhibited by progesterone, which interferes with prolactin action at the alveolar cell prolactin receptor level. Both estrogen and progesterone are necessary for the expression of the lactogenic receptor, but progesterone antagonizes the positive action of prolactin on its own receptor, while progesterone and pharmacologic amounts of androgens reduce prolactin binding.<sup>46,57,58</sup> In mice, progesterone stimulates a corepressor that blocks the promoter region of the casein milk protein gene, thus inhibiting transcription.<sup>59</sup> After delivery, the loss of progesterone leads to a decrease in the inhibitory peptide. The effective use of high doses of estrogen to suppress postpartum lactation indicates that pharmacologic amounts of estrogen also block prolactin action ([Figure 16.4](#)).

**FIGURE 16.4**

The principal hormone involved in milk biosynthesis is prolactin. Without prolactin, synthesis of lactose, lipids, and the primary protein, casein, will not occur, and true milk secretion will be impossible. The hormonal trigger for initiation of milk production within the alveolar cell and its secretion into the lumen of the gland is the rapid disappearance of estrogen and progesterone from the circulation after delivery. The clearance of prolactin is much slower, requiring 7 days to reach nonpregnant levels in a nonbreastfeeding woman. These discordant hormonal events result in removal of the estrogen and progesterone inhibition of prolactin action on the breast. Breast engorgement and milk secretion begin 3–4 days postpartum when the sex steroids have been sufficiently cleared. Maintenance of steroidal inhibition or rapid reduction of prolactin secretion (with a dopamine agonist) is effective in preventing postpartum milk synthesis and secretion. Augmentation of prolactin (by domperidone, metoclopramide, TRH, or sulpiride; all dopamine receptor blockers) results in increased milk yield.<sup>60</sup>

In the first postpartum week, prolactin levels in breastfeeding women decline approximately 50% (to about 100 ng/mL). Suckling elicits increases in prolactin, which is important in initiating milk production. Until 2–3 months postpartum, basal levels are approximately 40–50 ng/mL, and there are large (about 10–20-fold) increases after

suckling. Throughout breastfeeding, baseline prolactin levels remain elevated, and suckling produces a twofold increase that is essential for continuing milk production.<sup>61,62</sup> The pattern or values of prolactin levels do not predict the postpartum duration of amenorrhea or infertility.<sup>63</sup> The failure to lactate within the first 7 days postpartum may be the first sign of Sheehan syndrome (hypopituitarism following intrapartum infarction of the pituitary gland).

Maintenance of milk production at high levels is dependent on the joint action of both anterior and posterior pituitary factors. By mechanisms to be described in detail shortly, suckling causes the release of both prolactin and oxytocin as well as TSH.<sup>64,65</sup> Prolactin sustains the secretion of casein, fatty acids, and lactose and the volume of secretion, while oxytocin contracts myoepithelial cells and empties the alveolar lumen, thus enhancing further milk secretion and alveolar refilling. The increase in TSH with suckling suggests that TRH may play a role in the prolactin response to suckling. The optimal quantity and quality of milk are dependent upon the availability of thyroid, insulin and the insulin-like growth factors, cortisol, and the dietary intake of nutrients and fluids.

Secretion of calcium into the milk of lactating women approximately doubles the daily loss of calcium.<sup>66,67</sup> In women who breastfeed for 6 months or more, this is accompanied by significant bone loss even in the presence of a high calcium intake.<sup>68</sup> However, bone density rapidly returns to baseline levels in the 6 months after weaning.<sup>69,70</sup> The bone loss is due to increased bone resorption, probably secondary to the relatively low estrogen levels associated with lactation. It is possible that recovery is impaired in women with inadequate calcium intake; total calcium intake during lactation should be at least 1,500 mg/day. Nevertheless, calcium supplementation has no effect on the calcium content of breast milk or on bone loss in lactating women who have normal diets.<sup>71</sup> In addition, fetuses and lactating mothers, except in unusual circumstances, do not suffer from a significant deficiency in vitamin D.<sup>72</sup> Furthermore, studies indicate that any loss of calcium and bone associated with lactation is rapidly restored, and therefore, there is no impact on the risk of postmenopausal osteoporosis.<sup>73,74,75,76,77</sup> Rarely, a pregnant woman can present with osteoporosis and vertebral fractures, probably a consequence of very inadequate calcium intake and severe vitamin D deficiency.<sup>78</sup> Case reports of pregnancy-associated osteoporosis indicate that this acute condition can be successfully treated with either bisphosphonates or teriparatide, the parathyroid hormone fragment.<sup>79,80</sup>

Antibodies are present in breast milk and contribute to the health of an infant. Besides the proteins, carbohydrates, and fats that provide a complete and balanced diet, human milk prevents infections in infants both by transmission of immunoglobulins and

by modifying the bacterial flora of the infant's gastrointestinal tract. Viruses can be transmitted through breast milk; however, women infected with hepatitis B may breastfeed if the child is immunized with HBIG passive prophylaxis and vaccine active prophylaxis.<sup>81</sup> Women infected with hepatitis A and C or cytomegalovirus may breastfeed if following routine hygienic precautions. Women with human immunodeficiency viruses and active herpetic outbreaks on the breasts are advised not to breastfeed. Vitamin A, vitamin B<sub>12</sub>, and folic acid are significantly reduced in the breast milk of women with poor dietary intake. As a general rule, approximately 1% of any drug ingested by the mother appears in breast milk. Prolonged breastfeeding has many health benefits for both the mother and infant, including lowered risk of maternal breast cancer, ovarian cancer, diabetes, hypertension, and heart disease and lowered risk of infant infectious disease, sudden infant death syndrome, and metabolic disease including diabetes and obesity in childhood.

Frequent emptying of the lumen is important for maintaining an adequate level of secretion. Indeed, after the fourth postpartum month, suckling appears to be the only stimulant required; however, environmental and emotional states also are important for continued alveolar activity. Vigorous aerobic exercise does not affect the volume or composition of breast milk, and therefore, infant weight gain is normal.<sup>82</sup> Maternal diet and hydration have little impact on lactation; the primary control of milk output is under the control of the infant's suckling.<sup>83</sup>

Suckling studied with ultrasonography indicates that the infant's instinctive attachment to a nipple immediately establishes a vacuum seal.<sup>84</sup> The tongue moves up and down, increasing the vacuum and producing milk flow during the downward motion. However, the ejection of milk from the breast does not occur only as the result of a mechanically induced negative pressure produced by suckling. Tactile sensors concentrated in the areola activate, via thoracic sensory nerve roots 4, 5, and 6, an afferent sensory neural arc that stimulates the paraventricular and supraoptic nuclei of the hypothalamus to synthesize and transport oxytocin to the posterior pituitary. The efferent arc (oxytocin) is blood-borne to the breast alveolus-ductal systems to contract myoepithelial cells and empty the alveolar lumen. Milk contained in major ductal repositories is ejected from 15–20 openings in the nipple. This rapid release of milk is called "letdown." This important role for oxytocin is evident in knockout mice lacking oxytocin who undergo normal parturition but fail to nurse their offspring.<sup>85</sup> The milk ejection reflex involving oxytocin is present in all species of mammals. Oxytocin-like peptides exist in fish, reptiles, and birds, and a role for oxytocin in maternal behavior may have existed before lactation evolved.<sup>83</sup>

In many instances, the activation of oxytocin release leading to letdown does not require initiation by tactile stimuli. The central nervous system can be conditioned to

respond to the presence of the infant, or to the sound of the infant's cry, by inducing activation of the efferent arc. These messages are the result of many stimulating and inhibiting neurotransmitters. Suckling, therefore, acts to refill the breast by activating both portions of the pituitary (anterior and posterior) causing the breast to produce new milk and to eject milk. The release of oxytocin is also important for uterine contractions that contribute to involution of the uterus.

The oxytocin effect is a release phenomenon acting on secreted and stored milk. Prolactin must be available in sufficient quantities for continued secretory replacement of ejected milk. This requires the transient increase in prolactin associated with suckling. The amount of milk produced correlates with the amount removed by suckling. The breast can store milk for a maximum of 48 hours before production diminishes.

# Breastfeeding by Adopting Mothers

Adopting mothers occasionally request assistance in initiating lactation.<sup>86</sup> Successful breastfeeding can be achieved by ingestion of 25-mg chlorpromazine t.i.d. or metoclopramide 10 mg t.i.d. together with vigorous nipple stimulation using a breast pump every 3–4 hours.<sup>87</sup> Milk production will not appear for several weeks. This preparation ideally should begin about a month before the expected baby is due. Stasis of milk within the breast, without stimulation, will lead to cessation of lactation. Once adequate lactation is established, drug treatment should be discontinued, tapering the dose over 3 weeks.

# Cessation of Lactation

Lactation can be terminated by discontinuing suckling. The primary effect of this cessation is loss of milk letdown via the neural evocation of oxytocin. With passage of a few days, the swollen alveoli depress milk formation probably via a local pressure effect (although milk itself may contain inhibitory factors). With resorption of fluid and solute, the swollen engorged breast diminishes in size in a few days. In addition to the loss of milk letdown, the absence of suckling reactivates dopamine production so that there is less prolactin stimulation of milk secretion. Routine use of a dopamine agonist for suppression of lactation is not recommended because of reports of hypertension, seizures, myocardial infarctions, and strokes associated with its postpartum use.

# Contraceptive Effect of Lactation

A moderate contraceptive effect accompanies lactation and produces child spacing, which is very important in the developing world as a means of limiting family size. The contraceptive effectiveness of lactation depends on the intensity of suckling, the extent to which supplemental food is added to the infant diet, and the level of nutrition of the mother (if low, the longer the contraceptive interval; however, well-nourished and undernourished women resume ovulating at the same time postpartum<sup>88</sup>). If suckling intensity or frequency is diminished, contraceptive effect is reduced. Only amenorrheic women who exclusively breastfeed at least every hour, including nighttime, during the first 6 months have the contraceptive protection equivalent to that provided by oral contraception (98% efficacy); with menstruation or after 6 months, the chance of ovulation increases.<sup>89,90</sup> With full or nearly full breastfeeding, approximately 70% of women remain amenorrheic through 6 months and only 37% through 1 year; nevertheless, with exclusive breastfeeding, the contraceptive efficacy at 1 year is high, at 92%.<sup>90</sup> Fully breastfeeding women commonly have some vaginal bleeding or spotting in the first 8 postpartum weeks, but this bleeding is not due to ovulation.<sup>91</sup>

Supplemental feeding increases the chance of ovulation (and pregnancy) even in amenorrheic women.<sup>92</sup> Total protection is achieved by the exclusively breastfeeding woman for a duration of only 10 weeks.<sup>91</sup> Half of women studied who are not fully breastfeeding ovulate before the 6th week, the time of the traditional postpartum visit; a visit during the third postpartum week is strongly recommended for contraceptive counseling (Table 16.1).

**TABLE 16.1 Rule of 3s for Postpartum Initiation of Contraception**

Full breastfeeding	Begin in <i>3rd postpartum month</i>
Partial or no breastfeeding	Begin in <i>3rd postpartum week</i>

In nonbreastfeeding women, gonadotropin levels remain low during the early puerperium and return to normal concentrations during the 3rd to 5th week when

prolactin levels have returned to normal. In an assessment of this important physiologic event (in terms of the need for contraception), the mean delay before first ovulation was found to be approximately 45 days, while no woman ovulated before 25 days after delivery.<sup>89</sup> Half of women studied ovulated before the 6th postpartum week, underscoring the need to move the traditional postpartum medical visit to the 3rd week after delivery. In women who do receive dopamine agonist treatment at or immediately after delivery, return of ovulation is slightly accelerated, and contraception is required a week earlier, in the 2nd week postpartum.<sup>93,94</sup>

Prolactin concentrations are increased in response to the repeated suckling stimulus of breastfeeding.<sup>95</sup> Given sufficient intensity and frequency, prolactin levels remain elevated. Under these conditions, follicle-stimulating hormone (FSH) concentrations are in the low normal range (having risen from extremely low concentrations at delivery to follicular range in the 3 weeks postpartum), and luteinizing hormone (LH) values are also in the low normal range. Low levels of gonadotropins do not allow the ovary to display follicular development and secrete estrogen. Therefore, vaginal dryness and dyspareunia are commonly reported by breastfeeding women. **The use of vaginal estrogen preparations is discouraged because absorption of the estrogen can lead to inhibition of milk production. Vaginal lubricants should be used until ovarian function and estrogen production return.**

The mechanism of the contraceptive effect is of interest because a similar interference with normal pituitary-gonadal function is seen with elevated prolactin levels in nonpregnant women with breast milk production and amenorrhea. Earlier experimental evidence suggested that the ovaries might be refractory to gonadotropin stimulation while prolactin levels are high enough to produce galactorrhea.<sup>96</sup> Prolactin appears to affect granulosa cell function in vitro by inhibiting the synthesis of progesterone. It also may change the testosterone/dihydrotestosterone ratio, thereby reducing aromatizable substrate and increasing local antiestrogen concentrations. Nevertheless, a direct effect of prolactin on ovarian follicular development does not appear to be a major factor.

The alternative and predominant contraceptive mechanism is central. Elevated levels of prolactin inhibit the pulsatile secretion of GnRH.<sup>97,98</sup> Prolactin excess has short-loop positive feedback effects on dopamine. Increased dopamine reduces GnRH by suppressing arcuate nucleus function, perhaps in a mechanism mediated by endogenous opioid activity.<sup>99,100</sup> However, blockade of dopamine receptors with a dopamine antagonist or the administration of an opioid antagonist in breastfeeding women does not always affect gonadotropin secretion.<sup>101</sup> The exact mechanism for the suppression of GnRH secretion remains to be fully identified. The principle of GnRH suppression by prolactin is reinforced by the demonstration that treatment of

amenorrheic, lactating women with pulsatile GnRH fully restores pituitary secretion and normal ovarian cyclic activity.<sup>102</sup>

At weaning, as prolactin blood concentrations fall to normal, gonadotropin levels increase, and estradiol secretion rises. This prompt resumption of ovarian function is followed by the occurrence of ovulation within 14–30 days of weaning.

# INAPPROPRIATE

# LACTATION:

## GALACTORRHEA SYNDROMES

---

Galactorrhea refers to the mammary secretion of a milky fluid, which is nonphysiologic in that it is inappropriate (not immediately related to pregnancy or the needs of a child), persistent, and sometimes excessive. Although usually white or clear, the color may be yellow or even green. In the latter circumstance, local breast disease should be considered. To elicit breast secretion, pressure should be applied to all sections of the breast beginning at the base of the breast and working up toward the nipple. Galactorrhea can involve both breasts or just one breast. **Hormonally induced secretions usually come from multiple duct openings in contrast to pathologic discharge that usually comes from a single duct.** A bloody discharge is more typical of cancer. The quantity of secretion is not an important criterion. Amenorrhea does not necessarily accompany galactorrhea, even in the most serious provocative disorders. Any galactorrhea demands evaluation in a nulliparous woman or if at least 12 months has elapsed since the last pregnancy or weaning in a parous woman. This recommendation has evolved empirically, knowing that many women have the persistence of galactorrhea for many months after breastfeeding, and therefore, there is room for clinical judgment.

# Differential Diagnosis of Galactorrhea

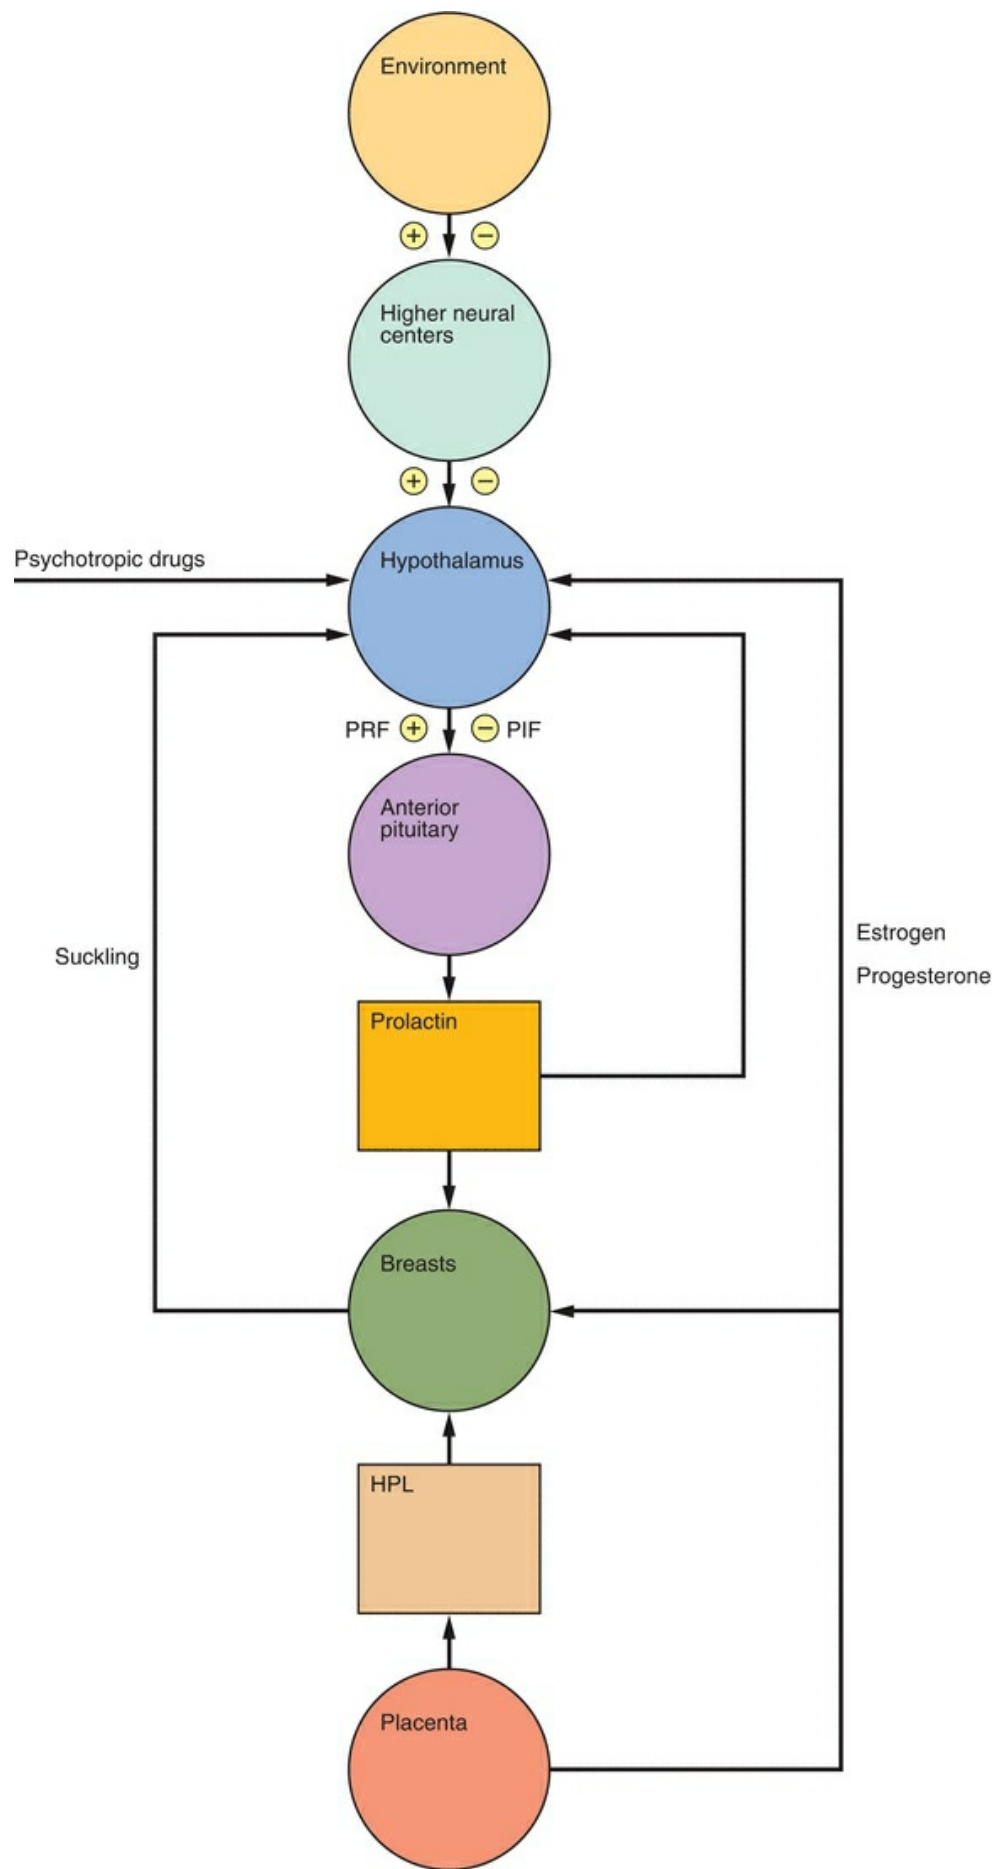

The differential diagnosis of galactorrhea is a complex clinical challenge. The difficulty arises from the multiple factors involved in the control of prolactin release. In most pathophysiologic states, the final common pathway leading to galactorrhea is an inappropriate augmentation of prolactin release. The following considerations are important:

1. Increased prolactin release can be a consequence of prolactin elaboration and secretion from pituitary tumors (discussed in [Chapter 10](#)), which function independently of the otherwise appropriate restraints exerted by PIFs from a normally functioning hypothalamus. This infrequent but potentially dangerous tumor, which has endocrine, neurologic, and ophthalmologic liabilities that can be disabling, makes the differential diagnosis of persistent galactorrhea a major clinical challenge. Beyond producing prolactin, the tumor may also suppress pituitary parenchyma by expansion and compression, interfering with the secretion of other tropic hormones. Other pituitary tumors may be associated with lactotroph hyperplasia and present with the characteristic syndrome of hyperprolactinemia and amenorrhea.
2. A variety of drugs can inhibit hypothalamic dopamine.<sup>103</sup> There are nearly 100 phenothiazine derivatives with indirect mammatropic activity. In addition, there are many phenothiazine-like compounds, reserpine derivatives, amphetamines, and an unknown variety of other drugs (opiates, diazepam, butyrophenones, verapamil,  $\alpha$ -methyldopa, and tricyclic antidepressants) that can initiate galactorrhea via hypothalamic suppression. The final action of these compounds is either to deplete dopamine levels or to block dopamine receptors. Chemical features common to many of these drugs are an aromatic ring with a polar substituent as in estrogen and at least two additional rings or structural attributes making spatial arrangements similar to estrogen. Thus, these compounds may act in a manner similar to estrogens to decrease dopamine and/or to act directly on the pituitary. In support of this conclusion, it has been demonstrated that estrogen and phenothiazine derivatives compete for the same receptors in the median eminence. Prolactin is uniformly elevated in patients on therapeutic amounts of these drugs, but essentially never as high as 100 ng/mL. Approximately 30–50% exhibit galactorrhea that should not persist beyond 3–6 months after drug treatment is discontinued.
3. Hypothyroidism (juvenile or adult) can be associated with galactorrhea. With diminished circulating levels of thyroid hormone, hypothalamic TRH is produced in excess and acts as a PRF to release prolactin from the pituitary. Reversal with thyroid hormone is strong circumstantial evidence to support the conclusion that

TRH stimulates prolactin.

4. Excessive estrogen (e.g., oral contraceptives) can lead to milk secretion via hypothalamic suppression, causing reduction of dopamine and release of pituitary prolactin, and direct stimulation of the pituitary lactotrophs. Galactorrhea developing during oral contraceptive administration may be most noticeable in the traditional dosing regimen during the 7 days free of medication (when the steroids are cleared from the body and the prolactin interfering action of the estrogen and progestin on the breast wanes). Galactorrhea caused by excessive estrogen disappears within 3–6 months after discontinuing medication. This is now a rare occurrence with the lower-dose pills.<sup>104</sup> A longitudinal study of 126 women did demonstrate a 22% increase in prolactin values over mean control levels, but the response to low-dose oral contraceptives was not out of the normal range.<sup>105</sup>
5. Prolonged intensive suckling can also release prolactin, via hypothalamic reduction of dopamine. Similarly, thoracotomy scars, cervical spinal lesions, eczema, and herpes (**Figure 16.5**) zoster can induce prolactin release by activating the afferent sensory neural arc, thereby simulating suckling. Galactorrhea and elevated prolactin levels have been observed secondary to nipple piercing.<sup>106</sup>
6. Stresses can inhibit hypothalamic dopamine, thereby inducing prolactin secretion and galactorrhea. Trauma, surgical procedures, and anesthesia can be seen in temporal relation to the onset of galactorrhea.
7. Hypothalamic lesions, stalk lesions, or stalk compression (events that physically reduce production or delivery of dopamine to the pituitary) allow release of excess prolactin leading to galactorrhea.
8. Increased prolactin concentrations can result from nonpituitary sources such as lung, ovarian, and renal tumors and even a uterine leiomyoma. Severe renal disease requiring hemodialysis is associated with elevated prolactin levels due to the decreased glomerular filtration rate.

## FIGURE 16.5

# The Clinical Problem of Galactorrhea

A variety of eponymic designations were applied in the past to variants of the lactation syndromes based on the presence of an intrasellar tumor or antecedent pregnancy. Currently, categorization of individual cases according to these eponymic guidelines neither is helpful nor does it permit discrimination of patients who have serious intrasellar or suprasellar pathology.

Galactorrhea and hyperprolactinemia are not completely correlated. The reported incidence of women with hyperprolactinemia displaying galactorrhea is about 33%. The disparity may be due partially to the variable zeal with which the presence of nipple milk secretion is sought during physical examination, the usually accompanying hypoestrogenic state, or heterogeneity of tropic hormones ([Chapter 1](#)). The immunoassay for prolactin may not discriminate among heterogeneous molecules of prolactin. A high circulating level of prolactin may not represent material capable of interacting with breast prolactin receptors. On the other hand, galactorrhea can be seen in women with normal prolactin serum concentrations. Episodic fluctuations and sleep increments may account for this clinical discordance, or in this case, bioactive prolactin may be present that is immunoreactive not detectable. Remember that at any one point in time, the bioactivity (galactorrhea) and the immunoreactivity (immunoassay result) of prolactin represent the cumulative effect of the family of structural and molecular prolactin variants present in the circulation.

Hyperprolactinemia or galactorrhea may be associated with a variety of menstrual cycle disturbances: corpus luteum insufficiency (luteal phase defect), oligoovulation, as well as amenorrhea. About one-third of women with secondary amenorrhea have elevated prolactin concentrations. Pathologic hyperprolactinemia inhibits the pulsatile secretion of GnRH, and the reduction of circulating prolactin levels restores menstrual function.

Mild hirsutism may accompany ovulatory dysfunction caused by hyperprolactinemia. Whether excess androgen is stimulated by a direct prolactin effect on adrenal cortex synthesis of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) or is primarily related to the chronic anovulation of these patients (and hence ovarian androgen secretion) is not settled. Another possibility is hyperinsulinemia. Women with elevated prolactin levels have been reported to have an association with hyperinsulinemia because of an increase in peripheral insulin resistance.<sup>107,108,109,110,111,112,113,114</sup> This association is independent of obesity; however, there is considerable variation and the mechanism is uncertain. We recommend that in patients with hyperprolactinemia who have a family history of early coronary heart disease or who have an abnormal lipid profile, consideration should be given to the evaluation and management of hyperinsulinemia as described in [Chapter 11](#).

In the pathophysiology of male hypogonadism, hyperprolactinemia is much less common, and the incidence of actual galactorrhea quite rare. Hyperprolactinemia in men usually presents with decreased libido and potency.

If galactorrhea has been present for 6 months to 1 year, or hyperprolactinemia is noted in the process of working up menstrual disturbances, infertility, or hirsutism, the probability of a pituitary tumor must be recognized. The evaluation and management of hyperprolactinemia are presented in detail in [Chapter 10](#).

Galactorrhea as an isolated symptom of hypothalamic dysfunction existing in an otherwise healthy woman does not require treatment. Periodic prolactin levels, if within normal range, confirm the stability of the underlying process. However, some patients find the presence or amount of galactorrhea sexually, cosmetically, and emotionally burdensome. Treatment with combined oral contraceptives, androgens, danazol, and progestins has met minimal success. Dopamine agonist treatment, as described in [Chapter 10](#), therefore, is the therapy of choice. Even with normal prolactin concentrations and normal imaging, treatment with a dopamine agonist can eliminate galactorrhea.

# THE MANAGEMENT OF MASTALGIA

---

The cyclic premenstrual occurrence of breast discomfort is a common problem and is occasionally associated with dysplastic, benign histologic changes in the breast. Neither a specific etiology (although the response is probably secondary to the hormonal stimulation of the luteal phase) nor an adverse consequence (such as an increased risk of breast cancer) has been established.<sup>115</sup> Approximately 70% of women report premenstrual breast discomfort in surveys, and interference with activities is recorded in 10–30%.<sup>115</sup>

Medical treatment of mastalgia has historically included a bewildering array of options. Several are of questionable value. Diuretics have little impact, and thyroid hormone treatment is indicated only when hypothyroidism is documented. Steroid hormone treatment has been tried in many combinations, mostly unsupported by controlled studies. An old favorite, with many years of clinical experience testifying to its effectiveness, is testosterone. One must be careful, however, to avoid virilizing doses. In recent years, these methods have been supplanted by several new approaches.

Danazol in a dose of 100–200 mg/day is effective in relieving discomfort as well as decreasing nodularity of the breast.<sup>116,117</sup> A daily dose is recommended for a period of 6 months. This treatment may achieve long-term resolution of histologic changes in addition to the clinical improvement. Doses below 400 mg daily do not assure inhibition of ovulation, and a method of effective contraception is necessary because of possible teratogenic effects of the drug. Significant improvement has been noted with vitamin E, 600 units/day of the synthetic tocopherol acetate. No side effects have been noted, and the mechanism of action is unknown.<sup>118</sup> Bromocriptine (2.5 mg/day, which can be administered vaginally if side effects are a problem) and antiestrogens such as tamoxifen (10 or 20 mg daily) are also effective for treating mammary discomfort and benign disease.<sup>117,119,120</sup> In a comparison study, tamoxifen was more effective than danazol.<sup>117</sup>

Clinical observations suggested that abstinence from methylxanthines leads to resolution of symptoms. Methylxanthines (caffeine, theophylline, and theobromine) are present in coffee, tea, chocolate, and cola drinks. In controlled studies, however, a significant placebo response rate (30–40%) has been observed. Careful assessments of this relationship in controlled studies failed to demonstrate a link between methylxanthine use and mastalgia, mammographic changes, or atypia (pre-malignant tissue changes).<sup>121,122</sup> In addition, studies have consistently failed to detect a convincing link between methylxanthine-containing beverages and the risk of breast cancer<sup>123,124,125,126,127</sup> (**Figure 16.6**).

### Cancer Site Incidence in US Women<sup>128</sup>

**FIGURE 16.6**

# CANCER OF THE BREAST

---

## Scope of the Problem

Currently, female American newborns have a lifetime probability of developing breast cancer of 12.4%, about one in eight, double the risk in 1940.<sup>128,129</sup> There are about 252,000 new cases of invasive breast cancer and 63,000 new cases of in situ breast cancer per year in the United States. Between 2002 and 2003, there was a 7% decrease in the incidence of invasive breast cancer, and since 2004, breast cancer incidence has stabilized.<sup>128</sup> This decrease and stabilization are believed to reflect a reduction in the use of postmenopausal hormone therapy following the publicized results of the Women's Health Initiative in 2002 (Chapter 17), as well as an increase in the utilization of mammography in the 1990s. About 97% of all breast cancers in the United States occur in women over age 40; 77% of all cases occur over age 50.<sup>128</sup>

Mortality rates remained disappointingly constant until a decline began in the 1990s. The 5-year survival rate for localized breast cancer (about 61% of breast cancers) has risen from 72% in the 1940s to 99%.<sup>128</sup> This is attributed to better therapy and earlier diagnosis because of the greater utilization of screening mammography. With regional spread, the 5-year survival rate for breast cancer is 85%; with distant metastases, the rate is 27%. The breast is the leading site of cancer in US women and is the second highest cause of cancer death in US women (behind lung cancer)<sup>130</sup> (Table 16.2, Figures 16.7 and 16.8).

**FIGURE 16.7**

**FIGURE 16.8**

Over the years, breast cancer continued to have a deadly impact despite advances in surgical and diagnostic techniques. Classically, the single most useful prognostic information in women with operable breast cancer has been the histologic status of the axillary lymph nodes.<sup>131,132</sup> The survival rate is higher with axillary lymph nodes negative for disease compared with positive nodes. Because of this recognition of the importance of the axillary nodes, the traditional surgical approach to breast cancer was based on the concept that breast cancer is a disease of stepwise progression. **There is an important change in concept. Breast cancer is now viewed as a systemic disease, with spread to local and distant sites at the same time. Breast cancer is best viewed as occultly metastatic at the time of presentation.** Therefore, dissemination of tumor cells has occurred by the time of surgery in many patients with invasive lesions and even in some patients with noninvasive tumors.

Because we have been dealing with a disease that has already reached the point of dissemination in many patients, we must move the diagnosis forward several years in order to have an impact on breast cancer mortality. Earlier diagnosis requires that we should be aware of what it is that makes a high-risk patient. **However, keep in mind that the great majority of women (85%) who develop breast cancer do not have an identifiable risk factor other than age, and therefore, every woman must be considered at risk.**

# Risk Factors

A constellation of factors influences the risk for breast cancer. These include reproductive experience, ovarian activity, benign breast disease, familial tendency, genetic differences, dietary considerations, and specific endocrine factors. Clinicians can calculate the risk for an individual patient at the National Cancer Institute Internet site: <http://www.cancer.gov/bcrisktool/> (Table 16.3).

## TABLE 16.3 Risk Factors for Breast Cancer<sup>130</sup>

Relative risk >4.0

Over age 65

Inherited mutations

Two or more first-degree relatives with early disease

Postmenopausal breasts that are at least 75% dense on mammography

---

Relative risk 2.1–4.0

One first-degree relative with breast cancer

Atypical hyperplasia on breast biopsy

High-dose radiation to the chest

High postmenopausal bone density

---

Relative risk 1.1–2.0

First full-term pregnancy after age 30

Menarche before age 12

Menopause after age 55

Nulliparity

Never breastfed

Postmenopausal obesity

Previous cancer of the endometrium, ovary, or colon

Alcohol consumption, 2–5 drinks daily

---

# Reproductive Experience

The risk of breast cancer increases with the increase in age at which a woman bears her first full-term child. A woman pregnant before the age of 18 has about one-third the risk of one who first delivers after the age of 35. To be protective, pregnancy must occur before the age of 30. Age at first birth and multiparity in women who experience their first birth before age 25 reduce the risk of breast cancer that is positive for estrogen and progesterone receptors.<sup>131,132</sup> Women over the age of 30 years at the time of their first birth have a greater risk than women who never become pregnant.<sup>133</sup> There is reason to believe that the age at the time of birth of the last child is the most important influence (an increasing risk with increasing age).<sup>134</sup> There is, however, a significant protective effect with increasing parity, present even when adjusted for age at first birth and other risk factors.<sup>135,136</sup> Delayed childbearing and fewer children in modern times are believed to have contributed significantly to the increased incidence of breast cancer observed in the 1990s.

Although pregnancy at an early age produces an overall lifetime reduction in risk, there is evidence that the first few years after delivery are associated with a transient increase in risk.<sup>137</sup> This increase probably reflects accelerated growth of an already present malignancy by the hormones of pregnancy. A very large case-control study concluded that pregnancy transiently increases the risk (perhaps for up to 3 years) after a woman's first childbirth, and this is followed by a lifetime reduction in risk.<sup>138</sup> And some have found that a concurrent or recent pregnancy (3–4 years previously) adversely affects survival (even after adjustment for size of tumor and number of nodes).<sup>139,140</sup> It is argued that breast cells that have already begun malignant transformation are adversely affected by the hormones of pregnancy, while normal stem cells become more differentiated and resistant, reducing the number of stem cells capable of malignant change. The number of breast stem cells available for this beneficial response diminishes with age and succeeding pregnancies.<sup>141</sup> Although it is likely that this effect is mediated by estrogen and progesterone, experimental evidence indicates the presence of LH receptors in breast tissue, and it is possible that human chorionic gonadotropin (hCG) contributes to the protective differentiation of breast cells.<sup>142,143,144</sup> Another possibility is an antiproliferative action of alpha-fetoprotein, a peptide that is secreted in the fetal liver and stimulated by the hormones of pregnancy.<sup>145,146</sup>

Initially, conflicting results were reported in over 20 studies examining the risk of breast cancer associated with the number of abortions (both spontaneous and induced abortions) experienced by individual patients.<sup>147,148</sup> Concern for an adverse effect was based on the theoretical suggestion that a full-term pregnancy protects against breast cancer by invoking complete differentiation of breast cells, but abortion increases the

risk by allowing breast cell proliferation in the first trimester of pregnancy, but not allowing the full differentiation that occurs in later pregnancy. In these studies, there was a major problem of recall bias; women who develop breast cancer are more likely to truthfully reveal their history of induced abortion than healthy women. In studies that avoided recall bias (e.g., by deriving data from national registries instead of personal interviews), the risk of breast cancer was identical in women with and without induced abortions.<sup>148,149</sup> More careful case-control studies failed to link a risk of breast cancer with either induced or spontaneous abortions.<sup>150,151</sup> Similarly, newer prospective cohort studies, including the Nurses' Health Study, also reported no association between the incidence of breast cancer and induced or spontaneous abortions.<sup>152,153,154</sup>

The fact that pregnancy early in life is associated with a reduction in the risk of breast cancer implies that etiologic factors are operating during that period of life. The protection afforded only by the first pregnancy suggests that the first full-term pregnancy has a trigger effect that either produces a permanent change in the factors responsible for breast cancer or changes the breast tissue and makes it less susceptible to malignant transformation. There is evidence for a lasting impact of a first pregnancy on a woman's hormonal milieu. A small but significant elevation of estriol, a decrease in DHEA and DHEAS, and lower prolactin levels all persist for many years after delivery.<sup>155,156</sup> These changes take on significance when viewed in terms of the endocrine factors considered below.

Lactation may offer a weak to moderate protective effect (20% reduction) on the risk of breast cancer, both estrogen receptor–positive and estrogen receptor–negative tumors.<sup>132,133,157,158,159,160,161,162,163,164,165</sup> The same beneficial effect has been reported in BRCA mutation carriers in one study, but not in another.<sup>166,167</sup> The Nurses' Health Study could not detect a protective effect of lactation, and a Norwegian prospective study, including a high percentage of women with long durations of breastfeeding, found no benefit on either premenopausal or postmenopausal breast cancer incidence.<sup>168,169</sup> The impact of lactation, if significant, must be small. However, an analysis of the worldwide available data concluded that breastfeeding would reduce the risk of breast cancer by 4.3% per year of breastfeeding and potentially could reduce the cumulative incidence by age 70 by more than 50%.<sup>170</sup> A meta-analysis indicated that breastfeeding reduced the risk of breast cancer by about 10–20%, and the impact was limited to premenopausal women.<sup>171</sup> There is a unique and helpful study of the Chinese Tanka, who are boat people living on the coast of Southern China.<sup>172</sup> The women of the Chinese Tanka wear clothing with an opening only on the right side, and they breastfeed only with the right breast. All breast cancers were in postmenopausal women, and the cancers were equally distributed between the two sides, suggesting a protective effect only for premenopausal breast cancer.

In both cohort and case-control studies, there is good evidence that cosmetic breast augmentation does not increase the risk of breast cancer.<sup>173,174</sup> Specifically, studies have failed to indicate an increased risk of breast cancer in women who have had cosmetic breast implants.<sup>175,176,177,178,179</sup>

# Ovarian Activity

Women who have a premenopausal oophorectomy have a lower risk of breast cancer, and the lowered risk is greater the younger a woman is when ovariectomized. There is a 70% risk reduction in women who have oophorectomy before age 35. There is a small decrease in risk with late menarche and a moderate increase in risk with late natural menopause, indicating that ovarian activity plays a continuing role throughout reproductive life.<sup>180</sup>

Observational studies indicated that anovulatory and infertile women (exposed to less progesterone) have a small increased risk of breast cancer later in life.<sup>181,182,183,184</sup> However, the statistical power of these observational studies was limited by small numbers (all fewer than 15 cases). Larger numbers are available in the Nurses' Health Study, where the opposite result was apparent: a reduction in the incidence of breast cancer in women with infertility attributed to ovulatory disorders.<sup>185</sup>

# Benign Breast Disease

Benign breast lesions are present in over 70% of women undergoing breast biopsy and are stratified into nonproliferative lesions, proliferative without atypia, atypical hyperplasia, and lobular carcinoma in situ.<sup>186</sup> Women with prior benign breast disease form only a small proportion of breast cancer patients, approximately 5%. The risk of developing future breast cancer depends on the severity of the lesion. Nonproliferative lesions such as simple cysts portend a 1.17 relative risk of future breast cancer. Fibrocystic change, a proliferative lesion without atypia, is characterized by dilation of terminal ducts (ductal ectasia) and alveoli, a process caused by obstruction of ducts (probably by stromal fibrosis), persistent secretion, and retention of the secretory material. Fibroadenomas are the most common cause of breast masses in premenopausal women and account for 12% of breast masses in menopausal women.<sup>187</sup> Other examples of proliferative lesions without atypia are intraductal papillomas and moderate hyperplasia of the usual type. In the Nurses' Health Study, biopsies with proliferative disease had a relative risk of breast cancer of 1.6.<sup>188</sup> Women with atypical hyperplasia had a relative risk of 5.3, while women with atypia and a family history of breast cancer had a relative risk of 11. Only 4–10% of benign biopsies have atypical hyperplasia. For most women, benign breast lesions are not a disease but a physiologic change brought about by cyclic hormonal activity<sup>189</sup> (Table 16.4).

## TABLE 16.4 Classification of Breast Biopsy Tissue According to Risk for Breast Cancer

No increased risk

---

Adenosis

Duct ectasia

Fibrosis

Mild hyperplasia (3–4 cells deep)

Mastitis

Periductal mastitis

Squamous metaplasia

Ordinary cysts (fibrocystic disease)

---

Slightly increased risk (1.5–2 times)

Moderately increased (4–5 times)

---

Atypical ductal hyperplasia

Atypical lobular hyperplasia

---

Markedly increased (8–10 times)

---

Ductal carcinoma in situ

Lobular carcinoma in situ

---

## Familial Tendency

Most breast cancers are sporadic, that is, they arise in individuals without a family history of breast cancer. However, female relatives of women with breast cancer have about twice the rate of the general population. There is an excess of bilateral disease among patients with a family history of breast cancer. Relatives of women with bilateral disease have about a 45% lifetime chance of developing breast cancer. The relative risks associated with first-degree relatives are presented in [Table 16.5](#).

**TABLE 16.5 Relative Risk with Affected First-Degree Relatives**<sup>190</sup>

One relative	1.80
Two relatives	2.93
Three relatives	3.90

It is worth emphasizing that only one of nine women who develop breast cancer has an affected first-degree relative, and most women with an affected relative will never have breast cancer.<sup>190</sup>

The breast and ovarian tumor suppressor gene (BRCA1) associated with familial cancer is on the long arm of chromosome 17, localized to 17q12–q21.<sup>191</sup> Although other genetic alterations have been observed in breast tumors, multiple, different mutations in BRCA1 are believed to be responsible for approximately 20% of familial breast cancer and 80% of families with both early-onset breast and ovarian cancer. **Overall, no more than 5–10% of breast cancers in the general population can be attributed to inherited mutations.**<sup>128,190</sup> Autosomal dominant inheritance of mutations in this gene can be either maternal or paternal; male carriers are at increased risk for colon and prostate cancers.<sup>192,193</sup> A second autosomal dominant locus of multiple mutations, BRCA2, on chromosome 13q12–q13 accounts for up to 35% of families with early-onset breast cancer (but a lower rate of ovarian cancer) and, in males, for prostate cancer, pancreatic cancer, and male breast cancer.<sup>193,194</sup> Together, BRCA1 and BRCA2

account for 80% of families with multiple cases of early-onset breast cancer.<sup>195</sup> **About 5–10% of women who develop ovarian cancer have mutations in BRCA1.**<sup>196,197,198</sup>

BRCA1 encodes a 1,863-amino acid protein with a zinc finger domain that is a tumor suppressor important in DNA repair. Mutations in many different regions of the BRCA1 gene cause a loss or reduction in its function.<sup>199,200</sup> Because not every individual with a mutation in this gene develops cancer, other factors are involved, making the accuracy of prediction more difficult and arguing against widespread screening for mutations of this gene. Providing accurate numbers is a difficult task, because breast cancer has a multifactorial etiology with both genetic and environmental factors. The BRCA1 gene could play a role in sporadic breast and ovarian cancer, but analysis of tumors has failed to find mutations in sporadic cancers that occur later in life.<sup>201</sup>

High-risk families have a high probability of harboring a mutation in a dominant breast cancer susceptibility gene. It is estimated that approximately 0.04–0.2% of women in the United States carry the BRCA1 susceptibility (and BRCA2 is less common).<sup>202</sup> Among women of Ashkenazi Jewish descent, the prevalence of BRCA1 and BRCA2 mutations is about 2%.<sup>203</sup> The percentage of breast cancer cases in the general population associated with a family history accounts for only a minor part of the overall prevalence, as low as 3%.<sup>204,205</sup> In addition, there appears to be great variability in different parts of the world, and the prevalence in minority populations has not been adequately measured.

The presence of ovarian cancer or breast cancer within a family should prompt genetic counseling and possibly genetic screening for hereditary breast and ovarian cancer syndromes.<sup>206</sup> High-risk families have the presence of multiple cases of breast cancer in close relatives (usually at least three cases) that follows an autosomal dominant pattern of inheritance; breast cancer is usually diagnosed before age 45; there may be cases of ovarian cancer in the family as well. Many of the cases, but not all, can be attributed to the susceptibility genes BRCA1 and BRCA2. High-risk families have the following cumulative breast cancer risk by the age of 80 as determined by the analysis of family histories<sup>202</sup> (Tables 16.6 and 16.7).

**TABLE 16.7 Risk of Breast Cancer Based on Family History**

<b>Affected Relative</b>	<b>Age of Affected Relative</b>	<b>Cumulative Breast Cancer Risk by Age 80</b>
One first-degree relative	<50 years old	13–21%
	50 or more years old	9–11%
One second-degree relative	<50 years old	10–14%
	50 or more years old	8–9%
Two first-degree relatives	Both <50 years old	35–48%
	Both 50 years or older	11–24%
Two second-degree relatives but both paternal or maternal	Both <50 years old	21–26%
	Both 50 years or older	9–16%

Each child of a BRCA mutation carrier has a 50% chance of inheriting the mutation. In the United States, women who are carrying the BRCA1 mutation have a 46% cumulative risk of developing breast cancer by age 70, 57% risk overall, and a 39% risk for ovarian cancer.<sup>207,208</sup> There is also a small increase in the risk for other cancers, specifically of the pancreas, colon, uterus, and cervix.<sup>209</sup> The male relatives who are carrying this mutation have an increased risk of prostate cancer and colon cancer in addition to a cumulative risk of breast cancer of 1.2%.<sup>210</sup> The cancer risk for women with BRCA2 mutations is 43% for breast cancer and 22% for ovarian cancer by age 70 and a 49% risk of breast cancer overall.<sup>207,208</sup> Male BRCA2 mutation carriers have a higher cumulative risk of breast cancer, 6.8%, compared with male BRCA1 carriers.<sup>210</sup> In addition, BRCA2 mutation carriers have increased risks of cancers originating in the pancreas, prostate, gallbladder and bile duct, stomach, and skin.<sup>211</sup> Breast cancer associated with BRCA1 mutations is histologically different (more often aneuploid and

receptor-negative) compared to BRCA2 mutations and sporadic cancers and appears to grow faster but, paradoxically, has a better survival in response to treatment.<sup>212</sup> Outcome results, however, have not been consistent. A well-done Dutch study could not detect a difference in disease-free and overall survival comparing breast cancer cases from families with proven BRCA1 mutations to patients with sporadic breast cancer<sup>213</sup> (Table 16.8).

**TABLE 16.8 Summary of Breast and Ovarian Cancer Risk in BRCA Carriers<sup>207</sup>**

	Breast Cancer Risk by Age 70 (%)	Ovarian Cancer Risk by Age 70 (%)
<i>BRCA1</i>	46	39
<i>BRCA2</i>	43	22

Because not all families with breast cancer carry mutations of BRCA1 or BRCA2, these families probably have other less common breast cancer susceptibility genes, some of which remain to be identified. In addition, the current screening methods do not detect all BRCA mutations. For example, a mutation in a gene involved in the recognition and repair of damaged DNA, CHEK2, is prevalent in families with hereditary breast and colorectal cancer.<sup>214</sup> Other genes that infrequently cause inherited breast cancer include the ATM gene, the p53 tumor suppressor gene, and the PTEN gene.<sup>129</sup> **When three or more closely related individuals within a family have been diagnosed with breast cancer, the likelihood that an inherited dominant genetic mutation is present is very high.** The affected women need not be first-degree relatives, but they must be related either all on the mother’s side or the father’s side. Identifying the families that carry the BRCA2 gene uses the same historical criteria as that for the BRCA1 gene. **The family presence of just one case of ovarian cancer further increases the likelihood of the BRCA1 mutation.** In contrast to BRCA1 families, BRCA2 families have only a moderately increased incidence of ovarian cancer.

Once it has been determined that a family is at high risk for a breast cancer gene

mutation, it is recommended that this family be referred to an appropriate laboratory and service that can be identified through the medical genetics department at a regional referral institution. Although blood samples can be mailed by overnight mail, involvement with an appropriate center is highly urged because of the importance of accurate informed consent, counseling, and follow-up care. The way in which information is communicated to patients has a profound impact on decision-making and compliance with surveillance.

If a patient tests positive for a genetically inherited predisposition to breast cancer, or if a patient has two or more first-degree relatives in which breast cancer was diagnosed before age 50, or if a patient has three or more first-degree relatives with breast cancer at any age, we recommend following at-risk screening guidelines for early detection of breast cancer.<sup>215</sup> For patients aged 25–29, this means an annual breast MRI with contrast and breast exams every 6–12 months.<sup>216,217</sup> For women over age 30, alternating annual breast MRI with contrast and annual mammogram every 6 months, as well as breast exams every 6–12 months, are appropriate.<sup>216,218</sup> Prophylactic mastectomy should also be discussed with these patients. High-risk women who have undergone prophylactic mastectomy experience a major reduction (more than 90%) in the number of breast cancers, although total prevention is not achieved.<sup>219,220,221</sup> Because the mutation is present in every cell, and prophylactic mastectomy does not remove all tissue, there is no guarantee that breast cancer will be totally prevented. Any discussion of mastectomy should include psychosocial considerations and side effects of surgery, which can include decreased sexual satisfaction; negative body image; decreased anxiety about the development of breast cancer; pain, tingling, or numbness at the surgical site; and a routine discussion of typical surgical complications such as infection or bleeding issues.<sup>222,223,224,225</sup> The same situation applies with prophylactic oophorectomy in that a carcinoma can arise from peritoneal cells. However, prophylactic salpingo-oophorectomy reduces the risk of ovarian cancer by about 90% and the risk of breast cancer by about 50%.<sup>225,226</sup> Risk-reducing salpingo-oophorectomy is recommended at age 35 or when childbearing is complete for patients carrying BRCA1 mutations, and by age 40 in BRCA2 carriers. In patients with a PTEN mutation, annual endometrial biopsy starting at age 30 and hysterectomy when childbearing is complete are also recommended as these patients are at risk of uterine cancer in addition to breast cancer.<sup>216</sup>

In contrast to being associated with a lower ovarian cancer risk, the impact of oral contraceptives on the risk of breast cancer in patients carrying a BRCA1 or BRCA2 mutation is not clear. A case-control study concluded that BRCA1 (but not BRCA2) mutation carriers had small increases in the risk of breast cancer in users for at least 5 years (OR = 1.33, CI = 1.11–1.60), in users before age 30 (OR = 1.29, CI = 1.09–1.52),

and in those who developed breast cancer before age 40 (OR = 1.38, CI = 1.11–1.72).<sup>227</sup> In contrast, another case-control study concluded that oral contraceptive use for at least 5 years doubled the risk of breast cancer before age 50 in BRCA2 carriers, but not in BRCA1 carriers.<sup>228</sup> A retrospective analysis of an international cohort of BRCA carriers indicated that an increased risk of breast cancer with both BRCA1 and BRCA2 carriers was present only with 4 or more years of use before a first full-term pregnancy.<sup>229</sup> A study that focused on low-dose oral contraceptives could detect no association with breast cancer risk in BRCA mutation carriers.<sup>167</sup> Another case-control study found no increase in the risk of breast cancer diagnosed before age 40 in either BRCA1 or BRCA2 carriers.<sup>230</sup> And finally, a case-control study could detect no significant increase in the risk of contralateral breast cancer among BRCA1 and BRCA2 carriers or in noncarriers with the use of oral contraceptives or postmenopausal hormones.<sup>231</sup>

**The data with oral contraceptives in BRCA mutation carriers are all observational and not robust. Until better information is forthcoming, it seems reasonable to inform carriers of BRCA mutations that the use of oral contraceptives is likely to reduce the risk of ovarian cancer, but the effect on breast cancer risk is uncertain.**

The effect of chemoprevention by tamoxifen and raloxifene has not been tested in BRCA mutation carriers by randomized trials. However, in subgroup analyses of the American trial assessing the effect of tamoxifen for prevention, tamoxifen reduced the risk of breast cancer by 62% in BRCA2 carriers but had no impact in BRCA1 carriers.<sup>232,233</sup> This is consistent with the fact that women with BRCA2 mutations have predominately estrogen receptor–positive tumors and women with BRCA1 mutations have mostly estrogen receptor–negative tumors. Raloxifene has been shown to decrease primary breast cancer by 7 cases per 1,000 women when compared to placebo.<sup>234</sup> When compared with raloxifene, tamoxifen prevented 5 more cases of primary breast cancer per 1,000 women.<sup>234</sup> In a randomized controlled trial of postmenopausal women at high risk of breast cancer, the aromatase inhibitor anastrozole was shown to decrease risk of primary breast cancer by about 50% over placebo.<sup>235</sup> Given the side effects associated with these drugs, the decision to use one of these agents for chemoprevention is a difficult one for both clinician and patient. Prophylactic bilateral salpingo-oophorectomy remains as the superior choice for risk protection, a procedure that can in most cases be easily performed by laparoscopy. Serial sectioning of the ovaries and tubes is mandatory to detect microscopic cancers.

In a cohort of women with BRCA1/2 who had oophorectomy, hormone therapy of any type did not alter the reduction in breast cancer.<sup>236</sup> The average length of follow-up

was 3.6 years. A case-control study of 472 postmenopausal women with a BRCA1 mutation found that women who used hormone therapy after prophylactic oophorectomy, either estrogen only or combined estrogen-progestin, not only did not have an increased risk of breast cancer, but hormone use was actually associated with a decreased risk.<sup>237</sup> The findings were the same regardless of duration of use or current or past use. The conclusion is encouraging but limited by the fact that 68% of the tumors in the study were estrogen receptor– negative, making the estrogen receptor–positive tumors (that are more likely to be influenced by hormone use) relatively small in number.

Women who are BRCA carriers face difficult decisions regarding hormonal treatment for menopausal symptoms. The experience thus far indicates that hormone therapy can be used safely for several years. Continuing follow-up of these patients may extend this period of safety even longer.

# Dietary Factors

The geographic variation in incidence rates of breast cancer is considerable (the United States has the highest rates and Japan the lowest), and it has been correlated with the amount of animal fat in the diet.<sup>236</sup> Lean women, however, have an increased incidence of breast cancer, although this increase is limited to small, localized, and well-differentiated tumors.<sup>237</sup> Furthermore, studies have failed to find evidence for a positive relationship between breast cancer and dietary total or saturated fat or cholesterol intake.<sup>238,239,240,241</sup> One study found that dietary fat is a stronger risk factor for postmenopausal breast cancer than for premenopausal breast cancer, but another study had the opposite conclusion.<sup>242,243</sup> Although a cohort study concluded that dietary fat is a determinant of postmenopausal breast cancer, the association did not achieve statistical significance.<sup>244</sup> And another very large cohort study in Europe demonstrated only a very weak link between saturated fat intake and the risk of breast cancer, only in nonusers of hormone therapy.<sup>245</sup> Thus, the epidemiologic literature provides little support for a major contribution of dietary fat to the risk of breast cancer. Nevertheless, there is a correlation between intra-abdominal fat (android obesity) and the risk of breast cancer, a consequence of excessive caloric consumption, however, not a specific dietary component.<sup>246</sup> Presumably, the connection between android obesity and breast cancer is through the metabolic perturbations, especially hyperinsulinemia, associated with excessive body weight.

The incidence of breast cancer is increased in countries associated with affluent, unfavorable diets (high fat content) and a lack of physical exercise. Indeed, increased physical activity in postmenopausal women reduces the risk of breast cancer.<sup>247</sup> The common denominator may be the peripheral insulin resistance and hyperinsulinemia that become prevalent with aging and weight gain in affluent, modern societies. This specific metabolic change is becoming a common theme in various clinical conditions, particularly noninsulin-dependent diabetes mellitus, anovulation and polycystic ovaries, hypertension, and dyslipidemia. Hyperinsulinemia is found more often in women with breast cancer.<sup>248</sup> There are, indeed, many reasons to avoid excess body weight. The risk of breast cancer is reduced in women who exercise regularly.<sup>249</sup>

The increased circulating levels of insulin that are a consequence of obesity-induced insulin resistance can directly stimulate breast tissue growth and can also increase levels of biologically active estradiol by lowering sex hormone-binding globulin (SHBG) synthesis in the liver. In a cohort of women enrolled in the Women's Health Initiative, an increase in the risk of breast cancer in obese women who were not using hormone therapy correlated with hyperinsulinemia and elevated estradiol levels, but not with IGF-1 levels.<sup>250</sup> An adjustment for estrogen levels indicated that the

hyperinsulinemia acted independently and was the more robust factor. The inability to demonstrate this association with hyperinsulinemia in hormone users may be a consequence of the lower insulin levels caused by estrogen treatment.

In the parts of the world where soy intake is high, there is a lower incidence of breast, endometrial, and prostate cancers. For example, a case-control study concluded that there was a 54% reduced risk of endometrial cancer, and other case-control studies found a reduction in the risk of breast cancer, in women with a high consumption of soy and other legumes.<sup>251,252,253</sup> It is by no means certain, however, that there is a direct effect of soy intake.<sup>254</sup> Soy intake may be a marker for other factors in lifestyle or diet that are protective. Short-term studies on breast secretions have actually indicated that soy intake produces an estrogenic response.<sup>255,256,257</sup> The effect of soy intake on the risk of breast cancer is discussed in greater detail in [Chapter 17](#).

After migration to the United States, Asian women gradually increase (sixfold) their risk of breast cancer over several generations, eventually reaching the level of white women.<sup>258</sup> Evidence indicates that this reflects a change in diet and lifestyle, with an increase in risk associated with a gain in height and weight.<sup>259,260</sup> Recent weight gain is especially associated with increased risk. A reduced risk, however, is observed in heavy, younger women.

The effect of body weight on the risk of breast cancer differs in premenopausal and postmenopausal women. In premenopausal women who are overweight, the risk of breast cancer is lower compared with normal-weight individuals, and in postmenopausal women, especially in nonusers of hormone therapy, excess weight is associated with either an unchanged or slightly increased risk.<sup>261,262,263,264</sup> This is attributed to a more marked increase in total and free estrogen levels in overweight postmenopausal women, in contrast to lower levels with increasing weight in premenopausal women. Postmenopausal obese women have later menopause, higher estrone production rates and higher free estradiol levels (because of insulin-induced lower SHBG levels), and a slightly greater risk for breast cancer.<sup>265</sup> A large Swedish case-control study and an American prospective cohort study suggested that the principal factor is weight gain during adulthood and that the impact on breast cancer emerges 10 years after menopause.<sup>264,266</sup> In the Women's Health Initiative, subjects who prospectively reported weight gain in adulthood were more likely to develop breast cancer postmenopausally.<sup>267</sup> As noted, this weight gain may be the important determinant in the increasing risk experienced by migrants from low-risk parts of the world who move to high-risk areas.

Evidence indicates that the intake of vitamins A, C, and E has no effect on the risk of breast cancer.<sup>268</sup>

## Alcohol in the Diet

There is a modest increase in the risk for estrogen receptor–positive breast cancer with the consumption of one or more alcoholic drinks of all forms per day.<sup>269,270</sup> Almost all of many studies conclude that 2 drinks daily increase the risk by about 20%.<sup>271,272</sup> It is speculated that breast cancer and alcohol are linked through estrogen, either a direct or an indirect effect (e.g., on hepatic enzymes) on estrogen metabolism. An effect of alcohol ingestion by premenopausal women was not demonstrated on circulating levels of estrone, estradiol, DHEAS, or SHBG in a cross-sectional study that depended upon a questionnaire to assess alcohol intake.<sup>273</sup> However, when alcohol is administered under experimental conditions, circulating estrogen concentrations are increased.<sup>274,275,276</sup> And in a prospective cohort study of premenopausal women in Italy, higher estradiol levels were correlated with an increased alcohol intake over a 1-year period of time.<sup>277</sup> Similarly, the increased caloric intake associated with alcohol use may also lead to increased adiposity and elevated insulin levels.

# Specific Endocrine Factors

## Adrenal Steroids

Subnormal levels of etiocholanolone (a urinary excretion product of androstenedione) were found from 5 months to 9 years before the diagnosis of breast cancer in women living on the island of Guernsey, off the English Coast.<sup>278</sup> A subnormal excretion of this 17-ketosteroid was also found in sisters of patients with breast cancer. A sixfold increase in the incidence of breast cancer was found between women excreting less than 0.4 mg of etiocholanolone and those excreting over 1 mg/24 hours. After 37 years of follow-up, low levels of androsterone and etiocholanolone were observed to correlate with an increase in breast cancer only in women under age 50; over age 50, the reverse was true.<sup>279</sup> Measurement of these 17-ketosteroids might be a useful screening procedure to detect a high-risk group of patients because approximately 25% of the population excretes less than 1 mg/24 hours, but these early results have never been pursued.

## Endogenous Estrogens and Androgens

Epidemiologic and other information continue to suggest some estrogen-/progesterin-related promoter function. These include the following: (1) the condition is 100 times more common in women than in men; (2) breast cancer invariably occurs after puberty; (3) untreated gonadal dysgenesis and breast cancer are mutually exclusive; (4) a 65% excess rate of breast cancer has been observed among women who have had an endometrial cancer; and (5) breast tumors contain estrogen and progesterone receptors, which are biologically active. Taken together, these data suggest an element of estrogen/progesterin dependence, if not provocation, in many breast cancers.

Estriol generally has failed to produce breast cancer in rodents, and in fact, estriol protects the rat against breast tumors induced by various chemical carcinogens (but so did estradiol).<sup>280</sup> The hypothesis is that a higher estriol level protects against the more potent effects of estrone and estradiol. This might explain the protective effect of early pregnancies. Women having an early pregnancy continue to excrete more estriol than nulliparous women. Premenopausal healthy Asiatic women have a lower breast cancer risk than Caucasians and also have a higher rate of urinary estriol excretion.<sup>281</sup> When Asiatic women migrate to the United States, however, the risk of breast cancer increases, and their urinary excretion of estriol decreases, perhaps a consequence of dietary changes as noted above. A study of Westernized Asian women also documented a reduction in estrogen 2-hydroxy metabolites, with decreasing values linked to increasing breast cancer risk associated with measures of Westernization.<sup>282</sup>

A major factor in the potency differences among the various estrogens (estradiol, estrone, estriol) is the length of time the estrogen receptor complex occupies the nucleus. The higher rate of dissociation with the weak estrogen (estriol) can be compensated for by continuous application to allow prolonged nuclear binding and activity. Estriol has only 20–30% affinity for the estrogen receptor compared to estradiol; therefore, it is rapidly cleared from a cell. But if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.<sup>283</sup>

In pregnancy, where the concentration of estriol is very great, it can be an important hormone, not just a metabolite. Thus, higher estriol levels are not necessarily protective. Indeed, antagonism of estradiol occurs only within a very narrow range of the ratio of estradiol to estriol, a range rarely encountered either physiologically or pharmacologically.<sup>284</sup> Below this range, estradiol is unimpeded; above this range, estriol itself exerts estrogenic activity. Indeed, no inhibition of mammary tissue proliferation markers could be detected in women administered with estriol in the presence of an estrogen-progestin oral contraceptive.<sup>285</sup> There have been no epidemiologic studies of breast cancer risk in women treated with estriol, and therefore, the contention that estriol protects against breast cancer remains speculative.

There have been many studies assessing the relationship between endogenous hormone levels and the risk of breast cancer. A pooled analysis of nine prospective studies concluded that the risk of breast cancer, especially estrogen receptor–positive tumors, increases with increasing concentrations of all endogenous estrogens and androgens, including estradiol, estrone, estrone sulfate, androstenedione, DHEA, DHEAS, and testosterone.<sup>286</sup> A prospective study in Sweden found that current use of any estrogen-containing product was associated with a slightly higher risk of breast cancer, but use of estriol specifically was associated with a lower risk of breast cancer, when compared to women who had never used exogenous hormones.<sup>287</sup> The overall increase in breast cancer risk was about twofold comparing the lowest endogenous levels in postmenopausal women with the highest levels. This relationship is seen with both estrogens and androgens.<sup>288,289</sup> Postmenopausal women who are overweight have an increased risk of breast cancer, and analyses that adjusted for the increase in circulating estrogens associated with obesity concluded that the increasing risk with increasing body weight is the result of the increase in estrogens and a decrease in SHBG.<sup>290,291</sup> The increased risk of breast cancer in a cohort of obese women not using hormone therapy in the Women’s Health Initiative was attributed to elevated circulating levels of insulin and biologically active estradiol, highlighting the critical role for hyperinsulinemia as discussed above.<sup>263</sup>

Bone mass is generally regarded as a marker of estrogen exposure, and women with the highest bone densities have a greater risk of breast cancer compared with women

who have low bone densities.<sup>292,293,294</sup> Another attempt to link the risk of breast cancer to the endogenous estrogen level focused on prenatal exposure. A reduced risk for breast cancer is observed for women born to mothers with pregnancy-induced hypertension, suggesting that this finding is due to the lower estrogen levels associated with preeclampsia.<sup>295,296</sup>

The biologic plausibility and epidemiologic support for a sex steroid link are impressive arguments. Whether the important factor is the total amount of estrogens or progestins, the amount of estrogen unopposed by progesterone, the amount of free (unbound) estradiol, the duration of exposure to estrogens and progestins, or some other combination is not known.

## Endogenous Progesterone

Because mitotic activity in the breast reaches its peak during the progesterone-dominant luteal phase of the menstrual cycle,<sup>297,298,299</sup> it is argued that progesterone is the key to influencing the risk of breast cancer. However, studies do not support a major role for a progestational influence. Indeed, evidence indicates that with increasing duration of exposure, progesterone can limit breast epithelial growth as it does with endometrial epithelium.<sup>14,15,16</sup> In vitro studies of normal breast epithelial cells reveal that progestins inhibit proliferation.<sup>300</sup> Human breast tissue specimens removed after the patients were treated with estradiol and progesterone indicate that progesterone inhibits in vivo estradiol-induced proliferation.<sup>14,16</sup> Women who ultimately develop breast cancer do not have different blood levels of progesterone.<sup>289,301</sup> In addition, several clinical observations would argue against progesterone as a key factor. Although there is some disagreement, most studies indicate that the high levels of estrogen and progesterone during pregnancy have no adverse impact on the course of breast cancer diagnosed during pregnancy or when pregnancy occurs subsequent to diagnosis and treatment.

## Exogenous Hormone Use

The large number of women taking or having taken oral contraceptive steroids, combined with the belief that sex steroids provoke or promote abnormal breast growth and possibly cancer, has provided a source of major concern for years. In Denmark, a recent prospective study has indicated a small increase in the risk of breast cancer associated with hormonal contraceptive users.<sup>302</sup> This study followed over 1.8 million women ages 15–49 for an average of 10.9 years, or 19.6 million person-years, to determine association between any type of hormonal birth control and development of breast cancer. They found an overall relative risk of breast cancer in women who used hormonal contraception for greater than 6 months of 1.08 (95% CI 1.03–1.13) as

compared to women who never used hormonal contraceptives. They found that the risk increased with increasing length of use of hormonal contraceptives, with women who used them for more than 10 years having a relative risk of 1.46 (95% CI 1.32–1.61). In women who used hormones for less than 1 year, the risk of breast cancer was not increased over women who never used hormones. Additionally, this study looked at the risk of developing breast cancer by hormone type. Patients who used norethindrone either alone or combined with estrogen in a pill, drospirenone with ethinyl estradiol orally, depot medroxyprogesterone acetate, and the contraceptive implant, patches, and rings did not appear to have an increased risk of breast cancer. Oral contraceptives with estrogen carrying levonorgestrel, norgestimate, desogestrel, oral contraceptives with levonorgestrel alone, and the levonorgestrel-releasing intrauterine device all appear to have a significant but modest increased risk for breast cancer development. To put this into perspective, for every 7,690 women using hormonal contraception for 1 year, there is one extra case of breast cancer.

Previous case-control studies focused on breast cancer diagnosed at a later age, varying histologic subtypes of breast cancer, and familial breast cancer in hormonal contraceptive uses and found no association. The largest case-control study is that performed by the Centers for Disease Control and Prevention, involving 4,575 American women with breast cancer, aged 35–64.<sup>303</sup> Initiation at a younger age had no impact. In this study, the risk of breast cancer was not increased in current users or past users of oral contraception. There was no adverse effect of increasing duration of use or higher doses of estrogen and no increase in risk in women with a family history of breast cancer. A multicenter, large case-control study of women younger than 55 years with breast cancer concluded that the use of oral contraceptives or postmenopausal hormone therapy either before or after diagnosis did not increase the risk of the first breast cancer or recurrent breast cancer.<sup>304</sup> This negative finding was not changed by the duration of use or age of use. Furthermore, no increase in breast cancer mortality can be detected in women who have used oral contraceptives.<sup>305,306</sup>

A team of epidemiologists from several institutions in the United States performed a case-control study of the association between oral contraceptive use and lobular and ductal breast cancer occurring in young women (under age 44), concluding that the use of oral contraceptives has no meaningful effects on breast cancer risk according to histologic subtype.<sup>307</sup> Lobular cancer is more hormonally sensitive than ductal breast cancer.

This is all to say that while clinicians should take heed of the prospective Danish study, the biggest risk in increases in breast cancer appears to be in early and recent use of oral contraceptives. It has long been a concern that studies showing this effect of hormones on a premenopausal population may affect the growth of a preexisting

malignancy. The literature we have on subpopulations, including patients with familial breast cancer, does not indicate that using hormonal birth control significantly increases their risk of developing breast cancer.<sup>308</sup>

Oral contraception appears to protect against benign breast disease. A French case-control study indicated a reduction of nonproliferative benign breast disease associated with low-dose oral contraceptives used before a first full-term pregnancy, but no effect on proliferative disease or with use after a pregnancy.<sup>309</sup> A Canadian cohort study that almost certainly reflected the use of modern low-dose oral contraceptives concluded that oral contraceptives do protect against proliferative benign disease, with an increasing reduction in risk with increasing duration of use.<sup>310</sup>

Women with a greater mammographic breast density have a higher risk of breast cancer.<sup>311</sup> If more than 75% of the breast is dense, the risk is 4–5 times increased. Mammographic density is associated with epithelial and stromal cell proliferation.<sup>312</sup> Studies in twins and families have indicated that there is a strong genetic determinant of an individual's breast density and that this genetic influence is shared with the other genetic factors that increase the risk of breast cancer.<sup>313,314,315,316</sup> In general, breast density declines with age and increasing body weight and numbers of pregnancies.

About 25% of women on estrogen-progestin therapy have an increase in their breast density. However, it is not certain that the short-term increase in density with hormone therapy changes an individual's risk of breast cancer. The increase in breast density associated with postmenopausal hormone therapy appears in some studies to be a transient, reversible change, a change not consistent with a persistent effect on cellular proliferation. After discontinuing hormone therapy, some reports indicated that breast density rapidly decreases.<sup>317,318,319,320</sup> However, in a large randomized trial of 1,704 women age 45–80, although suspension of hormone therapy for 1 or 2 months produced small but significant decreases in density, mammography recall rates of 10–12% were not affected.<sup>321</sup> In one small screening population of 47 women, a 4-week period without hormones before mammography had no measurable effect on density readings.<sup>322</sup> Therefore, the evidence is mixed regarding a recommendation to discontinue hormone therapy for 2–4 weeks prior to mammography in women who have dense breasts. Another approach is to consider lower doses of hormone therapy; there is some evidence that low-dose treatment has little effect on breast density.<sup>323</sup>

## **Thyroid, Prolactin, and Various Nonestrogen Drugs**

Despite isolated suggestions of increased risk, hypothyroidism, reserpine, and prolactin excess, whether spontaneous or drug-induced, are not associated with an enhanced risk of breast cancer.<sup>319,320</sup>

## Breast Cancer in Diethylstilbestrol-Exposed Women

From 1940 to 1970, diethylstilbestrol (DES), a potent synthetic estrogen, was prescribed in high doses in the mistaken belief that it would reduce the risk of pregnancy-related complications. Exposure to DES occurred in association with 2 million live births; therefore, the risk for induction of breast cancer during a period of breast differentiation could be significant if DES were a true breast carcinogen. The first study on this subject reported on the follow-up of women who participated in a controlled trial of DES in pregnancy between 1950 and 1952 at the University of Chicago. In this study, an increase in breast cancer risk that did not reach significance was observed with DES exposure.<sup>324</sup> A large collaborative study, involving approximately 6,000 women, concluded that there is a small but significant increase in the risk of breast cancer many years later in life in women exposed to DES during pregnancy.<sup>325</sup> In a longer follow-up (more than 30 years) of this large cohort of DES-exposed women, exposure to DES was associated with a significant, but modest (about twofold), increase in the risk of breast cancer.<sup>326</sup> Importantly, the relative risk did not increase with duration of follow-up and remained stable over time. This conclusion was confirmed in a prospective study by the American Cancer Society and in a national cohort of women followed since the 1970s.<sup>327,328</sup> Certainly, it is wise to recommend to DES-exposed women that they adhere to screening for breast cancer, including mammography as discussed later. More recently, as in utero-exposed DES daughters reach an age when breast cancer becomes more prevalent, an increased risk of cancer has been detected in daughters of DES-exposed women.<sup>329</sup> Thankfully, the relative risk is quite small and does not change the recommendations for breast screening. It will be important to track this population for further increases as they age.

# Receptors and Clinical Prognosis

There is a strong correlation between the presence of estrogen receptors and certain clinical characteristics of breast cancer.<sup>330</sup> Premenopausal, younger patients are more frequently receptor negative. Patients with receptor-positive tumors survive longer and have longer disease-free intervals after mastectomy than those with receptor-negative tumors. The presence of estrogen receptors correlates with increased disease-free interval regardless of the size and location of the tumors. Similarly, patients with estradiol receptor–negative tumors were noted to have the same high rate of recurrence as patients with axillary lymph node metastases. Patients with tumors that are positive for estrogen receptors are more likely to respond to endocrine treatment. Estrogen receptor status correlates with the degree of differentiation of the primary tumor. A large proportion of highly differentiated grade I carcinomas are receptor positive, while the reverse is true of grade III tumors.

Remember that estrogen stimulates the production of progesterone receptors. Overall, about 80% of breast cancers are positive for estrogen receptors, and of these, about 70% are positive for progesterone receptors; thus, about 58% of all breast cancers express both estrogen and progesterone receptors.<sup>331</sup> The best prognosis is seen in patients with positive progesterone receptors, even with subsequent disease if the recurrent disease is still progesterone receptor–positive. The loss of progesterone receptors is an ominous sign. Tumors that are estrogen receptor–positive, but progesterone receptor–negative, express higher levels of the epidermal growth factor receptors, HER-1 and HER-2, and are more aggressive and tamoxifen-resistant.<sup>331</sup> The total absence of estrogen and progesterone receptors indicates a very different disease, one that should be treated aggressively with chemotherapy.

# Hormone Therapy of Breast Cancer

## Tamoxifen

The purpose of adjuvant therapy of breast cancer is to provide treatment in the absence of recognized active disease in order to reduce the risk of future recurrence or to minimize systemic recurrence in the presence of metastatic disease. Tamoxifen is very similar to clomiphene (in structure and actions), both being nonsteroidal compounds structurally related to DES. In vitro, the estrogen binding affinity for its receptor is 100–1,000 times greater than that of tamoxifen. Thus, tamoxifen must be present in a concentration 100–1,000 times greater than estrogen to maintain inhibition of breast cancer cells. Dose-response studies with tamoxifen have failed to demonstrate an increase in activity with doses larger than the standard, 20 mg daily. When bound to the estrogen receptor, tamoxifen prevents gene transcription by the TAF-2 pathway. In vitro studies demonstrate that these actions are not cytotoxic, but rather cytostatic (and thus tamoxifen use must be long term). The mechanism of tamoxifen action is discussed in detail in [Chapter 1](#).

We have available a remarkable worldwide overview of 37,000 women involved in tamoxifen randomized trials.<sup>332</sup> Adjuvant treatment with the antiestrogen tamoxifen achieved highly significant reductions in recurrence and increases in survival. The beneficial effect of tamoxifen was evident no matter what the age of the patient, in both premenopausal and postmenopausal women, in node-positive and node-negative disease, and in both estrogen receptor–positive and estrogen receptor–negative tumors (however, the effect of tamoxifen on estrogen receptor–negative tumors is small). The impact on recurrence occurred in the first 5 years, but continued impact on survival occurred throughout 15 years.<sup>333</sup> Hormonal adjuvant treatment yields worldwide an extra 100,000 10-year survivors. With tamoxifen, there is an increased survival at 5 years of approximately 25%, most evident in women over age 50. Response rates in advanced breast cancer are 30–35%, most marked in patients with tumors that are positive for estrogen receptors, reaching 75% in tumors highly positive for estrogen receptors. There is a lower rate (a 47% reduction with 5 years of treatment) of a second primary breast cancer in the contralateral breast in women treated with tamoxifen.

Data from randomized clinical trials document that a treatment duration of 5 years is superior to 2 years.<sup>334</sup> It was previously thought that there was little reason to extend tamoxifen treatment of breast cancer patients beyond 5 years.<sup>335,336</sup> The data suggested that survival and recurrence rates worsened with longer therapy, probably due to the emergence of tamoxifen-resistant tumors. However, a randomized placebo-controlled trial looked at women with estrogen receptor–positive early breast cancer who had

completed 5 years of tamoxifen therapy and were considered disease-free, and these patients were randomized to either placebo or additional tamoxifen for 5 years.<sup>337</sup> In this study, it was found that women receiving 10 years of tamoxifen had fewer recurrences (relative risk after year 10 was 0.75, 95% CI was 0.62–0.9), lower breast cancer mortality (relative risk after year 10 was 0.71, 95% CI 0.58–0.88), and a lower overall mortality than women who received placebo (relative risk 0.87, 95% CI 0.78–0.97). The risk of pulmonary embolus and endometrial cancer was significantly higher in the tamoxifen continuation group, while the risk of ischemic heart disease was significantly lower.

The efficacy of tamoxifen is significantly dependent on the formation of active metabolites, 4-hydroxytamoxifen and endoxifen, which have a greater affinity for the estrogen receptor than tamoxifen. A cytochrome enzyme, P450 2D6, is involved in this metabolism, and genetic variants in the enzyme can account for lower activity leading to reduced efficacy for tamoxifen. Genotyping of CYP2D6 could allow better selection of patients for tamoxifen treatment.<sup>338</sup> However, others contend that the metabolite levels are sufficient for good efficacy even in the presence of reduced enzyme activity and that the studies linking CYP2D6 genotype and breast cancer recurrence have yielded heterogeneous results.<sup>339</sup> It is not certain that CYP2D6 variation is the explanation for recurrence of resistant tumors.

Tamoxifen has many important side effects, attributed to both its estrogen agonist action and its antiestrogen impact in different target tissues. The major disturbing side effect is an increase in hot flushing. The serious side effects of tamoxifen include endometrial cancer (discussed later), venous thrombosis, and cataracts. In a report from the prevention trial in England and in the US preventive trial, tamoxifen treatment of postmenopausal women prevented bone loss, but premenopausal women treated with tamoxifen had significant reductions in bone mineral density.<sup>234,340</sup> Blurred and decreased vision has been reported associated with retinal changes.<sup>341</sup> In a prospective study of 63 patients in Greece, 6.3% developed retinopathy, which was reversible except for retinal opacities.<sup>342</sup> In the 2,673 patients in the protocols of the Eastern Cooperative Oncology Group, premenopausal women who received tamoxifen and chemotherapy had significantly more venous and arterial thrombosis than those who received chemotherapy without tamoxifen, and in postmenopausal women, tamoxifen alone was associated with more venous thrombosis.<sup>343</sup>

Serum protein changes reflect the estrogenic (agonistic) action of tamoxifen. This includes decreases in antithrombin III, cholesterol, and LDL cholesterol, while HDL cholesterol and SHBG levels increase (as do other binding globulins). Because of the significant impact on SHBG, a marked increase in circulating estrogens has been observed in premenopausal women; however, unbound, free estrogen is actually

reduced. For example, in a clinical study of premenopausal women receiving tamoxifen, 20 mg daily, the percent free estradiol decreased from 1.72% to 1.47% after 3 months because of the increase in SHBG.<sup>344</sup>

The estrogenic activity of tamoxifen, 20 mg daily, is nearly as potent as 2-mg estradiol in lowering FSH levels in postmenopausal women, 26% versus 34% with estradiol.<sup>345</sup> The estrogenic actions of tamoxifen include the stimulation of progesterone receptor synthesis, an estrogen-like maintenance of the bone and the cardiovascular system, and estrogenic effects on the vaginal mucosa and the endometrium. Indeed, patients with breast cancer who have been treated with tamoxifen were reported to have less coronary heart disease in some studies, but not all.<sup>234,332,346,347</sup> Tamoxifen increases the frequency of hepatic carcinoma in rats at very large doses. This is consistent with its estrogenic, agonistic action, but this effect is unlikely to be a clinical problem, and it has not been observed at doses used clinically.<sup>332</sup>

## Gynecologic Problems with Tamoxifen

Tamoxifen is selective estrogen receptor modulator, having both estrogen receptor antagonist and agonist properties, depending on the tissue and genes examined. A tissue that is highly sensitive to estrogen, the endometrium, responds to the weak estrogenic action of tamoxifen, which is present in high doses for long durations in women receiving adjuvant treatment for breast cancer.

The National Surgical Adjuvant Breast and Bowel Project compared the rates of endometrial cancers in tamoxifen and non-tamoxifen-treated patients who had breast cancer.<sup>348</sup> The rate of endometrial cancer in the tamoxifen-treated group equaled an increased relative risk of 7.5. Although 88% of the endometrial tumors were stage I, four patients died of advanced endometrial cancer. It is worth noting that the incidence of endometrial cancer in the tamoxifen-treated group was estimated to be 6.3 per 1,000 patients after 5 years of treatment. This incidence is very similar to what would be expected with unopposed estrogen treatment, a similarity to be expected in that the agonistic estrogenic action of tamoxifen over the long term should be similar to the relatively low doses of estrogen used for postmenopausal hormone therapy. Similar results were reported from the Stockholm tamoxifen trial, and an increased rate of postmenopausal endometrial cancer was confirmed in the U.S. Breast Cancer Prevention Trial.<sup>234,349</sup> In the world overview of randomized trials, the incidence of endometrial cancer quadrupled with 5 years of tamoxifen treatment.<sup>332</sup> In addition, women being treated with tamoxifen were reported to develop atypical hyperplasia of the endometrium, endometrial polyps, ovarian cysts, growth of fibroids, adenomyosis, and rapid exacerbation of endometriosis.<sup>350,351,352,353</sup> The proper prevention, surveillance, and management of women being treated with tamoxifen are critical

problems.

It is inappropriate to advocate oral progestational treatment to prevent the endometrial response to tamoxifen. The progestational impact (at the low doses currently used for endometrial protection) on the risk of breast cancer recurrence and the interaction with tamoxifen are not known. Indeed, a relatively high dose of norethindrone (2.5 mg daily for 3 months) was **unable** to exert a protective effect on the endometrium in healthy women participating in the U.K. tamoxifen prevention trial, and a high dose of megestrol acetate failed to reverse endometrial hyperplasia.<sup>354,355</sup> **The levonorgestrel intrauterine device (IUD) effectively effectively protects the endometrium against hyperplasia and polyps in women using tamoxifen or postmenopausal estrogen therapy.**<sup>356,357,358,359,360,361,362,363,364</sup> **Breakthrough bleeding is a problem in the early months, but this method is suitable for both premenopausal and postmenopausal women using tamoxifen. This IUD can also be used to treat endometrial hyperplasia.**<sup>365,366,367,368,369,370</sup> **However, the persistence of atypia at biopsy follow-up after 6 months is an indication that regression is unlikely to occur. Although the levonorgestrel IUD confidently provides good protection against endometrial hyperplasia, clinicians should maintain a high degree of suspicion of unusual bleeding (bleeding that occurs after a substantial period of amenorrhea) and aggressively assess the endometrium.**

Most tamoxifen-treated women who have developed endometrial cancer have been symptomatic with vaginal bleeding, but not all. Vaginal bleeding in tamoxifen users should always prompt uterine evaluation. Unfortunately, some women with amenorrhea have had advanced, invasive uterine disease. Stage III and stage IV endometrial cancers with a poor prognosis were reported more frequently in long-term tamoxifen users.<sup>371</sup> In addition, tamoxifen is associated with a higher rate of mixed mesodermal tumors and sarcomas of the endometrium.<sup>371</sup> It makes sense to detect abnormal changes as early as possible, but an ideal surveillance method had eluded clinicians. The progestin challenge test may be a cost-effective method to detect the presence of stimulated endometrium, and small prospective studies reported 100% sensitivity and positive predictive value for endometrial pathology.<sup>372,373</sup> Periodic transvaginal ultrasound using a cutoff endometrial thickness of 9 mm has been studied as a surveillance method, and it has been shown to be ineffective at identifying endometrial cancer in this patient population with a sensitivity of 63%, specificity of 60%, and positive predictive value of only 1.4%.<sup>374</sup> The use of ultrasonographic measurement of endometrial thickness, with saline instillation sonohysterography when the appearance is not totally benign, may be used. In a retrospective study using endometrial thickness cutoffs of 9.5 mm on regular ultrasonography and 5.5 mm on saline sonography yielded sensitivities of 89% and 78% and specificities of 78% and 84%. When using either the presence of polypoid

lesions or endometrial thickness of 5.5 mm or greater on saline sonography, sensitivity increased to 100%.<sup>375</sup> Tamoxifen is associated with an ultrasonographic image that is unique, characterized by sonolucent changes that are subepithelial in the presence of atrophic epithelium, thus the usefulness of saline instillation to discriminate epithelial thickness from combined endometrial changes.<sup>376</sup> Periodic endometrial aspiration biopsy would likely be sufficient for surveillance, but this procedure carries with it the potential for a very significant negative effect on patient compliance (with her tamoxifen and with her clinician) and a low rate of positive results.

It is also logical to expect patients on tamoxifen to be at increased risk for the development and progression of endometriosis. There are case reports of women being treated with tamoxifen, 20 mg daily, who required hysterectomy and oophorectomy for severe endometriosis.<sup>377,378,379,380</sup> In addition, women receiving tamoxifen develop adenomyosis, ovarian cysts, and endometrioid cancer of the ovary.<sup>380,381,382,383</sup> In our view, an annual pelvic examination is not sufficient; every 6 months is best.

A woman being treated for breast cancer will naturally focus her attention and energy on the cancer itself, especially in the early years of treatment. The same can be said for the specialist who is monitoring the treatment. It falls to the patient's health care manager, her primary clinician, to look at the broader picture. A clinician interacting with patients being treated for breast cancer has an obligation to consider the impact of the patient's treatment on other body systems and functions. Tamoxifen offers the hope of adding many years to a woman's life. Medical intervention by a clinician can help make those years better with good preventive health care.

# Aromatase Inhibitors for the Treatment of Breast Cancer

Aromatase inhibitors block the conversion of androgen precursors to estrogen at all target tissue sites, nearly completely inhibiting total body estrogen production in postmenopausal women. This inhibition is not as complete in premenopausal women. The modern aromatase inhibitors include two nonsteroidal inhibitors, anastrozole (Arimidex) and letrozole (Femara), and one steroidal inactivator, exemestane (Aromasin).

The aromatase enzyme is present in the stromal tissue of normal and abnormal breast tissue and in breast epithelial cells. Aromatase activity is increased in breast cancer tissues, associated with a switch from a promoter controlled primarily by glucocorticoids and cytokines to a promoter regulated through cyclic AMP pathways.<sup>384</sup> However, aromatase activity in malignant breast epithelial cells is either undetectable or very low. Thus, growth stimulation of hormonally sensitive breast cancer is presumed to be influenced by local estrogen synthesis in adjacent stromal cells that is increased in a paracrine fashion by malignant cells activating alternative aromatase gene promoters.<sup>385</sup> A relationship between the aromatase and prostaglandin cyclooxygenase systems may explain the beneficial effects of nonsteroidal anti-inflammatory drugs in epidemiologic reports on the risk of breast cancer.<sup>386</sup> Cyclooxygenase is overexpressed in breast cancer, and the treatment combination of aromatase and cyclooxygenase inhibitors is being evaluated in clinical trials.<sup>387</sup>

The specific inhibitors of P450arom that have been developed produce intense blockage of estrogen production and, importantly, reduce estrogen biosynthesis in the cells adjacent to breast tumors. The initial development of drugs that reduce estrogen production focused on alterations of the androstenedione molecule to produce competitive inhibitors. The preparation of a large number of altered steroid agents yielded exemestane, a steroidal inactivator of the aromatase enzyme, that clinically is grouped in the family of aromatase inhibitors.

The first nonsteroidal inhibitors, such as aminoglutethimide, affected other CYP-450 enzymes, producing unwanted toxic effects. The current generation of nonsteroidal aromatase inhibitors containing a triazole ring, anastrozole and letrozole, are highly specific with no effect on the biosynthesis of other steroids. These agents are 100–3,000 times more potent than aminoglutethimide and reduce total body aromatization by 97–99%.<sup>388</sup>

The first studies with the nonsteroidal aromatase inhibitors demonstrated that anastrozole (1 mg daily) and letrozole (2.5 mg daily) were more effective than

tamoxifen in women with advanced breast cancer.<sup>389,390,391</sup> Similar results were reported with exemestane.<sup>392</sup> More recent clinical trials focused on the treatment of early breast cancer.

**The ATAC Trial.**<sup>393,394,395</sup> The Arimidex, Tamoxifen, Alone or in Combination trial included 9,366 patients in 380 sites in 23 countries. Eighty-four percent had estrogen receptor–positive tumors and one-third had positive lymph nodes. The patients were randomized to daily treatment with anastrozole, 1 mg; tamoxifen, 20 mg; or a combination of both for 5 years.

Compared with tamoxifen, anastrozole increased the disease-free survival by 14%, decreased the incidence of new contralateral primary tumors by 38% (although this difference did not reach statistical significance), and increased the time to recurrence by 17%. The combination treatment was not better than anastrozole alone. In patients negative for estrogen and progesterone receptors, the small effect of anastrozole was equivalent to that of tamoxifen. After long-term follow-up, it was apparent that the carryover effect after 5 years of treatment was greater with anastrozole compared with tamoxifen.<sup>395</sup>

There were significant differences in comparing the adverse effects of the two drugs (Table 16.9).

## **TABLE 16.9 Side Effects of Hormone Therapies for Breast Cancer**

	Anastrozole (%)	Tamoxifen (%)
Hot flushes	34.3	39.7
Vaginal bleeding	4.5	8.2
Endometrial cancer	0.1	0.5
Venus thromboembolism	2.1	3.5
Joint complaints	27.8	21.3
Fractures	5.9	3.7

Adverse gynecologic events occurred less frequently with anastrozole compared with tamoxifen in the ATAC trial.<sup>396</sup> These events included lower incidences of vaginal hemorrhage, vaginal discharge, endometrial polyps, endometrial hyperplasia, and endometrial cancer. As a result, there was a fourfold increase in hysterectomy in the women treated with tamoxifen. Importantly, more women remained adherent to treatment with anastrozole.

**The BIG Trial.** The Breast International Group trial randomized 8,028 women to either tamoxifen or letrozole for 5 years and reported an improved disease-free survival in the letrozole group.<sup>397,398</sup>

**The ITA Trial.** The Italian Tamoxifen Anastrozole Trial of 448 women compared 5 years of tamoxifen to a group switched to anastrozole after 2–3 years of tamoxifen.<sup>399</sup> The disease-free survival was significantly increased in the sequentially treated group.

**The IES Trial.** The Intergroup Exemestane Study included 4,742 patients and compared 5 years of tamoxifen with a sequential group switched to exemestane, 25 mg daily, after 2–3 years of tamoxifen.<sup>400,401</sup> There was a 32% reduction in risk with exemestane for recurrence, contralateral breast cancer, or death that equaled an improvement of 4.7% in disease-free survival. The risk of contralateral breast cancer was reduced by 56%.

**The TEAM Trial.** The Tamoxifen Exemestane Adjuvant Multinational Study randomized 9,775 women to either exemestane, 25 mg daily, or tamoxifen, 20 mg daily.<sup>402</sup> In 2004, the trial was modified, switching tamoxifen patients to exemestane after 2.5–3 years of treatment to complete 5 years of treatment total. After 10 years of follow-up, there was no difference in disease-free survival.<sup>403</sup>

**The MA.17 Trial.** After 5 years of tamoxifen treatment, 5,187 women were randomized to 5 years of letrozole or placebo.<sup>404,405</sup> The analysis indicated an improvement in disease-free survival with letrozole, 94.3% compared to 91.4% in the placebo group. This impact was present in both patients with positive nodes and negative nodes. Overall, the letrozole group experienced a 39% reduction in contralateral primary breast cancer, a 42% reduction in recurrences, and a 38% reduction in distant metastases. Because of these benefits, the trial was unblinded and patients were given the option of switching from placebo to letrozole. In an updated analysis, disease-free survival was improved with letrozole treatment.<sup>406,407</sup> This study reported significantly more joint complaints and more hot flushing compared with placebo and an increase in fractures and cardiovascular events.

Aromatase inhibitors are more effective than tamoxifen for the treatment of estrogen-sensitive breast cancers in postmenopausal women, either for early disease or for metastatic breast cancer. The three aromatase inhibitors have similar side effect profiles. The major problem has been an increase in fractures due to the bone loss associated with the profoundly low estrogen levels (nearly a 99% decrease), an effect that can be prevented with bisphosphonate treatment. Besides hot flushing, other major side effects are joint arthralgias, reduced sexual function, and myalgia.<sup>408</sup> Compared with tamoxifen, there is less, if any, endometrial stimulation and less venous thromboembolism. Anecdotal experience has suggested that anastrozole users have an increased prevalence of retinal hemorrhages, presumably due to vascular fragility secondary to estrogen depletion.<sup>409</sup>

A decision analysis using computer modeling suggested that a modestly improved outcome is associated with sequential therapy (tamoxifen for 2.5 years followed by an aromatase inhibitor) compared with 5 years of an aromatase inhibitor alone. The actual increase was only 1–2%.<sup>410</sup> This small difference was not supported by a phase 3 clinical trial, a continuation of the BIG trial, comparing letrozole monotherapy with tamoxifen-letrozole sequential therapy, in which the overall survival in the treatment groups did not differ.<sup>411</sup>

The American Society of Clinical Oncology and the National Comprehensive Cancer Network, based on the results of the clinical trials, now make the following recommendations<sup>405,412</sup>:

- Postmenopausal women with hormone-positive breast cancers should be treated with an aromatase inhibitor for 5–10 years, tamoxifen for 5–10 years, or tamoxifen for 5 years followed by 5 years of aromatase inhibitor treatment.
- Premenopausal women with hormone-positive breast cancers should be treated with tamoxifen for 5–10 years, with the option of switching to an aromatase inhibitor after 5 years if the patient becomes postmenopausal during treatment.
- Aromatase inhibitors are appropriate as initial treatment for women with contraindications to tamoxifen.
- Aromatase inhibitor treatment has been associated with better response rates compared with tamoxifen in postmenopausal women with tumors overexpressing HER-2. This evidence is not strong but should be considered.
- There is insufficient evidence available to support the use of tamoxifen after treatment with an aromatase inhibitor.

A reasonable and important addition to these recommendations is to promote adequate calcium and vitamin D supplementation and to consider prophylactic bisphosphonate treatment to prevent bone loss and fractures. Treatment with zoledronic acid (4 mg intravenously every 6 months) increased bone density in women being treated with letrozole and even improved disease-free survival rates.<sup>413,414</sup> Similar bone density results were obtained with the once-a-month oral bisphosphonate, ibandronate.<sup>415</sup> **More effective protection against bone loss and fractures is achieved by starting bisphosphonate treatment simultaneously with an aromatase inhibitor.**<sup>416</sup>

Bisphosphonates appeared to have an independent beneficial impact on the incidence of breast cancer in observational studies. In the Women's Health Initiative, oral bisphosphonate users had a significant 32% reduction in estrogen receptor–positive breast cancer incidence.<sup>417</sup> However, randomized controlled trials looking at 3–4 years of bisphosphonate use in women ages 55–89 showed no difference in the risk of developing breast cancer.<sup>418</sup>

A meta-analysis of randomized trials looking at 19,818 patients comparing aromatase inhibitors with tamoxifen in early breast cancer focused on cardiovascular risk.<sup>419</sup> The relative risk for grade III and IV cardiovascular adverse events with aromatase inhibitors as compared to tamoxifen was unexpectedly 1.31 (CI = 1.07–1.60). However, there was a 47% reduced risk of thromboembolic events with aromatase inhibitors, RR = 0.53 (CI = 0.42–0.65). Additionally, a meta-analysis of randomized controlled trials looking at 16,349 patients comparing extended aromatase inhibitor therapy with placebo in patients with early breast cancer showed an increase in relative risk of cardiovascular events of 1.18 (95% CI = 1.0–1.4).<sup>420</sup>

The increase in cardiovascular disease with aromatase inhibitors reflects the

absence of a beneficial influence of estrogen on the lipid profile and on important vascular epithelial functions such as nitric oxide synthesis. The meta-analyses suggest that this is a relatively low risk. Furthermore, it is inadvisable to consider only one of the estrogen deficiency side effects. The overall impact on a patient will be determined by the additive effects on all estrogen target tissues. The effects on cognition and the risk of Alzheimer disease are major potential issues. Cognitive assessments were performed in a subgroup of women in the IBIS anastrozole trial for prevention of breast cancer; no significant differences were observed comparing the treatment group with the placebo group; however, the duration of the study was only 2 years.<sup>421</sup> Another study reported worse verbal and visual learning in women treated with anastrozole compared with tamoxifen treatment.<sup>422</sup> Dutch women in the TEAM trial who were tamoxifen users performed worse than healthy controls on verbal memory and executive function testing, whereas no adverse effects were observed in exemestane users after 1 year.<sup>423</sup> Continuing follow-up of treated women over a longer period of time will be necessary to acquire a better understanding of the impact of aromatase inhibitors on cognition.

Some important questions regarding aromatase inhibitors remain unanswered. The optimal duration of therapy is not established. At the present time, treatment longer than 5 years awaits appropriate clinical trial data. The long-term safety is unknown; will a low estrogen and a relatively high androgen hormonal environment lead to clinical consequences? Balancing the benefits and risks will require this information. Nevertheless, aromatase inhibitor treatment has justifiably usurped the place of tamoxifen in the adjuvant treatment of breast cancer; the reason being that it is more effective to pharmacologically block estrogen biosynthesis, especially at the local level, than it is to interfere with estrogen action.

# Tamoxifen, Raloxifene, and Aromatase Inhibitors for Prevention of Breast Cancer

## Tamoxifen

Women at increased risk for breast cancer participated in a breast cancer prevention trial initiated in the United States in 1992. The study compared two groups of women, one treated with placebo and one with 20-mg tamoxifen daily for 5 years. Early in 1998 (after about 4 years of follow-up), the study was unblinded because there were 49% fewer cases of invasive breast cancer and 50% fewer cases of noninvasive breast cancer in the tamoxifen-treated arm of the study.<sup>232</sup> This outcome was not without risk. There was a 2.4-fold increase in postmenopausal endometrial cancer, a 2.8-fold increase in pulmonary embolism, a 1.6-fold increase in venous thrombosis, and a 1.6-fold increase in cataracts.

There have been four randomized placebo-controlled tamoxifen prevention trials. In the 7-year follow-up report of the American tamoxifen for prevention study, the risk for breast cancer was 0.57 (CI = 0.46–0.79), a 43% reduction, not the 50% cited in the results above, and the risk for in situ disease was 0.63 (CI = 0.45–0.89), a 37% reduction.<sup>233</sup> Follow-up of the Italian national trial demonstrated a 23% reduction of estrogen receptor–positive cancers in the group of women considered to be at the highest risk of cancer.<sup>424</sup>

The Royal Marsden randomized, double-blinded tamoxifen breast cancer prevention trial began in 1986, enrolling 2,494 women with a positive first-degree family history of breast cancer.<sup>425</sup> The treatment group received 20 mg tamoxifen daily for 8 years. Twenty years later (median follow-up of 13 years), there were 139 estrogen receptor–positive breast cancers for a 39% reduction (HR = 0.61, CI = 0.43–0.86). The lowered risk did not become statistically significant until after the 8-year treatment period.

The International Breast Cancer Intervention Study (IBIS), also a randomized, double-blinded trial, began in 1992 and enrolled 7,145 women; the treatment period with tamoxifen 20 mg daily was 5 years.<sup>426</sup> After a median follow-up of 8 years, there was a 34% reduction in estrogen receptor–positive cancers (RR = 0.66, CI = 0.50–0.87). The IBIS trial found a greater reduction during the treatment period, but when the analysis was restricted to estrogen receptor–positive cancers, the IBIS and Royal Marsden trials were similar, finding a greater effect after treatment. The differences among these trials are attributed to variations in risk factors in the studied populations. The American trial enrolled women with risk assigned by the Gail model, a risk

assessment tool for invasive breast cancer that has been validated in white women.<sup>427</sup> The women in the International trial were at a lower risk than those in the Royal Marsden trial, and the women in the Italian trial were not assessed for risk.

Epidemiologists from England, Italy, and Australia reviewed the combined results of the breast cancer tamoxifen prevention trials and added updated results.<sup>428</sup> The combined data indicated a 48% reduction in estrogen receptor–positive cancers and no effect on the incidence of estrogen receptor–negative cancers. The overall relative risk of endometrial cancer with tamoxifen was increased 2.4-fold, and the relative risk of venous thromboembolic events was 1.9. The length of follow-up and patient numbers do not allow data regarding breast cancer mortality. The impact of 5 years of tamoxifen treatment on 1,000 high-risk women should yield an 18% reduction in mortality within 10 years of diagnosis. Experts and organizations in the breast cancer world have agreed that tamoxifen reduces the incidence of estrogen receptor–positive cancers in high-risk women. In an assessment of the women in the American preventive trial, tamoxifen reduced the incidence of breast cancer among BRCA2 carriers, but not in BRCA1 carriers, perhaps reflecting the fact that most of the BRCA2 carriers have estrogen receptor–positive tumors in contrast to the prevalence of estrogen receptor–negative tumors in BRCA1 carriers (another problem was small numbers, 8 with BRCA1 mutations and 11 with BRCA2 mutations).<sup>429</sup>

The evidence supports tamoxifen reduction of the risk for estrogen receptor–positive breast cancer, but at the same time, tamoxifen should be recommended as a preventive agent only for women at very high risk. This conclusion is based upon the degree of reduction in risk compared with the incidence of side effects. An evaluation by the National Cancer Institute is very helpful.<sup>430,431</sup> Because the risks associated with tamoxifen (endometrial cancer, stroke, pulmonary embolism, and deep vein thromboembolism) increase with age, balancing the risks and benefit indicates that tamoxifen is best for younger women with an elevated risk of breast cancer (an increased relative risk of approximately 1.7). A similar conclusion was reached by a working group of the American Society of Clinical Oncology.<sup>432</sup> This means that only a relatively small number of women qualify, about 5% of American white women and 0.6% of black women.<sup>430</sup>

There is one lingering concern. There has been a slight increase in estrogen receptor–negative cancers in the follow-up period after treatment in all of the prevention trials. It is uncertain if this is related to tamoxifen exposure; however, in the trials assessing tamoxifen treatment of breast cancers, survival and recurrence rates worsened with longer therapy, probably due to the emergence of tamoxifen-resistant tumors.

In conclusion, tamoxifen exposure for 5–8 years is associated with about a 30–50%

reduction in estrogen receptor–positive breast cancers for at least 15 years after the treatment ends. An estimate of the absolute impact puts this in better perspective. The absolute reduction in cumulative overall incidence of breast cancer after 5 years is estimated to about 1.1% and after 10 years 1.7%. This small impact, combined with the serious side effects, has made tamoxifen treatment an unattractive option.

## Raloxifene

The MORE trial, the Multiple Outcomes of Raloxifene Evaluation trial, was a randomized, double-blind, multicenter clinical study of postmenopausal women with osteoporosis that reported a 72% reduction in estrogen receptor–positive invasive breast cancer in the treatment group after 4 years compared with placebo.<sup>433</sup> The CORE trial, the Continuing Outcomes Relevant to Evista trial, was designed to measure the impact of 4 additional years of raloxifene (60 mg/day), to begin during the fourth year of the MORE trial.<sup>434</sup> Of the 7,705 participants initially randomized in the MORE trial, 3,510 women elected to continue raloxifene treatment (2,336 completed the CORE trial) and 1,703 continued on placebo (1,106 completed the trial). During the 4-year CORE study, raloxifene treatment was associated with a 66% (HR = 0.34, CI = 0.18–0.66) reduction of estrogen receptor–positive invasive breast cancers in the treated group. There was no difference in estrogen receptor–negative tumors. Over the entire 8-year period, the reduction in estrogen receptor–positive cancers reached 76%. In the 8-year period, there was no difference in the number of deaths in the two groups.

The Study of Tamoxifen and Raloxifene (STAR) trial enrolled 19,747 women at increased risk of breast cancer who were randomized to treatment with either raloxifene, 60 mg daily, or tamoxifen, 20 mg daily, in more than 500 centers in the United States, Canada, and Puerto Rico.<sup>435</sup> The reported results after an average treatment period of almost 4 years were as follows<sup>435</sup> (Table 16.10).

### TABLE 16.10 STAR Trial Results

	<b>Raloxifene (9,745 Women)</b>	<b>Tamoxifen (9,726 Women)</b>
Invasive breast cancer	167 cases	163 cases
Breast cancer in situ	81	57
Deep venous thrombosis	65	87
Pulmonary embolus	35	54
Strokes	51	53
Fractures	96	104
Cataracts	313	394
Uterine cancer	23	36

The numbers of invasive breast cancers were identical in the two groups of women. It was estimated that these results were equivalent to about a 50% reduction (based on the previous results in the tamoxifen prevention trial),<sup>232,233</sup> but without a placebo arm, an accurate assessment was impossible. Thus, raloxifene appears to achieve the same reduction as tamoxifen in invasive breast cancers with a lesser increase in venous thrombosis and perhaps no increase in cataracts and uterine cancer. “Quality of life” was said to be the same for both drugs.

The fracture rates in the hip, wrist, and spine in the STAR trial were similar in the two groups. In the 7-year follow-up report of the U.S. Breast Cancer Prevention Trial with tamoxifen, osteoporotic fractures were reduced by 32%; compared with placebo, there were 11 fewer hip fractures, 13 fewer spinal fractures, and 9 fewer fractures of the radius.<sup>233</sup> However, even after 8 years of follow-up of the raloxifene trial involving women with osteoporosis, no effect of raloxifene has been evident on nonvertebral fractures.<sup>436</sup> A similar fracture rate in the STAR trial with the two treatments must

reflect the incidence of spinal fractures. Neither tamoxifen nor raloxifene can achieve the efficacy in preventing all fractures well-proven with both hormone therapy and bisphosphonate treatment. Raloxifene's lack of effect on the risk of hip fractures makes it less advantageous than tamoxifen for bone protection.

The rate of strokes was equivalent in the two treatment arms of the STAR trial. The rate of stroke was increased by 42% in the tamoxifen prevention trial (but this did not achieve statistical significance).<sup>233</sup> This is a serious risk for both drugs.

## Aromatase Inhibitors

Exemestane has been studied as a breast cancer prevention method in postmenopausal women at risk for breast cancer.<sup>437</sup> After 3 years of follow-up, this randomized control study has shown a 65% relative reduction in the annual incidence of invasive breast cancer, which is statistically significant, with no increased risk of adverse event including fracture or cardiovascular event. A randomized trial has also been completed with anastrozole.<sup>235</sup> After 5 years of follow-up, the hazard ratio is 0.47. A third study (STELLAR) has been proposed, comparing letrozole and raloxifene.<sup>438</sup> The MAP1 randomized trial evaluated the effect of letrozole treatment on breast density; no effect on breast density was observed after 1 year of treatment.<sup>439</sup> The French Onco-03/LIBER trial is assessing the use of letrozole in BRCA mutation carriers.

## Summary

These results lead us to recommend tamoxifen prophylaxis (20 mg daily for 5 years) or raloxifene prophylaxis (60 mg daily for 5 years) for those women who are diagnosed with carcinoma in situ of the breast or who have atypical hyperplasia in a breast biopsy (especially if a positive family history of breast cancer is also present). For others who seek preventive treatment, we advise that the final answers are not in and that clinical trial results from long-term follow-up will be necessary before fully informed decision-making is possible. Women at very high risk for breast cancer who choose tamoxifen or raloxifene treatment deserve support and appropriate surveillance. Bisphosphonate treatment is recommended to prevent bone loss and gain the added benefit of a further reduction in breast cancer risk.

# Vasomotor Symptoms with Tamoxifen and Aromatase Inhibitors in Breast Cancer Survivors

The problem of hot flushing should not be underrated. Women have vasomotor symptoms on tamoxifen, raloxifene, and aromatase inhibitors, and those that already had flushing sometimes have worse flushing. Various treatments are available, discussed in [Chapter 17](#).

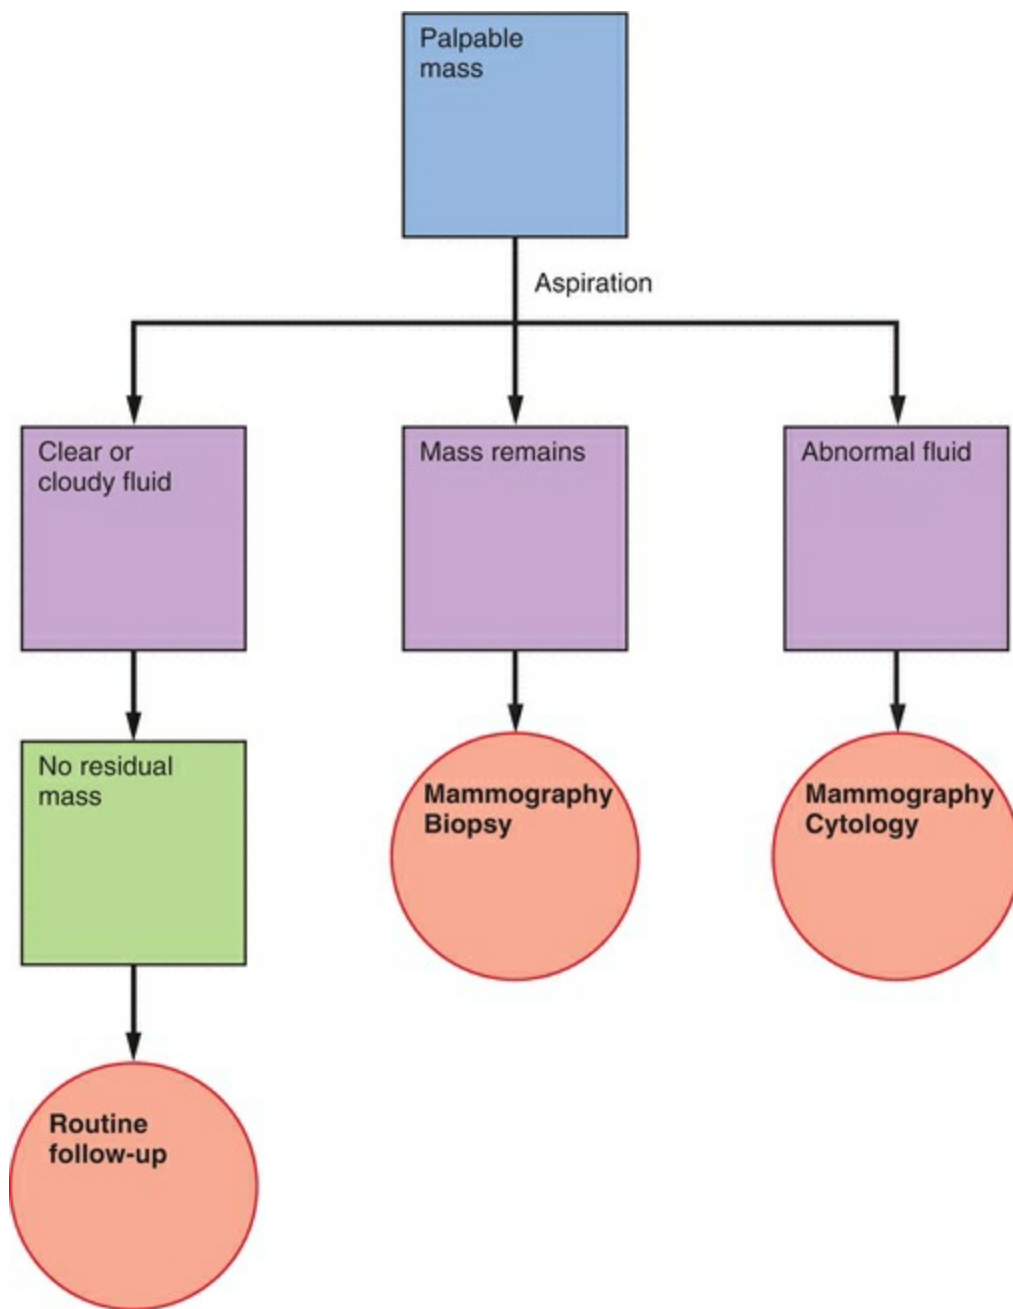

The SSRIs are the best choice after hormone therapy. It is worth trying to titer the dose down to its lowest effective level because of a low but bothersome incidence of decreased libido. In addition, clinical experience indicates that it is best to slowly titrate upward to the recommended dose and, likewise, to wean the patient slowly when discontinuing treatment. SSRIs are effective for flushing secondary to both tamoxifen and hypoestrogenemia, and the efficacy is similar in women with and without breast cancer.<sup>440</sup> An added advantage of the SSRIs is the fact that the clinical studies have also reported improvements in depression, anxiety, and sleep.

There is a concern that is of potential clinical importance. Tamoxifen is converted to an active metabolite by enzymes that are inhibited by SSRIs. Paroxetine coadministration decreases plasma concentrations of the active metabolite.<sup>441,442</sup> A lesser effect is associated with fluoxetine and sertraline. In a retrospective cohort study, only paroxetine use during tamoxifen therapy was associated with an increased risk of death due to breast cancer.<sup>443</sup> **Paroxetine, fluoxetine, and sertraline are best avoided in women being treated with tamoxifen.**

# NEEDLE ASPIRATION

---

Needle aspiration of breast lumps can be part of the practice of everyone who cares for women.<sup>444</sup> The technique is easy. A small infiltrate of lidocaine is placed in the skin (many clinicians believe that local anesthesia is unnecessary). Holding the lesion between thumb and index fingers with one hand, the other hand passes a 22-gauge needle attached to a 3-finger control syringe into the lesion. Aspiration will reveal the presence of cystic fluid from a cyst. If the mass is solid, the needle should be passed at least 2–4 times (even more if nothing is being obtained) back and forth through the lesion with continuous suction on the syringe. Air is forcibly ejected through the needle onto a cytology slide for smearing and fixing. The usual Pap smear fixative can be used (**Figure 16.9**). The procedure is very cost-effective. When aspiration yields clear or cloudy, green-gray, or yellow fluid and the mass disappears, the procedure is both diagnostic and therapeutic. Fluid of any other nature requires cytologic assessment.<sup>445</sup> Failure to obtain material for cytologic evaluation or the persistence of a mass requires biopsy. The mass should not have returned at the follow-up examination 1 month after the aspiration. Locally, recurrent cysts should be surgically removed for histologic diagnosis.

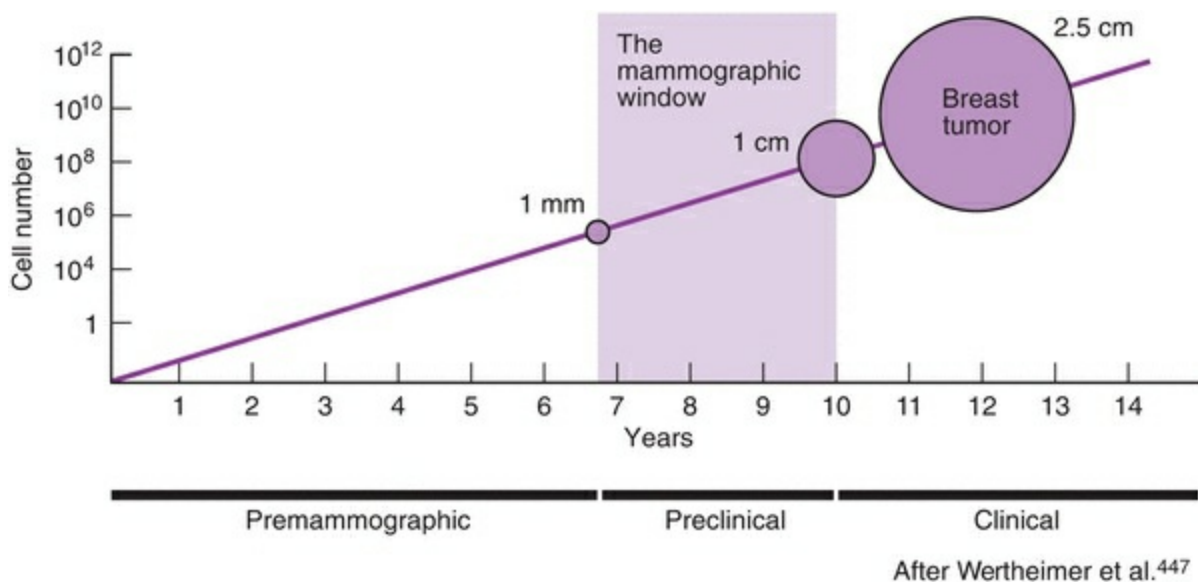

**FIGURE 16.9**

# SCREENING MAMMOGRAPHY

Mammography is a means of detecting a nonpalpable cancer. Technical advancements have significantly improved the mammographic image and reduced the radiation dose.<sup>446</sup> The doubling time of breast cancer is very variable, but in general, a tumor doubles in size every 100 days. Thus, it takes a single malignant cell approximately 10 years to grow to a clinically detectable 1-cm mass, but by this time, a tumor of 1 cm has already progressed through 30 of the 40 doublings in size, which is estimated to be associated with fatal disease.<sup>447</sup> Furthermore, the average size at which a tumor is detected has been (prior to mammography) 2.5 cm, a size that has a 50% incidence of lymph node involvement. Studies of breast self-examination have been disappointing in their failure to demonstrate an impact on breast cancer stage of disease and mortality.<sup>448</sup> To decrease the mortality from breast cancer, we must utilize a technique to find the tumors when they are smaller (**Figure 16.10**).

**FIGURE 16.10**

Mammography is the only method that detects clustered microcalcifications. These calcifications are less than 1 mm in diameter and are frequently associated with malignant lesions. More than five calcifications in a cluster are associated with cancer 25% of the time and require biopsy. Besides microcalcifications, the following mammographic findings usually require surgical evaluation: the appearance of a mass, calcifications associated with a mass, an area of distortion or asymmetrical density, and a stellate lesion. A pattern of dysplasia on the mammogram carries with it an increased risk (2.0–3.5 times normal) of breast cancer.

Mammography has a false-negative rate of 5–10%. This means that some masses are palpable but not visible. Mammography cannot and should not replace examination by patient and clinician. Breast examinations by clinicians do detect cancers that are missed by mammography.<sup>449</sup> Cancer commonly presents as a solitary, solid, painless (only 10% of cancers are painful), hard, unilateral, irregular nonmobile mass. A mass requires biopsy regardless of the mammographic picture.

# The Effectiveness of Mammography

Mammography reduces breast cancer mortality. The clinical trial results indicate increased survival with tumors detected by screening mammography, and in addition, early detection increases the options for treatment. About a 30% reduction in mortality can be expected with screening mammography of asymptomatic women over age 50.<sup>450,451</sup>

The U.S. Preventive Services Task Force recommends against routine screening mammography in women aged 40–49 and for extending the screening interval for women aged 50–74 to every 2 years.<sup>452</sup> The task force further recommends the discontinuation of breast self examinations. The recommendations of the U.S. Preventive Services Task Force represent the consensus of a panel of clinicians, academicians, and epidemiologists after a systematic review of the literature. The various task forces are often very conservative, refusing to make clinical judgments when evidence is deemed insufficient and focusing on a collective impact that includes not only clinical outcome but cost as well. We disagree with the task force recommendation on screening mammography for the following reasons.

About 20% of breast cancers occur in women 40–49, accounting for approximately 9% of all deaths due to breast cancer.<sup>128</sup> The American Breast Cancer Detection Demonstration Project demonstrated that screening was just as effective for women in their 40s as in women over their 50s.<sup>453</sup> This program that was organized by the American Cancer Society and the National Cancer Institute began operating in 1973 in 28 locations throughout the United States, enrolling more than 280,000 women. Despite the fact that this was not an organized research study with a control group, the massive database permits many valuable conclusions. From 1977 to 1982, similar high survival rates (87%) for women in their 40s compared with women in their 50s verify that screening was just as effective in the younger women. A 5-year survival rate for patients under 50 with breast cancers detected by examination was 77% compared to 95% in those patients with breast cancers detected by mammography.<sup>454</sup> In a randomized trial in Gothenburg, Sweden, women ages 39–49 undergoing mammographic screening every 18 months had a 45% reduction in breast cancer mortality in an early report and a 31% reduction after 13 years of follow-up.<sup>455,456</sup> Meta-analyses of randomized clinical trials concluded that in women aged 40–49 offered mammography screening, there was about a 20% reduction in breast cancer mortality.<sup>451,457,458</sup>

It takes longer for a significant difference in mortality to appear in 40–49-year-old women compared with women over age 50. There are two explanations. One is that tumors grow faster in younger women, and the other is the greater difficulty in achieving accurate mammography because of the denser, more glandular breasts in younger

women compared to the more fatty breasts in older women. Because the breast density changes gradually, rapid tumor growth must be the more critical factor.

Once detected by mammography, the stage of disease and survival expectations are the same in comparing women aged 40–49 with women over age 50.<sup>459</sup> However, cancers that are detected between screenings have lower survival rates (at all ages). Therefore, another reason that it has been difficult to demonstrate an impact of screening in the age group 40–49 is that because of less than annual screening, more of the cancers are detected late (between screenings). This in turn reflects the faster tumor growth in younger women.<sup>460</sup> Because the randomized clinical trials have screened younger women at 2-year or longer intervals, it is not surprising that screening has been less effective for these faster growing tumors. It is logical that women aged 40–49 should have annual screening mammography.<sup>461,462</sup> A randomized trial in the United Kingdom of annual mammographic screening beginning at age 40 indicated a 24% reduction in breast cancer mortality in the screened women.<sup>463</sup>

There are problems to be anticipated with extensive mammography screening. Small nonpalpable lesions have less than a 5% chance of being malignant, and overall only about 20–30% of biopsy specimens contain carcinoma. About 10% of mammograms require additional evaluation. That means there will be a large number of biopsies and mammograms performed (including the treatment of clinically irrelevant lesions), which involves costs to the health care system and cost to the individual in terms of stress and anxiety. Nevertheless, mammography is the most potent weapon we possess in the battle against breast cancer. Mammography not only lowers mortality, but it also decreases morbidity because less radical surgery is necessary for smaller lesions. Most importantly, the number of unnecessary surgical procedures can be minimized by combining physical examination and mammography with needle aspiration.<sup>464</sup> With the so-called triple approach (examination, mammography and possibly ultrasonography in young women, and needle aspiration), the detection of a malignancy with at least one of the three diagnostic tests is very reliable; open biopsy can be avoided.<sup>465,466,467</sup>

It is appropriate to be concerned over the increased cost of annual screening. However, analysis of the increased cost, taking into account the greater efficacy of capturing early tumors comparing annual to biannual screening, reveals that the overall benefit is worthwhile and compares favorably to the cost and benefits of Pap smear screening for cervical cancer.<sup>468,469</sup>

There is a special problem with elderly women. Old women are less likely to be screened with mammography, probably due to both patient misconceptions and erroneous clinician beliefs. Mammography reduces mortality and is cost-effective over age 65.<sup>470</sup> Decision analysis of available data predicts a major benefit for elderly

women, and a retrospective study indicated that screening mammography in women over age 74 is as beneficial as it is in younger women.<sup>471,472</sup> Older women need to be reminded that risk continues to increase with increasing age.

# Digital Mammography

Digital mammography replaces the screen and x-ray film with a detection system that converts x-ray photons to electric charge that is then converted to a digital image. This method performs better in women with dense breasts, accounting for the results in a randomized trial in which digital and film screening yielded equal results in women over age 50, but digital mammography was superior in younger women.<sup>473,474</sup> Digital mammography has some important advantages: easier access to images, more efficient storage of images, the use of computer-aided reading, and rapid data transfer between clinical sites. Studies have also indicated lower recall rates because of better image quality and fewer artifacts.

# Adding Ultrasound to Mammography

A prospective, multicenter, randomized trial was designed to validate the performance of screening ultrasound in conjunction with mammography in women with dense breasts and at high risk for breast cancer.<sup>475</sup> The study is known as ACRIN, the American College of Radiology Imaging Network, 6666 trial. Each patient underwent mammography and ultrasound in a randomized sequence. Forty cases of cancer were diagnosed, 12 on ultrasound alone, 12 on mammography alone, 8 suspicious with both techniques, and 8 with negative exams. Adding ultrasound yielded an additional 4.2 cancers per 1,000 high-risk women. The false-positive rate for mammography alone was 4.4%, for ultrasound alone 8.1%, and for combined mammography plus ultrasound 10.4%. Thus, adding ultrasound to mammography screening in high-risk women with dense breasts improved the sensitivity of screening but increased the rate of false-positive examinations. Breast cancer mortality was not an endpoint in this trial, but the fact that the cancers detected by ultrasound are usually asymptomatic, node-negative, and not detected by mammography should yield a reduction in mortality.

Ultrasound screening can detect cancers not seen on mammography, and its performance is not affected by dense breast tissue. Adding ultrasound to a screening program seems straightforward, even though its impact on mortality reduction has not been measured in a large trial. In the single-center studies of screening ultrasound that have been published, cancers were found only by ultrasound, and most were small, early-stage tumors. An Italian multicenter study reported that 29 cancers were found by ultrasound in 6,449 women with dense breasts and negative mammograms.<sup>476</sup> Nevertheless, a majority of facilities do not offer screening ultrasound because of a lack of qualified personnel and standardized protocols.

The problem with all screening methods is a substantial rate of false positives. In the American study, 91.4% of suspicious ultrasound findings were benign.<sup>475</sup> The positive predictive value for ultrasound was only 8.6%, but the value for mammography was only 14.7%. Remember that ultrasound tends to find earlier tumors. The crucial question is how many false positives are worth the gain in additional cancer diagnoses. In the American study, the gain was an additional 29% (the number of cancers detected only by ultrasound). In women with elevated risks or dense breasts, this seems worthwhile. **Women at high risk probably have a greater fear of diagnosing breast cancer late than of a false positive.**

# Adding MRI to Mammography

MRI is the most sensitive technique, but it is very expensive, requires the intravenous injection of contrast, and isn't always tolerated by patients. Ultrasound has the advantage of being less expensive, easily tolerated, and widely available. Thus, the combination of ultrasound and mammography seems best for women of intermediate risk. Ultrasound has a disadvantage of not detecting ductal carcinoma in situ, which is detected by mammography and MRI. **Combining MRI with mammography yields a very high sensitivity, and this is now recommended for women at very high risk for breast cancer, especially younger women.**<sup>477,478,479</sup>

MRI is more sensitive in diagnosing breast ductal carcinoma in situ.<sup>480</sup> Ductal carcinoma in situ is a precursor of invasive breast cancer, with progression occurring more often and more rapidly with higher-grade in situ lesions, and the subsequent invasive disease is of a higher grade with a poorer prognosis. Diagnosis of higher-grade ductal carcinoma in situ is, therefore, highly desirable. Mammography has led to an increase in the diagnosis of ductal carcinoma in situ from 2% of breast cancers in 1980 to 20% today. Earlier studies concluded that MRI was no better and even worse than mammography in diagnosing ductal carcinoma in situ. However, it has been learned that diagnostic criteria differ with the two techniques, incorporating not only morphology but enhancement kinetics with contrast during MRI. MRI detects lesions without microcalcifications (a different group of tumors), whereas mammography detects cases of ductal carcinoma in situ that have microcalcifications caused by necrosis.

Both film-screen mammography and digital mammography have limited sensitivity for diagnosing ductal carcinoma in situ (determined by the size of microcalcifications). An important message is that MRI is better for the detection of the higher-grade ductal carcinoma in situ associated with worse prognosis. The reason for this is the contribution of contrast enhancement. Tissues with higher-grade lesions will have greater capillary permeability and an increase in microvasculature, accounting for more contrast enhancement.

The availability of MRI in general population screening is currently limited by an insufficient number of radiologists with the required level of expertise, but there are an increasing number of specialty centers with the expertise and technology to perform accurate MRIs. The full use of MRI to detect breast cancer at its earliest stage awaits the results of a large multicenter trial that is obviously now indicated.

The final protocol for the best screening use of the three modalities, mammography, ultrasound, and MRI, will also require consideration of cost. The total cost is a complex summary of the technology, the time consumed, the increase in patient anxiety and

discomfort, and the expense of additional testing because of false positives. Nevertheless, the evidence now seems sufficient to individualize decision-making and to recommend more than the single technique of mammography for high-risk patients (defined as a combination of factors that produces a threefold increase in risk), especially in women with dense breasts. Thus far, over 90% of cancers detected only on ultrasound were in women with dense breasts.

Every woman should be regarded as at risk. Health care professionals who interact with women have the opportunity to initiate an aggressive program of preventive health care. The major deterrent to patient use of screening is the absence of a strong clinician recommendation. We urge you to follow these guidelines:

# SCREENING FOR BREAST CANCER

---

- **Women ages 25–39 should be offered a clinical breast examination every 1–3 years, and women ages 40 and over should be offered clinical breast examination annually.**
- **Women with a first-degree relative with premenopausal breast cancer should begin annual mammography 5 years before the age of the relative when diagnosed.**
- **Annual mammography should be performed in all women over age 39.**
- **Digital mammography is preferred for women with dense breasts.**
- **It is advisable to add ultrasonography to mammography for hormone users who develop dense breasts and density that persists despite a short period without hormone therapy.**
- **MRI should be added to mammography for women at very high risk for breast cancer (defined as a combination of factors that produces a threefold increase in risk), especially younger women. For an individual identified to be at high risk, especially women with inherited mutations, clinical breast examination is recommended every 6 months and annual mammography and MRI beginning at age 25. Clinical evaluation every 6 months is appropriate because the BRCA1-related tumors have been demonstrated to be faster growing tumors. Support should be provided for those women who choose prophylactic mastectomy. Risk-reducing salpingo-oophorectomy is recommended at age 35 or when childbearing is complete for patients carrying BRCA1 mutations, and by age 40 in BRCA2 carriers.**

# Menopause Transition and Menopause Hormone Therapy

# AN OVERVIEW

---

Throughout recorded history, multiple physical and mental conditions have been attributed to the menopause. Although medical writers often wrote colorfully in the past, unfortunately they were also less than accurate, unencumbered by scientific information and data.

A good example of the stereotypical, inaccurate thinking promulgated over the years is the following written in 1887<sup>1</sup>:

The ovaries, after long years of service, have not the ability of retiring in graceful old age, but become irritated, transmit their irritation to the abdominal ganglia, which in turn transmit the irritation to the brain, producing disturbances in the cerebral tissue exhibiting themselves in extreme nervousness or in an outburst of actual insanity.

The belief that behavioral disturbances are related to manifestations of the female reproductive system is an ancient one that has persisted to contemporary times. This belief regarding the menopause is not totally illogical; there is reason to associate the middle years of life with negative experiences. The events that come to mind are impressive: onset of a major illness or disability (and even death) in a spouse, relative, or friend; retirement from employment; financial insecurity; the need to provide care for very old parents and relatives; and separation from children. Thus, it is not surprising that a middle-aged event, the menopause, shares in this negative outlook.

The scientific study of all aspects of menstruation has been hampered by the overpowering influence of social and cultural beliefs and traditions. Problems arising from life events have often been erroneously attributed to the menopause. But data, especially more reliable community-based longitudinal data, now establish that the increase in most symptoms and problems in middle-aged women reflects social and personal circumstances, not the endocrine events of the menopause.<sup>2,3,4,5,6,7,8,9,10,11</sup> The variability in menopausal reactions makes the cross-sectional study design particularly unsuitable. Longitudinal studies are better for documenting what is normal and the variations around normal.

The Massachusetts Women's Health Study, a large and comprehensive prospective, longitudinal study of middle-aged women, provides a powerful argument that the menopause is not and should not be viewed as a negative experience by the vast majority of women.<sup>3,12</sup> The cessation of menses was perceived by these women (as have the women in other longitudinal studies) as having almost no impact on subsequent physical and mental health. This was reflected by women expressing either positive or

neutral feelings about menopause. An exception was the group of women who experienced surgical menopause, but there is good reason to believe that the reasons for the surgical procedure were more important than the cessation of menses.

Changes in menstrual function are not symbols of some ominous “change.” There are good physiologic reasons for changing menstrual function, and understanding the physiology will do much to reinforce a healthy, normal attitude. Attitude and expectations about the menopause are very important. Women who have been frequent users of health services and who expect to have difficulty do experience greater symptoms and higher levels of depression.<sup>4,8,9</sup> The symptoms that women report are related to many variables within their lives, and the hormonal change at menopause cannot be held responsible for the common psychosocial and lifestyle problems we all experience. It is important to stress the normalcy of this physiologic event. Menopausal women do not suffer from a disease (specifically a hormone deficiency disease), and postmenopausal hormone therapy should be viewed as specific treatment for symptoms in the short term and preventive pharmacology in the long term.

It can be further argued that physicians have had a biased (negative) point of view, because the majority of women, being healthy and happy, do not seek contact with physicians.<sup>13,14</sup> It is vital, therefore, that clinicians not only are familiar with the facts relative to the menopause but also have an appropriate attitude and philosophy regarding this period of life. Medical intervention at this point of life should be regarded as an opportunity to provide and reinforce a program of preventive health care. The issues of preventive health care for women are familiar ones. They include family planning, cessation of smoking, control of body weight and alcohol consumption, prevention of cardiovascular disease and osteoporosis, maintenance of mental well-being (including sexuality), cancer screening, and treatment of urologic problems.

# GROWTH OF THE OLDER POPULATION

We are experiencing a relatively new phenomenon: we can expect to become old. We are on the verge of becoming a rectangular society. This is a society in which nearly all individuals survive to advanced age. In 1,000 b.c., life expectancy was only 18 years. By 100 b.c., the time of Julius Caesar, it had reached 25 years. In 1900, in the United States, life expectancy still had reached only 49 years (**Figure 17.1**). In 2005, the average life expectancy was 80.7 years for women and 75.4 for men.<sup>15</sup> Today, once you reach 65, if you are a man, you can expect to reach 83 and if you are a woman, age 85.<sup>16</sup> We can anticipate that eventually, about two-thirds of the population will survive to 85 or more, and more than 90% will live past age 65—this would be the nearly perfect rectangular society (**Figure 17.2**).<sup>17,18</sup> Currently, Sweden and Switzerland are closest to this demographic composition.

After **Cope E.** Physical changes associated with the post-menopausal years, In: Campbell S, ed. *The Management of the Menopause & Post-Menopausal Years*, University Park Press, Baltimore, 1976, p. 33.

After Fries JF, Crapo LM, Vitality and Aging, W.H. Freeman and Co., San Francisco, 1981.<sup>29</sup>

A good general definition of elderly is 65 and older, although it is not until age 75 that a significant proportion of older people show the characteristic decline and problems. Today, the elderly population is the largest contributor to illness and human need in the United States. There are more old people (with their greater needs) than ever before.<sup>19</sup> In 1900, there were approximately 3 million Americans 65 and older (about 4% of the total population), and in 2000, there were 35 million (about 12% of the total population). By 2030, the elderly population in the United States will reach about 70 million, and about one in five Americans will be elderly.<sup>19</sup> The world's elderly population will be more than double from 1998 to 2025, rising from 264 million in 2009 to 416 million in 2050.<sup>20</sup> Population aging must be added to population growth as very important social problems.

Two modern phenomena have influenced the rate of change. The first was the post-World War II baby boom (1946–1964) that temporarily postponed the aging of the population, but now is causing a faster aging of the general population. The second major influence has been the decline in old-age mortality. Our success in postponing death has increased the upper segment of the demographic contour (**Figure 17.3**). By 2050, the current developed nations will be rectangular societies. China, by 2050, will contain more people over age 65 than the number of people of all ages currently living in the United States (**Table 17.1**).

From McDevitt TM, Stanecki KA, Way PO , Report WP/98, World Population Profile: 1998, Washington, DC: US Census Bureau; 1999.<sup>21</sup>

This is a worldwide development, not limited to affluent societies.<sup>21</sup> The population of the earth will continue to grow until the year 2100 or 2150, when it is expected to stabilize at approximately 11 billion. After 2020, all of this growth will occur in developing countries.<sup>20</sup> In 2000, the poorest countries (located in Africa and Asia) accounted for 87% of the world's population. In 1950, only 40% of people 60 and older lived in developing countries. By 2050, about 80% will live in those countries, as fertility in the developing regions is expected to drop from 2.73 children per woman in 2005–2010 to 2.05 by 2050.<sup>20</sup>

In aging populations, a gender differential in survival is recognized. In 1900, men over age 65 in the United States outnumbered women by 102 to 100. Now, there are only 70 men for every 100 women over age 65.<sup>22</sup> By age 85, only 39 men are alive for every 100 women. Nearly 90% of white American women can expect to live to age 70. Vital statistics data indicate that this gender difference is similar in both the black and white populations in the United States (**Figure 17.4**).<sup>23</sup> Approximately 55% of girls, but only 35% of boys, live long enough to celebrate their 85th birthday.<sup>24</sup> One in 5,600 individuals can expect to live to be 100.<sup>22</sup>

**FIGURE 17.4**

The 10 leading causes of death in the United States in 2016 were as follows<sup>16</sup>:

- 1. Heart disease**
- 2. Cancer**
- 3. Unintentional injuries**
- 4. Chronic lower respiratory diseases**
- 5. Stroke**
- 6. Alzheimer disease**
- 7. Diabetes mellitus**
- 8. Influenza and pneumonia**
- 9. Kidney diseases**
- 10. Suicides**

Men and women reach old age with different prospects for older age, a sex differential that (it can be argued) is due in significant part to the sex hormone–induced differences in the cholesterol-lipoprotein profile and other cardiovascular factors and thus the greater incidence of atherosclerosis and earlier death in men. From a public health point

of view, the greatest impact on the sex differential in mortality would be gained by concentrating on lifestyle changes designed to diminish atherosclerosis: low-cholesterol diet, no smoking, optimal body weight, and active exercise. The death rate is higher for men at all ages, and therefore women are overrepresented in aging populations (Table 17.2). Coronary heart disease (CHD) accounts for 40% of the mortality difference between men and women. Another one-third is from lung cancer, emphysema, cirrhosis, accidents, and suicides. It is interesting to note that in our society, the mortality difference between men and women is largely a difference in lifestyle. Smoking, drinking, coronary-prone behavior, and accidents account for most of the higher male mortality rate over age 65. It has been estimated that perhaps two-thirds of the difference have been due to cigarettes alone. But we should emphasize that this is due to a greater prevalence of smoking in men. Women whose smoking patterns are similar to those of men have a similar increased risk of morbidity and mortality.<sup>25</sup>

## **TABLE 17.2 The Older US Female Population**

Age	1990	2000	2010	2020
55–64	10.8 mill. (8.6%)	12.1 mill. (9.0%)	17.1 mill. (12.1%)	19.3 mill. (12.9%)
65–74	10.1 (8.1%)	9.8 (7.3%)	11.0 (7.8%)	15.6 (10.4%)
≥75	7.8 (6.2%)	9.3 (7.0%)	9.8 (6.9%)	11.0 (7.3%)
<b>Total</b>	28.7	31.2	37.9	45.9

From McDevitt TM, Stanecki KA, Way PO, Report WP/98, World Population Profile: 1998, Washington, DC: US Census Bureau; 1999.<sup>21</sup>

The mortality sex difference has been decreasing since 1979. The U.S. Census Bureau projects that the difference in life expectancy between men and women will increase until the year 2050 and then level off. In 2050, life expectancy for women will be 82 years and for men, 76.7 years.<sup>26</sup> There will be 33.4 million women 65 years and older, compared with 22.1 million men.

In addition to the growing numbers of elderly people, the older population itself is getting older. For example, in 1984, the 65–74 age group in the United States was over 7 times larger than in 1900, but the 75–84 group was 11 times larger, and the 85 and older group was 21 times larger. In the 1990s, the population 85 years and older increased by 38%.<sup>22</sup> The most rapid increase is expected between 2010 and 2030 when the post–World War II baby boom generation will be age 65 and over. In the next century, the only age groups in the United States expected to experience significant growth will be those past age 55. In this older age group, women will outnumber men by 2.6 to 1. By the year 2040, in the United States, there will be 8 million to 13 million people 85 years of age or older; the estimate varies according to pessimistic to optimistic projections regarding disease prevention and treatment.

Unmarried women will be an increasing proportion of the elderly. Elderly women are more likely to be widowed (59%) than elderly men (22%).<sup>27</sup> Half of men 85 and older live with their wives, but only 10% of elderly women live with their husbands.<sup>28</sup> Because the unmarried tend to be more disadvantaged, there will be a need for more

services for this segment of the elderly population. Older unmarried people are more vulnerable, demonstrating higher mortality rates and lower life satisfaction.

# The Rectangularization of Life

The life span is the biologic limit to life, the maximal obtainable age by a member of a species. The general impression is that the human life span is increasing. Actually, life span is fixed, and it is a biologic constant for each species.<sup>29</sup> In fact, differences in species' life spans argue in favor of a species-specific genetic basis for longevity. If life span were not fixed, it would mean an unlimited increase of our elderly. But a correct analysis of survival reveals that death converges at the same maximal age; what has changed is life expectancy—the number of years of life expected from birth. Life expectancy cannot exceed the life span, but it can closely approximate it. Thus, the number of old people will eventually hit a fixed limit, but the percentage of a typical life spent in the older years will increase (**Figure 17.2**).

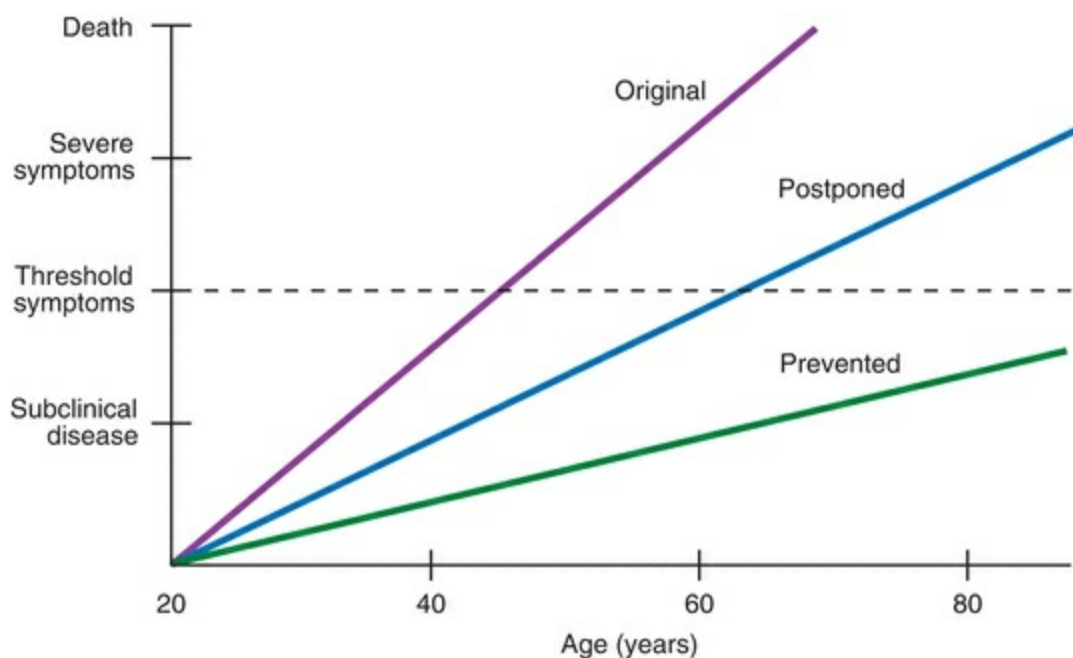

Our society has almost eliminated premature death. Diseases of the heart and the circulation, and cancers are now the leading causes of death. The reason for this is not an increase or an epidemic; it is a result of our success in virtually eliminating infectious diseases. Now, the major determinant is chronic disease, affected by genetics, lifestyle, the environment, and aging itself. Even if cancer, diabetes, and all circulatory diseases were totally eliminated, life expectancy would not exceed 90 years.<sup>17</sup>

J.F. Fries described three eras in health and disease.<sup>30</sup> The first era existed until sometime in the early 1900s and was characterized by acute infectious diseases. The second era, highlighted by cardiovascular diseases and cancer, is now beginning to fade into the third era, marked by problems of advancing age (fading eyesight and hearing, impaired memory and cognitive function, decreased strength and reserve). Much of our medical approach is still based on the first era (find the disease and cure it), and now we have conditions that require a combination of medical, psychological, and social approaches. Our focus has been on age-dependent, fatal chronic diseases. The new challenge is with the nonfatal, age-dependent conditions, such as Alzheimer disease, osteoarthritis, osteoporosis, obesity, and incontinence. It can be argued that health programs in the future should be evaluated by their impact on years free of disability, rather than on mortality.

# The Concept of the Compression of Morbidity

Chronic illnesses are incremental in nature. The best health strategy is to change the slope, the rate at which illness develops, thus postponing the clinical illness and, if it is postponed long enough, effectively preventing it. There has been a profound change in public consciousness toward disease. Disease is increasingly seen as something not necessarily best treated by medication or surgery but by prevention.

Preventing illness was expressed by J.F. Fries as the **compression of morbidity**.<sup>29,31</sup> We would live relatively healthy lives and compress our illnesses into a short period of time just before death. Is this change really possible? A good affirmative example is the decrease in atherosclerosis in the United States. Reasons include changes in the use of saturated fat, more effective detection and treatment of hypertension, increased exercise, and decreased smoking (**Figure 17.5**).

After Fries JF, Crapo LM, Vitality and Aging, W.H. Freeman and Co., San Francisco, 1981.<sup>29</sup>

Physician smokers have declined from a high of 79% to a small minority.<sup>32</sup> It is interesting, and amusing, to note that the greatest decrease has been among pulmonary surgeons, not surprising, while the least decrease has been among proctologists. From the mid-1970s to the early 1990s, smoking among physicians in the United States declined from 18.8% to 3.3%. Unfortunately, that still amounted to approximately 18,000 physicians who smoke. Approximately 35% of people in the United States who have not obtained a high school diploma are smokers, but only 12% of those with higher

education are smoking and only 5.7% of those with graduate degrees. Currently, approximately 17.5% of men and 13.5% of women are smokers.<sup>16</sup> Cigarette smoking among high school students peaked in 1997 and then declined to the current level of 15.5%.<sup>16</sup> In addition, 14% of high school students smoke cigars and 8% use chewing tobacco. The use of chewing tobacco, pipe smoking, and cigars contributes significantly to morbidity and mortality. Tobacco, therefore, continues to be the single most preventable cause of premature illness and death in the United States. It is important to note that smoking has a greater adverse effect on women compared with men.<sup>33</sup> Women who smoke only 1–4 cigarettes per day have a 2.5-fold increased risk of fatal CHD.<sup>34</sup>

Quitting smoking after decades of smoking is beneficial, and the beneficial effects are seen as early as 1 month after quitting.<sup>35</sup> In the Nurses' Health Study, 61% of the excess risk of CHD mortality and 42% of stroke mortality were eliminated within 5 years after quitting smoking.<sup>36</sup> The improvement in respiratory disease mortality is slower, and a small increased risk of lung cancer mortality persists even after 30 years. However, by 20 years after cessation, all the excess risk of vascular mortality and death due to respiratory diseases other than lung cancer reached the level of a never smoker. Even older patients who already have coronary artery disease have improved survival if they quit smoking.<sup>37</sup> No matter how old you are, if you continue to smoke, you have an increased relative risk of death. But no matter how old you are, if you quit smoking, your risk of death decreases. Nevertheless, the risk of lung cancer remains elevated even in long-term ex-smokers.<sup>38</sup>

Since 1970, the death rate from CHD has declined approximately 50% in the United States. Between 1973 and 1987, in the United States, cardiovascular mortality declined in nearly every age group. In the combined age groups up to 54 years, cardiovascular mortality decreased to 42% and in people 55–84 years old, 33%.<sup>33</sup> Despite our progress, we must continue to exert preventive efforts on the risk factors associated with cardiovascular disease, especially obesity, hypertension, and lack of physical activity.

The effort to improve the quality of life has an important value to society; it will decrease the average number of years that people are disabled, which is a major health and social problem of society. Most significantly, this is a major financial challenge for health care systems and social programs. With evolution toward a rectangular society, the ratio of beneficiaries to taxpayers grows rapidly, jeopardizing the financial support for health and social programs. Compression of morbidity is at least one attractive solution to this problem.

# MENOPAUSE AS AN OPPORTUNITY

---

Menopause is a normal phase of life, much like puberty; it should not be viewed as abnormal. For many women, it is a welcome change—no further menses or premenstrual syndrome (PMS) and no need for contraception/concern for conceiving. Clinicians who interact with women at the time of the menopause have a wonderful opportunity and, therefore, a significant obligation. Medical intervention at this point of life offers women years of benefit from preventive health care. This phase of life represents an opportunity that should be seized.

**While not underrating the importance of good health habits among the young, we would argue that the impact of teaching preventive care is more observable and more tangible at middle age. The prospects of limited mortality and the morbidity of chronic diseases are viewed with belief, understanding, and appreciation during these older years. The chance of illness is higher, but the impact of changes in lifestyle is greater.**

# Stages of Reproductive Aging: Reproductive Years to Perimenopause (Older Terminology) or Menopausal Transition (Newer Term) to Menopause

In 2001, the Stages of Reproductive Aging Workshop (STRAW) standardized the nomenclature for the stages of the menopausal transition.<sup>39</sup> Prior to this workshop, there was no accepted system for defining the stages of reproductive aging leading up to menopause. In 2010, at a follow-up workshop (“STRAW + 10”), the criterion was updated to reflect advances in changes in the hypothalamic-pituitary function occurring throughout reproductive aging.<sup>40</sup> The STRAW staging system divides female life span into three broad phases: reproductive phase, menopausal transition phase, and postmenopause phase. Each of the three phases is divided into stages based on information obtained through clinical (menstrual cycle pattern, symptoms) and investigative (serum levels of follicle-stimulating hormone [FSH] and antimüllerian hormone [AMH] and ultrasound-based ovarian antral follicle count [AFC]) data. The menopausal transition is a finite period of physiologic changes that eventually culminates in reproductive senescence. This phase of life can be associated with unique challenges that can have significant effects on population’s well-being and on quality of life.<sup>39</sup> A woman is said to have reached menopause if she has remained amenorrheic for a consecutive of 12-month interval and demonstrates biochemical evidence of hypergonadotropic (elevated FSH and luteinizing hormone [LH] levels) hypogonadism (low estradiol levels). The last or final menstrual period (FMP) is identified as stage “0” marking a watershed between reproductive and postreproductive periods of life. The reproductive phase itself is broken down into five stages (early [−5], peak [−4], and late [−3]). The menopause transition phase is broken down into two stages (early [−2] and late [−1]). The postmenopause phase is also divided into two stages (early [+1] and late [+2]).<sup>40</sup> **The FMP thus serves as the reference point for interpretation of the rest of the stages across the three specified phases of reproductive aging (Figure 17.6).**

Adapted and modified from Harlow SD, Gass M, Hall JE, Lobo R, Maki P, Rebar RW, Sherman S, Sluss PM, de Villiers TJ; STRAW + 10 Collaborative Group, Executive summary of the Stages of Reproductive Aging Workshop + 10: addressing the unfinished agenda of staging reproductive aging, *Climacteric* 15(2):105, 2012.<sup>40</sup>

## Late Reproductive Stage (STRAW Stage -3)

A decline in fecundability is apparent as the earliest hallmark of transition followed by a spectrum of clinically apparent phenomenon, such as changes in menstrual cycle pattern. As covert endocrinologic changes set in well before noticeable and clinically apparent features (such as changes in the menstrual cycle), STRAW +10 recommended that the late reproductive stage be divided into substages -3b and -3a. In stage -3b, the menstrual cycles are relatively unchanged, the early follicular phase serum levels of FSH are relatively low and in normal premenopausal range, whereas AMH and AFC (and likely inhibin B) are low.<sup>41</sup> In stage -3a, menstrual cycles become shorter and early follicular FSH increases, while AMH, AFC, and inhibin B are low.<sup>41</sup>

## Early Menopausal Transition (STRAW Stage -2)

This stage is characterized by increasing irregularity of the menstrual cycle length. This irregularity is defined as a recurrence of 7-day difference in cycle length over 10 cycles. This stage is also characterized by variable elevations in early follicular phase FSH levels, with persistently low AMH levels and low AFC.<sup>41</sup>

## Late Menopausal Transition (STRAW Stage -1)

This stage is characterized by missed menses with periods of amenorrhea lasting greater than or equal to 60 days. Menstrual cycles are increasingly irregular in length, with variability in reproductive hormonal levels and high incidence of anovulation. FSH levels are usually elevated in the menopausal range, although at times can be in the premenopausal range with concomitant high estradiol levels. An FSH level of greater than 25 IU/L is commonly seen in this late transition stage. This stage lasts 1–3 years and is when vasomotor symptoms such as hot flashes begin to occur.<sup>41</sup>

## **Early Postmenopause (STRAW Stage 1, Substages +1a, +1b, +1c)**

In the early postmenopause, FSH levels continue to rise, while estradiol levels continue to decline until 2 years after the FMP, after which these hormone levels stabilize. The substages +1a and +1b in early menopause last 1 year each and culminate once fluctuations in FSH levels stabilize. Stage +1a marks the completion of the 12-month interval required to define the FMP. This substage also marks the end of the perimenopause (i.e., the time near menopause, which starts at stage –2 and ends 12 months following the FMP).<sup>41</sup> Stage +1b includes the continued changes in levels of FSH and estradiol; vasomotor symptoms are most common in stage +1a and +1b. In stage +1c, the elevated FSH and low estradiol levels become the new normal. This substage lasts for up to 3–6 years. As such, the early postmenopause stage spans a total of 5–8 years.<sup>41</sup>

## **Late Postmenopause (Stage +2)**

At this stage, reproductive hormone levels are essentially plateaued and stable. While the burden of vasomotor symptoms eases off for many, physical symptoms attributable to lack of estrogen, such as vaginal dryness and urogenital symptoms, become more prominent at this stage. Interestingly, FSH levels may decline further with age, although more research is needed to confirm this observation.<sup>41</sup>

# THE MENOPAUSAL TRANSITION

---

There is only one marker, menstrual irregularity, that can be used to objectively define and establish what is called the menopausal transition. This irregularity will be perceived by patients as skipped menstrual periods or longer durations (about 40–60 days) between periods.<sup>42</sup> There is no universal pattern; each woman will perceive a change that is her own individual characteristic alteration.

The **menopause** is that point in time when permanent cessation of menstruation occurs following the loss of ovarian activity. Menopause is derived from the Greek words men (month) and pausis (cessation). **Climacteric**, an older, more general, and less precise term, indicates the period of time when a woman passes from the reproductive stage of life through the menopausal transition and the menopause to the postmenopausal years. Climacteric is from the Greek word for ladder. **Perimenopause** is the newer term that includes the years prior to the FMP during which menstrual cycles progress from a regular ovulatory and predictable pattern to irregular and increasingly anovulatory cycles to eventual cessation of menses.<sup>41</sup>

Menstrual cycle length is determined by the rate and quality of follicular growth and development, and it is normal for the cycle to vary in individual women. Informative data come from two seminal longitudinal studies (with very similar results): the study of Vollman of more than 30,000 cycles recorded by 650 women and the study of Treloar of more than 25,000 woman-years in a little over 2,700 women.<sup>43,44</sup> The earlier observations of Vollman and Treloar that documented a normal evolution in length and variation in menstrual cycles. were subsequently confirmed by Cole et al.<sup>45</sup> (**Figure 17.7**).

**FIGURE 17.7**

Following onset of menarche, there is approximately a 2- to 3-year period of relatively long menstrual cycles at first, and then, there is increasing regularity as cycles shorten to reach the usual reproductive age pattern. In the 40s, cycle length may begin to alter again. The highest incidence of anovulatory cycles is under age 20 and over age 40.<sup>46,47</sup> At age 25, over 40% of cycles are between 25 and 28 days in length; from 25 to 35, over 60% are between 25 and 28 days. The perfect 28-day cycle is indeed the most common mode, but it totaled only 12.4% of cycles described by Völlman whereby overall, approximately 15% of reproductive age cycles are 28 days in length. Only 0.5% of women experience a cycle less than 21 days long and only 0.9% a cycle greater than 35 days.<sup>48</sup> Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles.<sup>49</sup>

When women are in their 40s, anovulation becomes more prevalent, and prior to anovulation, menstrual cycle length increases, beginning 2–8 years before menopause.<sup>44</sup> Cycles greater than 40 days in length are quite prevalent in the year before menopause.<sup>50</sup> In an Australian longitudinal study, when cycle length exceeded 42 days, menopause predictably followed within 1 or 2 years.<sup>51</sup> This period of longer cycles commonly precedes menopause no matter the age when menses cease, whether menopause is early or late.<sup>52</sup> The duration of the follicular phase is the major determinant of cycle

length.<sup>53,54</sup> This menstrual cycle change prior to menopause is marked by elevated FSH levels and decreased levels of inhibin but normal levels of LH and slightly elevated levels of estradiol.<sup>55,56,57,58,59,60,61</sup> **Importantly, even irregular cycles with long intervals (>50–60 days) can be ovulatory, as many as 25%, and although fecundity is markedly reduced, late perimenopausal women remain at risk for unplanned pregnancy.**<sup>62</sup>

**In the average woman, a decline in fertility begins around age 37–38, and menopause follows approximately 13 years later (average age 51).** However, in epidemiologic studies, approximately 10% of women in the general population become menopausal by the age of 45,<sup>63,64</sup> while the exact mechanisms underlying spontaneous early menopause (before age 45) remain unclear, and are not generalizable, it is probable that some women are born with a smaller than normal ovarian follicular pool that gets functionally depleted at an earlier age. Menopause occurs when the number of remaining ovarian follicles falls below a critical threshold, about 1,000, regardless of age.

Contrary to older belief (based on a seminal report by Sherman et al. in 1976<sup>53</sup>), **estradiol levels do not gradually wane in the years before the menopause, but remain in the normal range, and even be slightly elevated, until about 1 year before follicular growth and development cease.** Sherman et al. conducted a small cross-sectional study wherein serum samples were collected over a single menstrual cycle from eight women, aged 46–56, for the study of reproductive hormones. More recent longitudinal studies of women as they pass through the menopausal transition reveal that estrogen levels do not begin a major decline until about a year before menopause (**Figure 17.8**).<sup>59,65,66</sup> Indeed, women experiencing the menopausal transition actually have higher overall estrogen levels, a response that is logically explained by an increased ovarian follicular reaction in response to the higher circulating FSH levels during this period.<sup>67</sup> Variability in estrogen levels is characteristic of the menopausal transition, with greater hormonal variability observed in menstrual cycles that display greater irregularity.<sup>68</sup>

**Reproductive Hormone Profile From Menopause Transition (or Perimenopause) Into Menopause**  
(mean circulating hormone levels)

**FIGURE 17.8**

As noted, most women experience a 2- to 8-year period of time prior to the FMP when the occurrence of anovulation becomes common.<sup>44</sup> During this time, ovarian follicles continue their rate of loss until eventually the reservoir is finally depleted.<sup>69,70</sup> In a study of human ovaries, the loss that began when the total number of follicles reached approximately 25,000, usually at age 37–38, correlated with a subtle but real increase in FSH and decrease in inhibin levels.<sup>71</sup> Aging-related decline in the quantity of ovarian follicles is directly related to the rise in FSH levels that occurs with advancing age; this rise in FSH results from reduced secretion of inhibin, a granulosa cell product that exerts an important negative feedback influence over FSH secretion by the pituitary gland. It is possible that both inhibin A and inhibin B may be involved, because luteal phase levels of inhibin A and follicular phase levels of inhibin B decrease with aging and antedate the rise in FSH.<sup>72,73,74</sup> A careful study in Australia, however, indicated that the increase in FSH was correlated only with a decrease in inhibin B, and in response to elevated FSH, estradiol levels increased slightly.<sup>65</sup>

Decrease in inhibin production by the follicular granulosa cells could reflect either a shrinking number of ovarian follicles, or a reduced functional capacity of the older follicles, or both.<sup>75</sup> **The observation that preovulatory follicular fluid inhibin concentrations are similar in young and older cycling women suggests that the number of remaining follicles is the most important factor.**<sup>76</sup>

In the late reproductive stage, driven by higher FSH levels, the process of follicular recruitment and development gets accelerated with resulting shortening of the follicular phase. This accelerated pace of follicular development in the late reproductive stage is reflected in higher estradiol levels being attained earlier in the follicular phase, suggesting that higher FSH levels stimulate more rapid follicular development.<sup>77</sup> **Careful studies indicated that the earlier acute rise in estradiol levels results from advanced follicular development at the beginning of the cycle and earlier selection of the dominant follicle.**<sup>78,79</sup> Follicular phase and overall cycle length reach their nadir at approximately age 42. Over the subsequent 8–10 years preceding the FMP, average cycle length and variability steadily increase as ovulations become less regular and less frequent.<sup>43</sup> The aging-related changes in the endocrine characteristics of the menstrual cycle that result from progressive follicular depletion correlate with a measurable decrease in the ovarian volume and in the number of antral follicles observed by transvaginal ultrasonography during the early follicular phase.<sup>80,81,82,83,84,85,86</sup>

The inverse and tight relationship between FSH and inhibin indicates that inhibin is a sensitive marker of ovarian follicular competence and, in turn, that FSH measurement is a reflection of inhibin.<sup>56,57</sup> The decrease in inhibin secretion by the ovarian follicles begins early (around age 35), but accelerates after 40 years of age, and parallels the decline in fecundity that occurs with aging (as discussed in [Chapter 25](#)). **Furthermore, the ineffective ability to achieve suppression of gonadotropins with menopausal hormone therapy is a consequence of the loss of inhibin, and for this reason, FSH levels cannot be used to titrate estrogen dosage in menopausal women on hormone therapy regimens.**

The Michigan Bone Health and Metabolism Study is a longitudinal assessment of the menopausal transition in a cohort of 629 women initiated in 1992–1993. The initial rise in FSH in these women was modest until 7 years prior to menopause and then accelerated with an even greater increase in the 2 years before menopause, finally reaching a plateau about a year after menopause.<sup>87</sup> The major decrease in estradiol levels began about 2 years before menopause.<sup>88</sup> Declining levels of inhibin B and AMH reached a low to nondetectable point about 5 years before menopause.<sup>89</sup> Although the inhibin B and AMH results are in agreement with other reports, an exactness of the timing is limited by the fact that the blood samples were obtained from only 50 women

in the study. Furthermore, Depmann et al. also demonstrated that while AMH can help in predicting impending menopause as it relates to aging, this predictability is far from being robust.<sup>90</sup> Nevertheless, the Michigan study confirms the validity of AMH as a marker for residual ovarian follicles, a concept that is referred to as ovarian reserve. Unlike inhibin B, AMH is not a participant in the feedback relationship between the ovary and the pituitary gonadotropins, rather AMH, a product of the granulosa cells, and reflects the number of residual follicles awaiting FSH stimulation.<sup>91</sup> **The variability in these hormone measurements from individual to individual, however, precludes the practical use of these biomarkers to predict with accuracy the future date of menopause.**<sup>90</sup>

The transition or perimenopausal years are a time period during which postmenopausal levels of FSH (>20 IU/L) can be seen despite continued menstrual bleeding, while LH levels still remain in the normal range. Occasionally, corpus luteum formation and function occur, and the perimenopausal woman is not safely beyond the risk of an unplanned and unexpected pregnancy until persistently elevated levels of both FSH (25 IU/L) and LH (30 IU/L) can be demonstrated.<sup>58</sup> However, even under these circumstances, fluctuations can occur, with a transient period of ovarian failure (reflected in amenorrhea, elevated gonadotropins, and low estradiol levels) followed by spontaneous resumption of ovarian function for a brief period.<sup>57</sup> **Because variability is the rule, it would be wise to recommend the use of contraception until the postmenopausal stage is definitely established.** According to the Guinness Book of World Records, a woman from the United Kingdom holds the modern record for the oldest spontaneous pregnancy, conceiving when 59 years old via cesarean section. **Several months of amenorrhea together with a persistently elevated FSH level of 40 IU/L or more are reliable signals that menopause is either near or has already happened.**<sup>92</sup>

In the longitudinal Massachusetts Women's Health Study, women who reported the onset of menstrual irregularity were considered to be in the perimenopausal period of life.<sup>93</sup> The median age for the onset of this period was 47.5 years. **Only 10% of women ceased menstruating abruptly with no period of prolonged irregularity.** The menopausal transition from reproductive to postreproductive status was, for most women, approximately 4 years in duration. In the study by Treloar, the average age for entry into the menopausal transition was 45.1, and the age range that included 95% of the women was 39–51.<sup>63</sup> The mean duration of the menopausal transition was 5.0 years, with a range of 2–8 years (Table 17.3).

# Preventive Health Screening of Healthy Perimenopausal Women

The most important contribution a clinician can provide to the perimenopausal woman is the awareness and the knowledge that is required to allow aging women to make timely lifestyle and indicated therapeutic choices. This early educational process will help to build a solid relationship with patients, a relationship they will want to continue as they age. The following recommendations are derived from our own clinical experience:

- Provide reassurance that reproductive aging is a normal phenomenon and menopause is not a disorder.
- Provide guidance and education to facilitate a patient's decision-making.
- Provide time and an appropriate location for sensitive and uninterrupted discussions.
- Use educational materials, especially handouts, but also explain them using your own words.
- Involve family members during counseling and educational visits.
- Be accessible. Consider designating a member of your staff as the menopause resource person. Encourage phone calls and emails.
- Be involved in community and hospital educational programs for the public.
- Use an effective, well-trained counselor for patients who need in-depth help in coping with life's trials and tribulations.

Preventive intervention during the perimenopausal years has three major goals. The overall objective is to demystify reproductive aging and ensure that phases of menopause transition and postmenopause are approached as physiology and not pathology. The overarching goal is to optimize mental, physical, and social well-being. A specific goal is to detect as early as possible any of the major chronic diseases, including hypertension, heart disease, diabetes mellitus, and cancer, as well as impairments of vision, hearing, and teeth. Finally, the clinician should help symptomatic perimenopausal women to smoothly traverse the menopausal period of life. Preventive health care and management of the later reproductive years give clinicians an excellent opportunity to function as a woman's primary care provider.

## Key Points

- Regardless of chronological age, women should undergo annual medical

evaluations that should include a thorough medical history as well as physical examination.

- Annual visits should include assessment of vitals (blood pressure and pulse), body weight and BMI (body mass index), breast and pelvic examinations, and screening for sexually transmitted infections when appropriate. Thyroid function (TSH) should be assessed in the 40's and annually beginning at age 60 (as hypothyroidism, discussed in [Chapter 20](#), increases with aging and is more common in women).
- Annual screening mammography should begin at age 40 (discussed in [Chapter 16](#)).
- At each visit, appropriate testing is scheduled for specific chronic conditions (including abnormal lipids), indicated immunizations are provided, and counseling covers changing nutritional needs; physical activities; injury prevention; occupational, sexual, marital, and parental problems; urinary function; and use of tobacco, alcohol, and drugs. Stool hemocult testing should be performed annually after age 50.
- For low risk individuals without a family history of colon cancer, screening colonoscopy is recommended starting at age 50, and then every 10 years through age 75.

# Timing of Natural Menopause

Designating the average age of menopause has been somewhat difficult. Based on cross-sectional studies, the median age was estimated to be somewhere between 50 and 52.<sup>94</sup> These studies relied on retrospective memories and the subjective vagaries of the individual being interviewed. Until recently, studies with longitudinal follow-up to observe women and record their experiences as they pass through menopause were hampered by relatively small numbers. The Massachusetts Women's Health Study provides us with data from 2,570 women.<sup>93</sup>

The median age for menopause in the Massachusetts Study was 51.3 years. Only current smoking could be identified as a cause of earlier menopause, a shift of approximately 1.5 years. Those factors that did not affect the age of menopause in this study included the use of oral contraception, socioeconomic status, and marital status. Keep in mind that a **median** age of menopause means that only half the women have reached menopause at this age. In the classic longitudinal study by Treloar, the **average** age of menopause was 50.7 years, and the range that included 95% of the women was 44–56 years.<sup>95</sup> In a survey in the Netherlands, the average age of menopause was 50.2, and in an Italian longitudinal study, it was 50.9 years.<sup>64,96</sup>

The Study of Women's Health Across the Nation (SWAN) is an ongoing, national study, recording the health of American women as they pass through the perimenopausal transition (<http://www.edc.gsph.pitt.edu/swan/>). The study began in 1994 in seven research centers and enrolled 3,302 participants with five racial/ethnic groups and a variety of backgrounds for an initial cross-sectional survey. In 1996, these women began a longitudinal, follow-up study with extensive data collection occurring annually.

In the SWAN study, the median age of menopause was 51.4, with an earlier onset associated with current smoking, lower education, and lower socioeconomic status, whereas a later age was associated with parity and prior use of oral contraceptives.<sup>97</sup> In contrast, a Dutch study concluded that prior use of oral contraceptives was associated with earlier (<1 year) menopause.<sup>98</sup> About 1% of women have been reported to experience menopause before the age of 40.<sup>99</sup> The SWAN study reported a similar percentage of 1.1%, with a slightly higher rate in Black and Hispanic women and a lower rate of 0.5% in Chinese women and 0.1% in Japanese women.<sup>100</sup> Hispanic women experienced menopause about 6 months earlier compared with other ethnic groups, whereas Japanese women were about 3 months later.

Two large cohorts of European women reported average ages of menopause in various countries that centered around age 51 years, slightly higher in Northern Europe and slightly lower in Southern Europe.<sup>101</sup> Some countries, like India, report an average

age of menopause as much as 5 years earlier.<sup>102</sup> In epidemiologic studies, approximately 10% of women in the general population become menopausal by the age of 45.<sup>63,64</sup> Pedigree analysis has revealed that the genetic features of early menopause (age 40–45) and premature ovarian insufficiency (POI) or failure (cessation of ovarian function occurring at an age <40) are similar and suggest a dominant pattern of inheritance through maternal or paternal relatives.<sup>103,104</sup> There are two studies indicating that daughters of mothers with an early menopause (before age 46) also have an early menopause, with up to 15% of women having a first-degree relative with early menopause.<sup>105,106,107,108</sup>

There is sufficient evidence to suggest that chronically undernourished women and vegetarians may experience an earlier menopause.<sup>105,109</sup> Because of the contribution of body fat to estrogen production, thinner women experience a slightly earlier menopause.<sup>110</sup> Frequent consumption of alcohol is associated with a later menopause.<sup>106</sup> This is consistent with the reports that women who consume alcohol have higher blood and urinary levels of estrogen.<sup>111,112,113,114,115</sup>

In multiple studies, there has been no correlation between age of menarche and age of menopause, with the exception of one Swedish study concluding that an earlier menarche and earlier menopause go together.<sup>64,95,105,116,117</sup> In most studies, race, parity, and height have no influence on the age of menopause; however, three cross-sectional studies found later menopause to be associated with increasing parity.<sup>64,93,97,105,110</sup> Two studies found that irregular menses among women in their early 40s predicts an earlier menopause.<sup>118,119</sup> A French survey detected no influence of heavy physical work on early menopause (before age 45).<sup>120</sup> An earlier menopause has been reported to be associated with living at high altitudes.<sup>121,122</sup> And most intriguing, an earlier age of menopause has been reported in left-handed women compared with right-handed women.<sup>123,124</sup> Finally, intrauterine growth restriction in late gestation may predispose the affected female progeny to earlier menopause.<sup>125</sup>

It has been suggested, albeit inconsistently, that time to FMP may get accelerated in women undergoing pelvic surgery wherein ovarian vascular supply may get compromised, such as following an abdominal hysterectomy. Effects of pelvic surgery on biomarkers of ovarian reserve have been examined, with mixed results. A prospective study could find no elevations of FSH within the first 2 years after surgery.<sup>126,127,128</sup> Furthermore, in a cross-sectional study assessing ovarian reserve following ovarian cystectomy (for cysts other than endometriomas) and, or salpingectomy, there was no appreciable effect on ovarian reserve.<sup>129</sup>

Multiple studies have consistently documented that an earlier menopause (an

average of 1.5 years earlier) is a consequence of smoking. There is a dose-response relationship with the number of cigarettes smoked and the duration of smoking.<sup>130,131</sup> Even former smokers show evidence of an impact.<sup>101</sup>

Unlike the decline in age of menarche that occurred with an improvement in health and living conditions, most historical investigation indicates that the age of menopause has changed little since early Greek times.<sup>132,133</sup> Others (a minority) have disagreed, concluding that the age of menopause did undergo a change, starting with an average age of about 40 years in ancient times, and in Sweden, an increase of about 1 year over a span of 80 years.<sup>117,134</sup> If there has been a change, however, history indicates that it has been minimal. Even in ancient writings, 50 years is not uncommonly cited as the age of menopause.

# Sexuality, Aging, and Menopause

Sexuality is behavior that evolves and changes across the life span. It begins with birth (maybe before) and ends with death. The notion that sexuality ends with aging is inherently illogical. The need for closeness, caring, and companionship is lifelong. Old people today live longer, are healthier, have more education and leisure time, and have had their consciousness raised in regard to sexuality.

Younger people, especially physicians, underrate the extent of sexual interest in older people. In a random sample of women aged 50–82 in Madison, Wisconsin, nearly one-half of the women reported an ongoing sexual relationship.<sup>135</sup> In the Duke longitudinal study on aging, 70% of men in the 67–77 age group were sexually active, and 80% reported continuing sexual interest, while 50% of all older women were still interested in sex.<sup>136</sup> In the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, 60% of women 55–64 years old were sexually active.<sup>137</sup> In a national sample of American men and women, the prevalence of sexual behavior declined with aging; however, 26% of individuals aged 75–85 years were still sexually active.<sup>138</sup> The prevalence of self-reported sexual problems peaks in middle-aged women, sufficient to cause distress in about 22% of U.S. women and about 12% of women aged 45–64.<sup>139</sup> Up to 23% of menopausal women are negatively affected by decreased sexual desire.<sup>140</sup>

The decline in sexual activity with aging is influenced by culture and attitudes, as well as by nature and physiology (or hormones). As estradiol regulates serotonergic function, it can affect desire and sexual function.<sup>140</sup> In addition, the discomfort resulting from vaginal dryness and tissue atrophy consequent to low estradiol levels can make coitus unwelcome, even to the point of avoidance. Thus, a significant component of decline in sexual activity in reproductively aging women can be attributed to menopausal symptoms associated with decreasing estrogen levels, a problem that is easily ameliorated by targeted treatment.

There are two main sexual changes in the aging woman. There is a reduction in the rate of production and volume of vaginal lubricating fluid, and there is some loss of vaginal elasticity and thickness of the epithelium. Less vaginal atrophy is noted in sexually active women than in inactive women; presumably, the activity maintains vaginal vasculature and circulation. The spectrum of uncomfortable symptoms that are often described by transitioning and menopausal women with evidence of genital atrophy include a feeling of dryness and tightness, vaginal irritation and burning with penetration, and postcoital spotting and soreness. Given that these symptoms are the direct result of tissue estrogen deprivation, the underlying tissue changes can be effectively prevented by focal estrogen treatment. Systemic estrogen therapy may even have a positive impact on sexuality beyond effects on vaginal tissue.<sup>137</sup> In an ancillary

sexual study of the Kronos Early Estrogen Prevention Study (KEEPS)—a randomized, double-blinded, placebo-controlled trial—early menopausal women were randomized to receive either low-dose oral conjugated equine estrogen (CEE) or transdermal estradiol (transdermal E2), over the 4 years of intervention, while both routes of estrogen treatment resulted in an improvement in vaginal dryness and dyspareunia,<sup>140</sup> improvements in libido and sexual satisfaction were observed only in transdermal E2 users.<sup>140</sup> In an Australian study assessing changes in sexual functioning during the menopausal transition, a correlation with a decline in sexuality was demonstrated with estradiol levels, but not with testosterone levels. There are likely many important factors other than hormone levels that are relevant in determining midlife sexual function.<sup>140,141</sup>

## Illness and Sex

It is not uncommon to encounter medical or surgical underpinnings to disorders of sexuality. Surgical menopause (removal of both ovaries in premenopausal women) is probably one of the most commonly encountered iatrogenic contributors to altered sexual function. Remember that vaginal lubrication is an important physiologic sexual response, and therefore, vaginal dryness is a likely consequence following total hysterectomy even if the premenopausal ovaries are retained. Sexual problems are not limited, however, to surgical procedures and illnesses of the genitalia. Altered self-image such as following vulvectomy or mastectomy can also impact sexual function. However, studies have not found postmenopausal hysterectomy to have a detrimental impact on sexuality.<sup>137,142</sup>

Sexual counseling, to be effective, must be provided to couples both before and after surgery. It is not unexpected that the surgeon may not be fully capable of providing this counseling. A major contribution from an older woman's primary clinician is to arrange for competent and experienced sexual counseling. Unfortunately, most physicians operate on the principle that if no questions are raised, there is no problem. The expert surgeon should be grateful for the help of experts in psychosexual therapy. Seek out the potential for posttreatment sexual morbidity before the surgery. Assess the patient's abilities for coping and her sense of body image. Consider the quality of the patient's relationship, and be sensitive to the absence of a relationship. This entire effort may take some time. The normal state of presurgical anxiety, fear, and denial hampers good communication.

Increasing use of SSRI (selective serotonin reuptake inhibitor) antidepressants is another iatrogenic contributor to female sexual dysfunction that merits attention.<sup>143</sup>

Antihypertensive agents are frequently responsible for male sexual dysfunction, but little information is available regarding female sexual function. Adrenergic blocking

agents are especially noted to affect libido and potency in men. Similarly, psychotropic drugs of all categories have been associated with inhibition of sexual function. Finally, one should always suspect alcoholism when patients complain of sexual dysfunction. Androgen treatment for decreased female sexuality is discussed later in this chapter.

The two most important influences on sexual satisfaction in aging couples are the strength of relationship and the physical condition of each partner.<sup>137,138,144</sup> The single most significant determinant of sexual activity for older women is the lack of availability of partners due to divorce or demise as women are outliving men. Given availability of a partner, the same general high or low rate of sexual activity can be maintained throughout life.<sup>4,145</sup> Longitudinal studies indicate that the level of sexual activity is more stable over time than previously suggested.<sup>146,147,148</sup> Individuals who are sexually active earlier in life continue to be sexually active into old age. However, aging is associated with a decline in sexual function in many women, and this decline has been documented in the years well before the FMP.<sup>149,150</sup>

# HORMONE PROFILE OF MENOPAUSAL TRANSITION AND POSTMENOPAUSE

---

Shortly after the menopause, one can safely say that there are no remaining ovarian follicles.<sup>66,151</sup> Eventually, there is a 10–20-fold increase in FSH and approximately a 3-fold increase in LH, reaching a maximal level 1–3 years after menopause, after which there is a gradual, but slight, decline in both gonadotropins.<sup>152,153</sup> Elevated levels of both FSH and LH at this time in life are conclusive evidence of ovarian failure. FSH levels are higher than LH because LH is cleared from the blood so much faster (initial half-lives are about 20 minutes for LH and 3–4 hours for FSH) and perhaps because there is no specific negative feedback peptide for LH like inhibin. An aging-related decline in the gonadotropin levels in the latter years of postmenopausal life is well described and is believed to reflect aging of the pituitary gonadotropin-secreting cells, specifically a decrease in the ability to respond to the hypothalamic gonadotropin-releasing hormone (GnRH).

After menopause, the ovary secretes primarily androstenedione and testosterone, but the circulating level of androstenedione after menopause is about one-half that seen prior to menopause.<sup>154</sup> Most of this postmenopausal androstenedione is derived from the adrenal gland, with only a small amount secreted from the ovary, even though androstenedione is the principal steroid secreted by the postmenopausal ovary.<sup>155,156</sup> Dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S), originating in the adrenal gland, decline markedly with aging; in the decade after menopause, the circulating levels of DHEA are approximately 70% less and levels of DHEA-S are about 74% less than the levels in young adult life.<sup>157,158</sup>

Testosterone production decreases by approximately 25% after menopause, but the postmenopausal ovary in most, but not all women, secretes more testosterone than the premenopausal ovary, at least in the first years of the postmenopausal period. With the disappearance of follicles and estrogen, the elevated gonadotropins drive the remaining tissue in the ovary to a level of increased testosterone secretion. The ovarian cells of origin are uncertain; presumably, the steroidogenic tissue is that which has accumulated from ovarian follicles undergoing atresia because stromal cells believed to be of mesenchymal origin lack steroidogenic capability.<sup>159</sup> Suppression of gonadotropins with GnRH agonist or antagonist treatment of postmenopausal women results in a significant decrease in circulating levels of testosterone, indicating the gonadotropin-dependent postmenopausal ovarian origin.<sup>160,161,162</sup>

The total amount of testosterone produced after menopause, however, is decreased because the amount of the primary source, peripheral conversion of androstenedione, is

reduced. The early postmenopausal circulating level of androstenedione decreases approximately 62% from young adult life.<sup>157</sup> **The menopausal decline in the circulating levels of testosterone is not great, from no change in many women to as much as 15% in others.**<sup>59,153,157,163,164</sup> In an excellent longitudinal Australian study from 5 years before menopause to 7 years after menopause, the circulating levels of testosterone did not change.<sup>158</sup> Indeed, because of a decrease in sex hormone-binding globulin (SHBG), this Australian study calculated an increase in free androgens. Late postmenopause may be considered as a state of **relative androgen excess**.

Later in the postmenopausal years, the circulating androgen levels are nearly all, if not all, derived from the adrenal gland. A careful study could detect no circulating androgens in postmenopausal women (averaging 12 years distant from menopause) with complete adrenal insufficiency and no intraovarian testosterone or androstenedione.<sup>165</sup>

The circulating estradiol level after menopause is approximately 10–20 pg/mL, most of which is derived from peripheral conversion of estrone, which in turn is mainly derived from the peripheral conversion of androstenedione.<sup>154,166,167</sup> The circulating level of estrone in postmenopausal women is higher than that of estradiol, approximately 30–70 pg/mL (Table 17.4). The average postmenopausal production rate of estrogen is approximately 45 µg/24 h, almost all, if not all, being estrogen derived from the peripheral conversion of androgens. The androgen/estrogen ratio changes drastically after menopause because of the more marked decline in estrogen, and an onset of mild hirsutism is common, reflecting this marked shift in the sex hormone ratio. With increasing postmenopausal age, a decrease can be measured in the circulating levels of dehydroepiandrosterone sulfate (DHEA-S) and DHEA, whereas the circulating postmenopausal levels of androstenedione, testosterone, and estrogen remain relatively constant.<sup>153,154</sup>

## TABLE 17.4

**Blood Production Rates of Steroids<sup>168</sup>**

	<i>Reproductive Age</i>	<i>Postmenopausal</i>	<i>Oophorectomized</i>
Androstenedione	2–3 mg/day	0.5–1.5 mg/day	0.4–1.2 mg/day
Dehydroepiandrosterone	6–8	1.5–4.0	1.5–4.0
Dehydroepiandrosterone sulfate	8–16	4–9	4–9
Testosterone	0.2–0.25	0.05–0.18	0.02–0.12
Estrogen	0.350	0.045	0.045

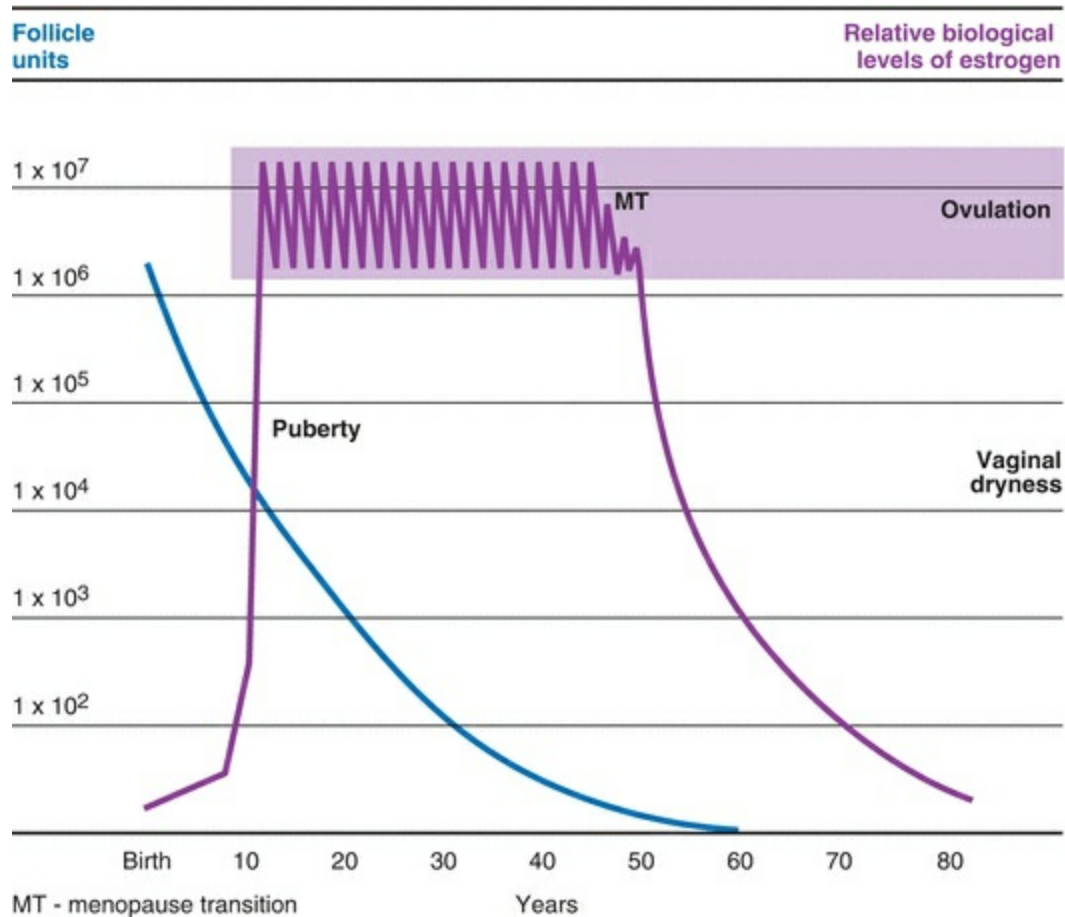

**Changes in Circulating Hormone Levels at Menopause<sup>59,154,166</sup>**

	<i>Premenopause</i>	<i>Postmenopause</i>
Estradiol	40–400 pg/mL	10–20 pg/mL
Estrone	30–200 pg/mL	30–70 pg/mL
Testosterone	20–80 ng/dL	15–70 ng/dL
Androstenedione	60–300 ng/dL	30–150 ng/dL

Estrogen production by the ovaries does not continue beyond the menopause; however, estrogen levels in postmenopausal women can be significant, principally due to the extraglandular conversion of androstenedione and testosterone to estrogen. The clinical impact of this estrogen varies from one postmenopausal woman to another, depending on the degree of extraglandular production, modified by a variety of factors.

The percent conversion of androstenedione to estrogen correlates with body weight. Increased production of estrogen from androstenedione with increasing body weight is probably due to the ability of fat to aromatize androgens. This fact and a decrease in the levels of SHBG (which results in increased free estrogen concentrations) contribute to the well-recognized association between obesity and the development of endometrial cancer. Body weight, therefore, has a positive correlation with the circulating levels of estrone and estradiol.<sup>154</sup> Aromatization of androgens to estrogens is not limited to adipose tissue, however, because almost every tissue tested has this activity.

Eventually, the ovarian steroidogenic tissue is exhausted and, despite huge reactive increments in FSH and LH, no further steroidogenesis of importance results from gonadal activity. The postmenopausal ovary weighs less than 10 g, but it can be visualized by ultrasonography.<sup>169</sup> With increasing age, the adrenal contribution of precursors for estrogen production proves inadequate. In this final stage of estrogen availability, levels are insufficient to sustain secondary sex tissues, such as the genitourinary epithelium (**Figure 17.9**).

**FIGURE 17.9**

In summary, the symptoms frequently seen and related to decreasing ovarian follicular competence and then estrogen loss in this protracted climacteric are:

- Disturbances in menstrual pattern, including anovulation and reduced fertility, decreased flow or hypermenorrhea, irregular frequency of menses, and then, ultimately, amenorrhea
- Vasomotor instability (hot flashes and sweats)
- Atrophic conditions: atrophy of the vaginal epithelium; formation of urethral caruncles; dyspareunia and pruritus due to vulvar, introital, and vaginal atrophy; general skin atrophy; and urinary difficulties such as urgency and abacterial urethritis and cystitis
- Health problems secondary to long-term deprivation of estrogen: the consequences of osteoporosis and cardiovascular disease

A precise understanding of the symptom complex the individual patient may display is often difficult to achieve. Some patients experience severe multiple reactions that may be disabling. Others show no reactions or minimal reactions that go unnoticed until

careful medical evaluation.

**It is helpful to classify the hormonal problems in three categories:**

- 1. Those associated with relative estrogen excess such as abnormal uterine bleeding, endometrial hyperplasia, and endometrial cancer**
- 2. Those associated with estrogen deprivation such as flushes, atrophic vaginitis, urethritis, and osteoporosis**
- 3. Those associated with hormone therapy (discussed later in this chapter)**

# SYMPTOMATOLOGY OF PERIMENOPAUSE AND MENOPAUSE

---

The period of transition should serve to remind both the patients and the clinicians that this is a time for communication to ensure improvements in patient awareness through education. Certainly, preventive health care education is important throughout life, but at the time of the menopause, a review of the major health issues can be especially rewarding. Besides the general issues of good health, attention is appropriately focused on cardiovascular disease and osteoporosis.

During the transition and early postmenopausal years in particular, some women may experience significantly bothersome symptoms, whereas others show no reactions or minimal reactions that can go unnoticed. The differences in menopause experience and in the spectrum and severity of symptoms across different cultures are poorly documented, and indeed, it is difficult to do so. Individual reporting is so conditioned by sociocultural factors that it is hard to determine what is due to biologic versus cultural variability.<sup>170,171</sup> For example, there is no word to describe a hot flush in Japanese, Chinese, and Mayan.<sup>172</sup> Nevertheless, there is reason to believe that the nature and prevalence of menopausal symptoms are common to most women and that variations among cultures and within cultures reflect not physiology, but differences in attitudes, lifestyles, socioeconomic status, and individual perceptions across societies.<sup>173,174,175,176,177,178</sup> Hormone levels during the perimenopausal years vary little among different ethnic groups; differences are mainly because of varying body sizes.<sup>179</sup>

# Abnormal Uterine Bleeding

Period of transition is characterized by an increasing incidence of anovulatory uterine bleeding. Thus, the late reproductive and early menopausal stages are characterized by longer periods of exposure to unopposed estrogen, of ovarian and extraovarian (from aromatization of androgens) origins. In the SWAN study, about 20% of cycles even early in the menopausal transition were anovulatory, associated with shorter intervals at the beginning of the transition and longer intervals later.<sup>180</sup> Irregular bleeding was most often due to anovulation, whereas heavy menstrual bleeding was associated with obesity and uterine abnormalities. The menopause transition and early menopause can thus be considered as times of relative estrogen excess. Although the greatest concern emerging from prolonged periods of exposure to estrogen unopposed by progesterone is of endometrial neoplasia, the most common of tissue finding is that of nonneoplastic tissue displaying estrogen effects unopposed by progesterone.

**In addition to relative excess of estrogen resulting from anovulation, there are four mechanisms that could result in higher endogenous estrogen levels in perimenopausal and menopausal women:**

- 1. Increased precursor androgen (functional endocrine tumors, liver disease, stress)**
- 2. Increased aromatization (obesity, hyperthyroidism, and liver disease)**
- 3. Increased direct secretion of estrogen (ovarian tumors)**
- 4. Decreased levels of SHBG (sex hormone–binding globulin) leading to increased levels of free estrogen**

In those presenting with abnormal uterine bleeding, whether perimenopausal or postmenopausal, whether on or off hormone therapy, specific organic causes for abnormal uterine bleeding (neoplasia, complications of unexpected pregnancy, or bleeding from extrauterine sites) must be ruled out. In addition to a careful history and physical examination, abnormal uterine bleeding, particularly in an aging individual, requires systematic endometrial evaluation. Transvaginal ultrasound (TVUS) measurement of endometrial thickness can be utilized in postmenopausal women to avoid unnecessary biopsies.<sup>181</sup> In postmenopausal women with abnormal bleeding, endometrial biopsy is considered unnecessary when the endometrial thickness on ultrasound is less than 4 mm as the risk of endometrial hyperplasia or cancer in this setting is unlikely.<sup>182,183,184</sup> Substantial evidence is however lacking to support the application of this criterion to the premenopausal population. **We believe that biopsy is unnecessary in postmenopausal women when the endometrial thickness is 4 mm or less. We further believe that endometrial biopsy is indicated when the clinical**

**history suggests long-term unopposed estrogen exposure (either prolonged periods of oligo-/amenorrhea in pre- and perimenopausal women or with iatrogenic estrogen use) even when the endometrial thickness is “normal” (5–12 mm for premenopausal women) and that biopsy should be considered when endometrial thickness is greater than 12 mm in the absence of abnormal uterine bleeding, even when clinical suspicion of disease is low.** A TVUS study can also help in identifying intracavitary lesions, particularly with intracavitary instillation of saline.<sup>185</sup> Saline infusion sonohysterogram (SHG) can identify intracavitary lesions (i.e., polyps and submucosal fibroids) that can be missed on routine 2D TVUS.<sup>185</sup> The sensitivity and specificity of TVUS for identifying intrauterine pathology are 56–73%,<sup>186</sup> whereas SHG has a sensitivity of 96–100% and a negative predictive value of 94–100% in evaluating for uterine pathology.<sup>185</sup> Hysteroscopy has an accuracy of 96% for intracavitary pathology, with abnormalities seen in about 47% of premenopausal and postmenopausal women with abnormal uterine bleeding.<sup>154</sup>

If the endometrial assessment is unremarkable but abnormal bleeding persists, then for reasons of both accuracy and cost-effectiveness, the next step should be of endometrial biopsy; when no focal pathology is evident on screening, then it is appropriate for the method of endometrial biopsy to be an office-based procedure. We recommend the use of a plastic endometrial suction device (such as a pipelle) as the procedure is easy to perform, requires no cervical dilation, and is frequently well tolerated and equipment is routinely available even in low-resource settings. An office-based endometrial biopsy has been shown to offer tissue yield that is near comparable to dilation and curettage (D&C) and has an 83% sensitivity for detecting endometrial cancer. Insertion should first be attempted without the use of a tenaculum. In many patients, this is feasible and avoids the sensation of the tenaculum grasping the cervix. Once the suction is applied, the endometrial cavity should be thoroughly curetted in all directions, just as one would with a sharp curette during a D&C. Although most patients report no problems with cramps or pain, the application of suction in some patients stimulates cramping that usually passes within 5–10 minutes. Because cramping can occur, an inhibitor of prostaglandin synthesis given at least 20 minutes before the procedure has been shown to minimize procedure-related discomfort. Less than 10% of postmenopausal women cannot be adequately evaluated by office biopsy. Most commonly, the reason is the inability to negotiate the cervical canal and gain entry into the uterine cavity. In such instances, it is very reasonable to proceed with procedure under anesthesia when a D&C can be performed in the operating room; however, pretreatment with misoprostol or cervical laminaria may allow completion of office endometrial biopsy and thus avoid the need for anesthesia and D&C. We recommend consideration for office hysteroscopy or a SHG prior to proceeding with office endometrial biopsy and undertaking concomitant hysteroscopy at the time of D&C being

undertaken for evaluation of abnormal uterine bleeding,<sup>154</sup> provided access to the equipment is available and the surgeon has the requisite expertise. Following a negative hysteroscopy result, the chance of endometrial cancer diagnosis is 0.4–0.5%.<sup>154</sup> If the vulva, vagina, and cervix appear normal on inspection, menopausal bleeding can be assumed to be intrauterine in origin. Confirmation requires the absence of abnormal cytology on the Pap smear. The principal symptom of endometrial cancer is abnormal vaginal bleeding, but carcinoma will be encountered in patients with bleeding in less than 3% of postmenopausal endometrial biopsies.<sup>187,188,189</sup> Normal endometrium is found over half the time, polyps in approximately 3%, endometrial hyperplasia about 15% of the time, and atrophic endometrium in the rest of patients with postmenopausal bleeding. Postmenopausal bleeding should always be taken seriously. Approximately 10% of patients who have benign findings at the initial evaluation subsequently develop significant pathology within 2 years.<sup>188</sup> **The persistence of abnormal bleeding demands repeated evaluation.**

Additional procedures to consider include the following:

- **Colposcopy and cervical biopsy** for abnormal cytology or obvious lesions
- **Endocervical assessment** by curettage for abnormal cytology (the endocervix must always be kept in mind as a source for abnormal cytology)

Keep in mind that the pathologic reading, “tissue insufficient for diagnosis,” when a patient is on estrogen-progestin treatment, often represents atrophic, decidualized endometrium that yields little to the exploring curette. If the clinician is confident in his or her technique, knowing that a full investigation of the intrauterine cavity has been accomplished, then as long as the patient does not persist in bleeding, this reading can be interpreted as comforting and benign, the absence of pathology. Specifically, as long as the clinician is certain that the true uterine cavity was sampled (i.e., no false passage or stenotic os encountered), then no further testing is indicated unless abnormal bleeding persists and risk factors for neoplasia are present. In the event of continued bleeding or concerning risk factors (i.e., long-standing history of unopposed estrogen, obesity, hypertension, diabetes, nulliparous), consideration for referral to a gynecologic oncologist would be a prudent approach.

In the absence of organic disease, appropriate management of uterine bleeding is dependent on the age of the woman and endometrial tissue findings. In the menopausal woman with abnormal uterine bleeding associated with evidence of simple endometrial hyperplasia (uncomplicated by atypia or dysplastic constituents), periodic oral progestin therapy is mandatory (such as 10 mg medroxyprogesterone acetate or 5–10 mg norethindrone acetate for 14 days each month). Intrauterine placement of a levonorgestrel intrauterine device (LNG-IUD) is increasingly being utilized as an

effective management approach with high regression rates. Higher-dose oral progestins (such as 10–20 mg medroxyprogesterone acetate or 10–15 mg norethindrone acetate) are always an option and should be considered in the setting of obesity.<sup>190,191</sup> Repeat endometrial sampling should be performed at 3 and 6 months of therapy. Most cases of simple hyperplasia will regress at 6 months; however, if there is no regression at 3–6 months, then consideration of increasing progestin dose or switching regimen (such as to megestrol acetate in daily doses of 40–80 mg or LNG-IUD) should be entertained. Persistence or progression of abnormal endometrium was observed in 28.4% of women with complex hyperplasia and in 26.9% of women with atypical hyperplasia despite treatment with a progestational agent.<sup>192</sup> At least two consecutive repeat negative biopsies should be conducted prior to stopping surveillance.<sup>190</sup> In the absence of any regression after 1 year of progestin therapy, or if there is evidence of progression from simple or complex without atypia to atypical hyperplasia despite progestin therapy, then hysterectomy is indicated and referral to a gynecologic oncologist is strongly advised.<sup>190</sup> Because hyperplasia with atypia carries with it a risk of concomitant cancer (even invasive), hysterectomy is the treatment of choice. However, progestational response was better with higher-dosage and longer-duration treatment. If histologic regression is not observed on office biopsy, a D&C should be considered before proceeding with hysterectomy.

Clinicians have often utilized a traditional postmenopausal hormone regimen to treat a woman with the kind of irregular cycles usually experienced in the perimenopausal years. This addition of exogenous estrogen without a contraceptive dose of progestin when a woman is not amenorrheic or experiencing menopausal symptoms is inappropriate and even risky (exposing the endometrium to excessively high levels of estrogen). **And most importantly, a postmenopausal hormonal regimen does not inhibit ovulation and provide contraception.**<sup>193</sup> The appropriate response is to regulate anovulatory cycles with monthly progestational treatment along with an appropriate contraceptive method or to utilize low-dose estrogen-progestin contraception. An oral contraceptive that contains 20 µg estrogen provides effective contraception, improves menstrual cycle regularity, diminishes bleeding, and relieves menopausal symptoms.<sup>194</sup> Treatment with the transdermal or vaginal method of estrogen-progestin contraception would also be appropriate.

A common clinical dilemma is when to change from estrogen-progestin contraception to postmenopausal hormone therapy. It is important to change because even with the lowest estrogen dose contraceptive available, the estrogen dose is fourfold greater than the standard postmenopausal dose, and with increasing age, the dose-related risks with estrogen become significant. One approach to establish the onset of the postmenopausal years is to measure the FSH level, beginning at age 50, on an

annual basis, being careful to obtain the blood sample on day 6 or 7 of the estrogen-progestin-free week in a standard 3-week regimen (when steroid levels have declined sufficiently to allow FSH to rise). Friday afternoon works well for patients who start new estrogen-progestin treatment on Sunday. When FSH is greater than 20 IU/L, it is time to change to a postmenopausal hormone program. Because of the variability in FSH levels experienced by women around the menopause, this method is not always accurate.<sup>195,196</sup> Indeed, in some women, FSH will not rise until 2 weeks after the last steroid contraception exposure. A 2-week wait is not very practical and places the patient at risk for an unwanted pregnancy. The treatment-free week method is practical and works for most women. Women who are dependent on contraceptives to prevent pregnancy can be allowed to enter their mid-50s on low-dose estrogen-progestin contraception and then empirically switched to a postmenopausal hormone regimen. **The empirical approach is necessary with patients using the newer extended-day or continuous dosing regimens of estrogen-progestin contraception.**

Because of the favorable impact of locally released progestin on the endometrium, the LNG-IUD is very effective for the treatment of menorrhagia, as effective as the administration of oral progestins (with less side effects), and compares favorably with endometrial resection or ablation.<sup>197,198,199,200,201</sup> In addition, this IUD can be used to treat endometrial hyperplasia.<sup>202,203,204,205,206,207</sup> Comparison studies of endometrial hyperplasia indicate that the levonorgestrel IUD is more effective than standard treatment with an oral progestin.<sup>203,208,209,210</sup> The levonorgestrel IUD may be associated with a slight increase in the formation of ovarian cysts, but they are asymptomatic and resolve spontaneously.<sup>211</sup>

In postmenopausal women, one must view any adnexal mass as cancer until proven otherwise. Surgical intervention is usually necessary, and appropriate consultation must be obtained not only for the surgical procedure but also for suitable preoperative evaluation and preparation. Nonpalpable, asymptomatic ovarian cysts are commonly detected by ultrasonography. Cysts that are less than 10 cm in diameter and without septations or solid components (unilocular) have a very low potential for malignant disease and can be managed with serial ultrasound surveillance (at 3 months, 6 months, 12 months, and then annually), especially if the serum CA 125 is normal.<sup>212,213</sup> Surgery is recommended for symptomatic cases, if growth occurs, if internal echoes are obtained, if fluid develops in the pelvis, or if there is a family history of breast or ovarian cancer.

# Vasomotor Symptoms

The vasomotor flush is viewed as the hallmark of the female climacteric, experienced to some degree by most postmenopausal women. The term “hot flush” or “hot flash” is descriptive of a sudden onset of reddening of the skin over the head, neck, and chest, accompanied by an increase in heart rate and a feeling of intense body heat. The flush is sometimes concluded by profuse perspiration. The duration varies from a few seconds to several minutes and, rarely, for an hour. The frequency may be rare to recurrent every few minutes. Flushes are more frequent and severe at night (when a woman is often awakened from sleep) or during times of stress. In a cool environment, hot flushes are fewer, less intense, and shorter in duration compared with a warm environment.<sup>214</sup> Most importantly, hot flushing can affect a woman’s quality of life and interfere with work or recreational activities.

In the longitudinal follow-up of a large number of women, fully 10% of the women experienced hot flushes before menopause, while in other studies, as many as 15–25% of premenopausal women reported hot flushes.<sup>8,93,215,216</sup> The frequency has been reported to be even higher in premenopausal women diagnosed with PMS.<sup>217</sup> In the Massachusetts Women’s Health Study, the incidence of hot flushes increased from 10% during the premenopausal period to about 50% just after cessation of menses.<sup>93</sup> By approximately 4 years after menopause, the rate of hot flushes declined to 20%. In a community-based Australian survey, 6% of premenopausal women, 26% of perimenopausal women, and 59% of postmenopausal women complained of hot flushing.<sup>218</sup> A large American cross-sectional survey reported that 57% of perimenopausal women and 49% of early postmenopausal women experienced significant hot flushing.<sup>177</sup> Another national survey in the United States reported hot flushing in 79% of perimenopausal women and 65% of postmenopausal women.<sup>219</sup>

In cross-sectional surveys, up to 40% of premenopausal women and 85% of menopausal women report some vasomotor complaints.<sup>216</sup> A longitudinal study in Gothenburg, Sweden, recorded a maximal prevalence of 60% at age 52–54, with a decline to 30% at age 60 and 9% at age 72.<sup>220</sup> In the SWAN study, 57% of perimenopausal women experienced hot flushing and about 50% after menopause up to age 55.<sup>221</sup> There is no difference in the prevalence of vasomotor complaints in U.S. surveys of black and white women.<sup>222,223</sup> Overweight women report more hot flushing, perhaps reflecting the effect of body fat causing a higher core body temperature.<sup>177,179,224</sup> Exact estimates on prevalence are hampered by inconsistencies and differences in methodologies, cultures, and definitions.<sup>225</sup> The prevalence in different societies is influenced by personal and social attitudes, individual psychological and physical health, familiarity with the portrayal of menopausal issues in

the literature and media, ethnic variation, different diets, and dissimilar living conditions; however, accounting for cultural differences, the overall prevalence and experience are similar throughout the world.<sup>226,227</sup>

**Although the flush can occur in the premenopause, it is a major feature of the menopause transition and postmenopause, peaking in the first year after the last menses, lasting in 50% of women for 4–5 years, but in some (as many as 25%) for longer than 5 years, and even up to 15 years in 10% (Table 17.5).<sup>228</sup> In an excellent Australian longitudinal cohort study, the average duration of vasomotor symptoms was 5.2 years (with a range of 2–10 years) in nonusers of hormone therapy and slightly longer, 5.5 years, in hormone users.<sup>229</sup> In the SWAN cohort, the median total duration of vasomotor symptoms was 7.4 years. Women who were premenopausal or early perimenopausal at first reporting of frequent symptoms experienced the longest duration (median, >11.8 years) and post-FMP persistence (median, 9.4 years), whereas women who first experienced vasomotor symptoms after onset of menopause had the shortest total duration of symptom (median, 3.4 years).<sup>230</sup>**

## **TABLE 17.5 The Hot Flush**

Premenopausal	10–25% of women
Perimenopausal	60%
Postmenopausal:	
No flushes	15–25%
Daily flushing	15–25%
Duration	1–2 years average: 15–20% 5 or more years: 25%
Other Causes	Psychosomatic Stress Thyroid disease Subacute, chronic infections Pheochromocytoma Carcinoid Leukemia Cancer

The physiology of the hot flush is still not understood. Studies suggest that women with hot flushes have a more narrow zone of temperature regulation, and therefore, smaller changes in core body temperature produce compensatory responses, such as shivering or flushing.<sup>231</sup> MRI scanning of the brain during hot flushing indicates widely distributed cortical activation rather than a precise location.<sup>232</sup> Hot flushes are definitely brought about by a decline in estrogen; however, not all hot flushes are due to estrogen deficiency. Flushes and sweating can be secondary to diseases, including pheochromocytoma, carcinoid, leukemias, pancreatic tumors, and thyroid

abnormalities.<sup>233</sup> **When the clinical situation is not clear and obvious, estrogen deficiency as the cause of hot flushes should be documented by elevated levels of FSH.**

The correlation between the onset of flushes and estrogen reduction is clinically supported by the effectiveness of estrogen therapy and the absence of flushes in hypoestrogen states, such as gonadal dysgenesis. Only after estrogen is administered and withdrawn do hypogonadal women experience the hot flush. Although the clinical impression that premenopausal surgical castrates suffer more severe vasomotor reactions is widely held, this was not borne out in the only objective study ever performed.<sup>234</sup>

Although the hot flush is the most common problem of the postmenopause, it presents no inherent health hazard. The flush is accompanied by a discrete and reliable pattern of physiologic changes.<sup>231,235</sup> The flush coincides with a surge of LH (not FSH) and is preceded by a subjective prodromal awareness that a flush is beginning. This aura is followed by measurable increased heat over the entire body surface. A flush is triggered by a small elevation in core body temperature. The body surface experiences an increase in temperature, accompanied by changes in skin conductance, and then the flush is followed by a fall in core temperature—all of which can be objectively measured. In short, the flush is not a release of accumulated body heat but is a sudden inappropriate excitation of heat release mechanisms. Its relationship to the LH surge and temperature change within the brain is not understood. The observation that flushes occur after hypophysectomy indicates that the mechanism is not dependent on or due directly to LH release. In other words, the same brain event that causes flushes also stimulates GnRH secretion and elevates LH. This is probably secondary to hypothalamic changes in neurotransmitters that increase neuronal and autonomic activity.<sup>236</sup>

Premenopausal women experiencing hot flushes should be screened for thyroid disease and other illnesses. A comprehensive review of all possible causes is available.<sup>237</sup> Clinicians should be sensitive to the possibility of an underlying emotional problem. Looking beyond the presenting symptoms into the patient's life is an important service to the patient and her family that eventually will be appreciated. This is far more difficult than simply prescribing estrogen, but confronting problems is the only way of reaching some resolution.

A striking and consistent finding in most studies dealing with menopause and hormonal therapy is a marked placebo response (at least 51% in the first weeks of treatment)<sup>238</sup> in a variety of symptoms, including flushing. In an English randomized, placebo-controlled study of women being treated with estrogen implants and requesting repeat implants, there was no difference in outcome in terms of psychological and

physical symptoms comparing the women who received an active implant to those receiving a placebo.<sup>239</sup>

A significant clinical problem encountered in our referral practice is the following scenario: a woman will occasionally undergo an apparently beneficial response to estrogen, only to have the response wear off in several months despite ongoing use of prescribed hormonal regimen. Rather than continuously increasing the estrogen dose, it is important to consider altering the mode of delivery (i.e., switching from oral to transdermal) or timing of medication (i.e., if administering orally, consider twice-daily dosing if giving estradiol as opposed to CEE). Importantly, uncommon differential diagnoses, such as pheochromocytoma or carcinoid, must be entertained when encountering recalcitrant vasomotor symptoms that remain unresponsive to increasing doses of estrogen therapy. Additionally, a careful inquiry must be undertaken to search for underlying psychosocial problems. To help persuade a patient that her symptoms are not due to low levels of estrogen, we find it very helpful and convincing to measure the patient's blood level of estradiol and share the result with her.

# Atrophic Changes: The Genitourinary Syndrome of Menopause

With extremely low estrogen production in the late postmenopausal age, or many years after castration, atrophy of vaginal mucosal surfaces takes place, accompanied by vaginitis, pruritus, dyspareunia, and stenosis. Genitourinary atrophy leads to a variety of symptoms that affect the ease and quality of living. Urethritis with dysuria, urgency incontinence, and urinary frequency are further results of mucosal thinning, in this instance, of the urethra and bladder. Recurrent urinary tract infections are effectively prevented by postmenopausal intravaginal estrogen treatment.<sup>240</sup> Vaginal relaxation with cystocele, rectocele, and uterine prolapse, and vulvar dystrophies are not a consequence of estrogen deprivation.

Deprived of estrogen, the vagina loses collagen, adipose tissue, and the ability to retain water. As the vaginal walls shrink, the rugae flatten and disappear. The surface epithelium loses its outer fibrous layer and thins to a few layers of cells, markedly reducing the ratio of superficial to basal cells. As a result, the vaginal surface is left friable, prone to bleeding with minimal trauma. While these changes are occurring, the blood vessels in the vaginal walls narrow, and secretions from sebaceous glands diminish. Over time, the vagina itself contracts and loses flexibility, while the labia minora become paler and smaller. In addition, pH becomes more alkaline, making the vaginal environment less hospitable to lactobacilli and more susceptible to infection by urogenital and fecal pathogens. Infecting organisms can ascend into the urinary system to cause urethritis, urinary tract infections, and cystitis.

Dyspareunia, sometimes with postcoital bleeding, is the inevitable consequence of a severely atrophied vagina and scanty lubrication. Even for women who are not sexually active, atrophic vaginitis can cause itching, irritation, and burning. These symptoms often go unmentioned, and it is important to inspect for signs of vaginal atrophy even in the absence of complaints. **Measuring pH is a simple way to determine estrogen's influence or absence. A pH greater than 4.5 is almost always observed with estrogen deficiency.**<sup>241,242</sup>

Dyspareunia seldom brings older women to our offices. A basic reluctance to discuss sexual behavior still permeates our society, especially among older patients and physicians. Gentle questioning may lead to estrogen treatment of atrophy and enhancement of sexual enjoyment. Objective measurements have demonstrated that vaginal factors that influence the enjoyment of sexual intercourse can be maintained by appropriate doses of estrogen.<sup>243</sup> Both patient and clinician should be aware that a significant response can be expected by 1 month, but it takes a long time to fully restore the genitourinary tract (6–12 months), and clinicians and patients should not be

discouraged by an apparent lack of immediate response. Raloxifene and tamoxifen have little impact on the vaginal epithelium, and vaginal dryness is worse with aromatase inhibitors. Sexual activity by itself supports the circulatory response of the vaginal tissues and enhances the therapeutic effects of estrogen. Therefore, sexually active older women have less atrophy of the vagina even without estrogen.

Although it is argued that genuine stress incontinence is not affected by treatment with estrogen, others contend that estrogen treatment improves or cures stress incontinence in over 50% of patients due to a direct effect on the urethral mucosa.<sup>244,245,246</sup> A meta-analysis concluded that improvement was reported only in nonrandomized studies.<sup>247</sup> Two randomized trials dedicated to this clinical problem failed to demonstrate a beneficial effect of estrogen treatment.<sup>248,249</sup> Most cases of urinary incontinence in elderly women are a mixed problem with a significant component of urge incontinence that is believed to be improved by estrogen therapy. However, the Heart and Estrogen-Progestin Replacement Study (HERS) randomized trial indicated a worsening of incontinence with hormone therapy for both urge and stress incontinence, and the Nurses' Health Study reported a small increase of incontinence in hormone users.<sup>250,251</sup> In the SWAN study, only 15% of incontinent women reported a worsening of urinary incontinence during the menopausal transition, largely because of weight gain.<sup>252</sup> The majority of incontinent women experienced either no change or an improvement. The SWAN study results imply that urinary incontinence is not a major symptom of menopause and the perimenopausal transition.<sup>252,253</sup> In contrast, a Cochrane review from 2012 found that compared to placebo, women who received local estrogen-based therapy for incontinence noted improvement in symptoms.<sup>254</sup> Interestingly, in trials using oral estrogen, women reported worsening of urinary symptoms.<sup>255</sup> **New-onset incontinence at midlife is not a consequence of hormonal changes.**

A decline in skin collagen content, elasticity, and skin thickness that occurs with aging can be considerably avoided by postmenopausal estrogen therapy.<sup>256,257,258,259,260</sup> The effect of estrogen on collagen is evident in both bone and skin; bone mass and collagen decline in parallel after menopause, and estrogen treatment reduces collagen turnover and improves collagen quality.<sup>261,262</sup> One study demonstrated not only an increase in facial skin thickness, but an improvement in wrinkles with topical estrogen.<sup>263</sup> A randomized trial demonstrated improvements in skin elasticity, skin hydration, and skin thickness comparing hormone treatment with placebo.<sup>264</sup> More impressively, data from the U.S. First National Health and Nutrition Examination Survey (NHANES) indicated that estrogen use was associated with a lower prevalence of skin wrinkling and dry skin.<sup>265</sup> Smoking is a major risk factor for facial skin

wrinkling, and hormone therapy cannot diminish this impact of smoking.<sup>266</sup> In a 1-year clinical trial, hormone therapy did not improve skin wrinkling already present.<sup>267</sup>

One of the features of aging in men and women is a steady reduction in muscular strength. Many factors affect this decline, including height, weight, and level of physical activity. Women currently using estrogen have been reported to demonstrate a lesser decline in muscular strength, although at least one study could detect no impact of estrogen.<sup>268,269,270,271,272,273</sup> This is an important issue because of the potential protective consequences against fractures, as well as a benefit due to the ability to maintain vigorous physical exercise.

# Mental Health

The view that menopause has a deleterious effect on mental health is not supported in the psychiatric literature or in surveys of the general population.<sup>215,216,274,275</sup> The concept of a specific menopause-induced psychiatric disorder (involutional melancholia) has been abandoned. Indeed, depression is less common, not more common, among middle-aged women, and the menopause cannot be linked to psychological distress.<sup>2,3,4,5,6,7,8,276</sup> The longitudinal study of premenopausal women indicates that hysterectomy with or without oophorectomy is not associated with a negative psychological impact among middle-aged women.<sup>277</sup> Longitudinal data from the Massachusetts Women's Health Study document that menopause is not associated with an increased risk of depression.<sup>278</sup> Although women are more likely to experience depression than men, this sex difference begins in early adolescence, not at menopause.<sup>279</sup>

The U.S. National Health Examination Follow-up Study includes both longitudinal and cross-sectional assessments of a nationally representative sample of women. This study has found no evidence linking either natural or surgical menopause to psychological distress.<sup>280</sup> Indeed, the only longitudinal change was a slight decline in the prevalence of depression as women aged through the menopausal transition. Results in this study were the same in estrogen users and nonusers.

**A negative view of mental health at the time of the menopause is not justified; many of the problems reported at the menopause are due to life events.**<sup>10,11,281,282</sup> Thus, there are problems encountered in the perimenopausal transition and the early postmenopause that are seen frequently, but their causal relation with estrogen is unlikely. These problems include fatigue, nervousness, headaches, insomnia, depression, irritability, and palpitations. Indeed, at this stage of life, both men and women express a multitude of complaints that do not reveal a gender difference that could be explained by a hormonal cause.<sup>283,284</sup> Nevertheless, midlife women report complaints more often than men,<sup>284</sup> perhaps reflecting the generally negative perceptions and connotations our cultures and societies have attributed to the menopause.

Sleep disturbances are a common complaint during the menopausal transition and in early postmenopausal years.<sup>285</sup> Difficulties with falling to sleep and with staying asleep, sleep interruptions, and early awakenings are all more often encountered during menopause transition and postmenopause compared to during the reproductive stage of aging. Disordered sleep itself can negatively affect health outcomes, including risk of depression.<sup>285</sup> While hormonal changes can affect sleep, it has been difficult to establish the extent to which hormonal changes contribute to poor sleep. Several epidemiologic

studies have demonstrated that men and women, upon entering midlife, experience poor sleep quality.<sup>286</sup> Increased nighttime awakening and overall loss of total sleep time are common in women in the menopausal transition and postmenopausal.<sup>286</sup> Perhaps not surprisingly, nocturnal vasomotor symptoms (hot flushes and night sweats) likely contribute to sleep disturbances.<sup>286</sup> The underlying body temperature dysregulation and stress activation during episodes of vasomotor phenomenon are detrimental to sleep.<sup>286</sup> Studies assessing correlation between vasomotor symptoms and sleep patterns on polysomnography, however, are conflicting suggesting existence of unidentified confounders.<sup>286</sup>

The high prevalence of sleep issues during menopause transition and postmenopause has been suggested to contribute to depressive symptoms and to an overall decline in quality of life.<sup>287,288,289</sup> Two longitudinal cohort studies assessed the new onset of depressive symptoms and disorders during the menopausal transition. The Penn Ovarian Aging Study followed over 8 years 436 women with no history of depression and correlated hormonal changes with the onset of depressed mood.<sup>290</sup> Fifty percent of the women developed an increase in measures of depression and 26% met the criteria for a clinical diagnosis of depressive disorder. Using the women as their own controls, the depression group was 2.5 times more likely to develop clinical depression comparing status during the perimenopausal transition to the premenopausal state. These symptoms during the perimenopausal transition were associated with greater variability (but no average differences) in estradiol levels, suggesting that fluctuations of estradiol can be an important destabilizing factor.

The Harvard Study of Moods and Cycles is a prospective cohort of women with and without histories of depression.<sup>291</sup> In the women who entered the menopausal transition, the risk of new depression was almost doubled compared with premenopausal women, from 9.5% to 16.6%, and this risk was linked to the presence of vasomotor symptoms. Importantly, a statistically significant increase in risk of new depressive symptoms was present only in women with a history of adverse life events (the events are not defined or specified in the report). Also of note, 83% of the women experienced no mood changes.

The SWAN study reported similar results. A first episode of depression in perimenopausal women was linked to poor physical health, anxiety disorders, stressful life events, and hot flushing.<sup>292</sup>

Additional studies have shed further light on the role of VMS, sleep disturbances, and depressive symptoms. In a pooled analysis of eight studies from the InterLACE consortium, it was found that sleep difficulties related to VMS explained to a large extent the relationship between VMS and depressed mood.<sup>288</sup> Interestingly, the OR of

depressed mood associated with often/severe vasomotor symptoms was not significant when adjusted for sleep disturbances at baseline.<sup>288</sup> However, having an often/severe depressed mood remained associated with subsequent risk of VMS.<sup>288</sup> Alternatively, using the SWAN cohort, a study by Kravitz et al. noted that while sleep disturbances increase across the menopausal transition, they did not necessarily worsen over time.<sup>293</sup> It is important to note, however, that vasomotor symptoms were significantly associated with the number of sleep disturbances experienced throughout the menopausal transition.<sup>293</sup>

This area of concern has been very difficult to study. Inconsistent results can reflect variations in study designs, selection of subjects, methods used to measure mood, and the definition of menopausal status. **However, the best reports provide reliable evidence of a vulnerable population of women.** Depressive mood changes are influenced by other factors, including body weight, smoking, PMS (discussed in [Chapter 14](#)), employment, and marital status. **PMS during reproductive years is a strong predictor of depressive symptoms arising in the menopausal transition.**

The most important questions are whether truly normal women experience an increase in depression during the menopausal transition and are there subtle or even clinically apparent psychological problems that identify a susceptible subgroup. In a cross-sectional analysis of the SWAN cohort, it was found that only 5% of women were affected with the “triad” of depressed mood, disturbed sleep, and sexual problems, suggesting that perhaps there is in fact a susceptible group of women predisposed to psychological consequences in the menopause.<sup>294</sup> Cohort studies support the argument that there is a vulnerable group of women who are at risk for experiencing new-onset depressive symptoms during the menopausal transition. Existing data are consistent with the idea that fluctuations in reproductive hormone levels, as is particularly prevalent during the menopause transition, are related to mood symptoms; however, it is impossible to know if this is a true cause-and-effect relationship. Until such a cause-and-effect relationship is elucidated, current efforts should focus on identifying and treating menopausal women suffering from sleep disturbances related to vasomotor symptoms. In a pooled analysis of individual participant data from four RCTs assessing the effect of various interventions for insomnia related to vasomotor symptoms, cognitive behavioral therapy (CBT) was most successful in reducing insomnia symptoms.<sup>289</sup> Exercise, venlafaxine, escitalopram, yoga, and estradiol were also effective, but less so when compared to CBT.<sup>289</sup>

**In summary, most women (over 85%) experience the menopausal transition without mood difficulties. Some however are at greater risk of new-onset depressive symptoms, and this is probably enhanced by hormonal variations and vasomotor symptoms. This “vulnerable” population is likely derived from a group**

**of premenopausal women with underlying psychological underpinnings. Although it can be hypothesized that the perimenopausal hormone milieu makes an individual less able to deal with adverse events in life, concrete data to support this concept are lacking.**

Attempts to study the effects of estrogen on these problems have been hampered by the subjectivity of the complaints (high placebo responses) and the “domino effect” of what a reduction of hot flushes does to the frequency of the symptoms. Using a double-blind crossover prospective study format, Campbell and Whitehead concluded many years ago that many symptomatic “improvements” ascribed to estrogen therapy result from relief of hot flushes—a “domino” effect.<sup>295</sup> Studies that have controlled for menopausal symptoms conclude that mood is very affected by vasomotor symptoms and sleep disturbances, besides reflecting life problems.<sup>149,296</sup>

A study of 2,001 Australian women aged 45–55 focused on the utilization of the health care system by women in the perimenopausal period of life.<sup>13</sup> Users of the health care system in this age group were frequent previous users of health care, were less healthy, and had more psychosomatic symptoms and vasomotor reactions. These women were more likely to have had a significant previous adverse health history, including a past history of premenstrual complaints. This study emphasized that perimenopausal women who seek health care help are different from those who do not seek help, and they often embrace hormone therapy in the hope it will solve their problems. Similar findings have been reported in a cohort of British women.<sup>297</sup> It is this population that is seen most often, producing biased opinions among clinicians regarding the menopause. We must be careful not to generalize to the entire female population the behavior experienced by a few. Most importantly, menopausal women who present to clinicians often end up being treated with estrogen inappropriately and unnecessarily. Nevertheless, it is well established that a woman’s quality of life is disrupted by vasomotor symptoms, and estrogen therapy provides impressive improvement.<sup>298,299,300</sup> Patients are grateful to be the recipients of this “domino” effect.

The Women’s Health Initiative (WHI, discussed later under Menopausal Hormone Therapy) concluded that estrogen-progestin therapy had no beneficial impact on health-related quality of life.<sup>301</sup> However, only 12.7% of the participants had moderate to severe vasomotor symptoms at entry to the study, and the symptom burden in this population can be questioned because the participants were willing to take placebo medication. The overall baseline quality of life in this study was relatively high, and the study participants were older (the average number of years distant from menopause was 12+). This randomized, clinical trial did not study the appropriate population of women in order to assess the effect of hormone therapy on measures of quality of life.

The Women’s International Study of Long Duration Oestrogen after the Menopause

(WISDOM) trial was a randomized, controlled trial in the United Kingdom, Australia, and New Zealand of 3,721 women aged 50–69 treated with either combined 0.625 mg conjugated estrogens to 2.5/5.0 mg medroxyprogesterone or placebo.<sup>302</sup> The original plan was to randomize 22,300 women to the study that would last 10 years. The study was canceled in October 2002 in reaction to the initial reports from the WHI. Unfortunately, the premature cancellation precludes the possibility of any long-term data from WISDOM. In 2,130 women who completed 1 year, there were statistically significant improvements in the treated women in the categories of vasomotor, sexual, and sleep symptoms. Treated women reported a reduction in aching joints and muscles, night sweats, insomnia, and vaginal dryness. The treated group reported more breast tenderness, but the percentages were notably low (16% in the treated group and 7% in the placebo group).

The WISDOM trial investigators argued that the small effects on quality of life reported by the WHI and HERS can be attributed to the insensitive measurement tools used in those clinical trials. The WISDOM trial used a survey tool specifically designed to assess postmenopausal physical and emotional well-being, plus a validated, generic questionnaire, the European quality of life instrument. Only the specific questionnaire detected significant changes; the European generic tool did not. This emphasizes the importance of using the appropriate study tool to investigate this area of postmenopausal health. Similar results with vasomotor symptoms, sleep, and joint complaints were actually reported by the WHI, but with a smaller difference between treated and placebo groups. The WHI survey had only one question devoted to sexuality.

The results of the WISDOM trial are not surprising; they reflect what all clinicians have observed in their own practices. The most important point to be made is this: the WISDOM, WHI, and HERS trials were all similar in that they enrolled postmenopausal women heavily tilted toward the oldest age group without symptoms. It is a simple and logical conclusion that hormone therapy in a younger, symptomatic group of postmenopausal women would produce greater quality of life benefits than that quantified in the clinical trials. All three clinical trials, therefore, underestimated the beneficial impact because of age and symptom status of their participants. However, in the WISDOM trial, even older postmenopausal women who were symptomatic benefited from hormone therapy. Age should not be the sole guiding factor in decision-making.

Emotional stability during the perimenopausal period can be disrupted by poor sleep patterns. Hot flushing does have an adverse impact on the quality of sleep.<sup>303,304,305</sup> Estrogen therapy improves the quality of sleep, decreasing the time to onset of sleep and increasing the rapid eye movement (REM) sleep time.<sup>298,306,307</sup> In the SWAN study, one-third of the women reported sleep problems, even without hot flushes or night sweats, and the prevalence of vasomotor symptoms was associated with an

increased risk of sleep disturbances; hormone therapy improved sleep quality.<sup>308,309</sup> Perhaps, flushing may be insufficient to awaken a woman but sufficient to affect the quality of sleep, thereby diminishing the ability to handle the next day's problems and stresses. An improvement in sleeping with estrogen treatment can even be documented in postmenopausal women who are reportedly asymptomatic.<sup>307</sup>

Thus, the overall "quality of life" reported by women can be improved by better sleep and alleviation of hot flushing. However, it is still uncertain whether estrogen treatment has an additional direct pharmacologic antidepressant effect or whether the mood response is totally an indirect benefit of relief from physical symptoms and, consequently, improved sleep. Utilizing various assessment tools for measuring depression, improvements with estrogen treatment were recorded in oophorectomized women.<sup>310,311</sup> In the large prospective cohort study of the Rancho Bernardo retirement community, no benefit could be detected in measures of depression in current users of postmenopausal estrogen compared with untreated women.<sup>312</sup> Indeed, treated women had higher depressive symptom scores, presumably reflecting treatment selection bias; symptomatic and depressed women seek hormone therapy. Others report that estrogen therapy has a more powerful impact on women's well-being beyond the relief of symptoms such as hot flushes.<sup>298,313,314</sup> In elderly depressed women, improvements in response to fluoxetine were enhanced by the addition of estrogen therapy.<sup>315</sup> In a 12-week, randomized, placebo-controlled trial of 55 perimenopausal women with clinically significant major depression, estradiol treatment with the 100 mg transdermal method significantly improved mood.<sup>316</sup> A similar American short-term study of 34 perimenopausal women with both major and minor depressions treated with 50 mg estradiol transdermally demonstrated improvements independently of an effect on vasomotor symptoms.<sup>317</sup> These small clinical trials argue that estrogen treatment is beneficial for the treatment of clinical depression. This conclusion is supported by the successful treatment of postpartum depression with estradiol treatment.<sup>318,319</sup>

**The most common cause of mood problems is already-existing depression,<sup>9,320</sup> but there does exist a small population of women whose moods are sensitive to hormonal changes.** In the American SWAN study, the prevalence of mood changes increased from the premenopause to the early menopause, from about 10% to about 16.5%.<sup>320</sup> There are three possible explanations: (1) the decline in estrogen at menopause affects neurotransmitters that regulate mood; (2) mood is adversely affected by vasomotor symptoms (the domino theory); and (3) mood is affected by the vicissitudes of life that are commonly prevalent around menopause. Some would argue that these mood swings are in response to the hormonal fluctuations that occur during the perimenopausal years. These fluctuations do indeed occur,<sup>67</sup> but whether they cause any symptoms remains to be determined. It seems logical that individuals with mood

problems can reflect all of these mechanisms.

# Cognition and Dementia

Depending on the method of assessment, evidence for beneficial effects of estrogen on cognition can be found in the literature, especially in verbal memory.<sup>321,322</sup> However, the effects in healthy women are not impressive and perhaps of little clinical value. A short-term study failed to document an objective improvement in memory, although a slight improvement in mood was recorded.<sup>323</sup> Another short-term (3 months) randomized, double-blind study could detect no improvement in cognitive performance compared with placebo treatment.<sup>324</sup> The Melbourne Women's Midlife Health Project could not document an effect on verbal memory during the menopausal transition.<sup>325</sup> A longitudinal study in Chicago could not detect a cognitive decline through the menopause, as assessed by working memory and perceptual speed.<sup>326</sup> On the other hand, estrogen treatment of women immediately after bilateral oophorectomy was associated with improvement in certain, but not all, specific tests of memory, and healthy postmenopausal women taking estrogen scored higher on tests of immediate and delayed recall.<sup>327,328,329</sup> In a case-control study of women aged 55–93 years, estrogen users had better recall of proper names, but no improvement in word recall.<sup>330</sup> Women in the Baltimore Longitudinal Study of Aging who were using estrogen performed better in tests of visual learning and memory.<sup>331,332</sup> In a New York City cohort of women, the use of estrogen was associated with better performance in tests of cognition, and better performance in verbal memory, but the cohort in the Study of Osteoporotic Fractures demonstrated no effect of estrogen use on the age-related decline in cognition.<sup>333,334</sup> In Connecticut, a randomized, placebo-controlled trial demonstrated better reading ability and verbal memory in the estrogen-treated group of postmenopausal women.<sup>335</sup> Perhaps, a lack of agreement is due to the variability in test vehicles and the specific aspects of memory function studied. Furthermore, there is impressive individual variability, and when differences have been observed, they have not been large and perhaps of little clinical importance. In addition, any beneficial effects may be attenuated by progestational agents.<sup>322</sup>

Another possibility for the variable effects of estrogen treatment on cognition is the variability among women in endogenous estrogen levels. Using sensitive assays for free, non-protein-bound estradiol and bioavailable (loosely bound) estradiol, cognitive decline occurred at a greater rate in women with low estradiol levels.<sup>336</sup> Studies of cognition may have to differentiate between low- and high-risk women according to endogenous, biologically active estradiol levels. Similarly, a beneficial effect on cognitive decline has been observed only in women negative for the gene associated with Alzheimer disease, APOE- $\epsilon$ 4, which encodes the  $\epsilon$ 4 allele of the glycoprotein known as apolipoprotein E, which has, as one of its functions, the shuttling of lipids

during neuronal repair.<sup>337</sup>

Up to 3 times as many women as men develop Alzheimer disease. Estrogen is capable of protecting central nervous system function by means of multiple mechanisms. For example, estrogen protects against neuronal cytotoxicity induced by oxidation; estrogen reduces the serum concentration of amyloid P component (the glycoprotein found in Alzheimer amyloid plaques); and estrogen increases synapses and neuronal growth, especially dendritic spine density.<sup>338,339,340</sup> Estrogen protects against the cerebrovascular toxicity exerted by amyloid peptides and promotes synaptic formation and neuronal growth and survival.<sup>341,342,343</sup> Progestational agents do not exert similar actions.

Case-control and cohort findings indicated that Alzheimer disease and related dementia occurred less frequently (perhaps as much as 60% less) in estrogen users, and the effect was greater with increasing dose and duration of use.<sup>344,345,346</sup> In the Baltimore Longitudinal Study of Aging (a prospective cohort), the risk of Alzheimer disease was 54% reduced; in a cohort in New York City, the risk was reduced 60%; and in the Italian Longitudinal Study of Aging, the risk was 72% reduced in estrogen users.<sup>347,348,349</sup> The findings are not uniformly positive; a case-control study with accurate information on clinical diagnoses and estrogen use from the U.K. General Practice Research Database could detect no impact of estrogen treatment on the risk of developing Alzheimer disease, but the number of estrogen users was very small.<sup>350</sup>

The short-term administration of unopposed estrogen to patients with Alzheimer disease (secondary prevention) has been reported to improve cognitive performance, but mostly to have no effect.<sup>351,352,353,354,355</sup> The administration of combinations of estrogen and progestin has also failed to demonstrate a beneficial impact in Alzheimer disease.<sup>356</sup> The presence of estrogen therapy has been reported to enhance the beneficial response to tacrine in women with Alzheimer disease,<sup>357</sup> but overall, the evidence is consistent with a failure of estrogen to influence already-existing Alzheimer disease or other forms of dementia.<sup>358</sup>

**The data do support, however, a primary preventive effect.** Most revealing is a prospective cohort study of women living in Cache County, Utah.<sup>359</sup> Hormone therapy provided about a 41% reduced risk of developing Alzheimer with any use and an 83% reduction with 10 or more years of use. This cohort also demonstrated improved cognition in estrogen users.<sup>360</sup> Most importantly, if women had initiated hormone therapy within a period of time that encompassed 10 years before the development of clinical symptoms, there was no effect. The Utah study strongly suggested that hormone therapy must be used for a significant duration of time very early in the postmenopausal period in order to have an impact on the risk of Alzheimer disease. As neurons become

changed by the pathology of dementia, they lose their ability to respond favorably to estrogen.<sup>293</sup>

The importance of timing is supported by findings from the large WHI clinical trial. The oldest women in the WHI being treated with either estrogen alone or combined estrogen-progestin (treatment began at age 65 or older) had impaired cognition and an increased risk of dementia.<sup>361,362,363</sup> In a subset of these women, MRI scans demonstrated greater brain atrophy in the women receiving hormone therapy.<sup>364</sup> The mechanism for this adverse effect of hormonal therapy in old women may be a neurotoxic action because the WHI study with MRI scanning could not detect an increase in ischemic brain lesions.<sup>365</sup> Smaller MRI studies of younger women treated with hormone therapy found beneficial trophic changes in brain morphology, associated with improved cognition.<sup>366,367,368</sup> The KEEPS-Cognitive and Affective Study was an ancillary study to the KEEPS, a randomized, double-blind, placebo-controlled trial of menopausal hormone therapy (further discussed later in this chapter under the section on Menopausal Hormone Therapy). While the parent study examined the timing hypothesis from the perspective of cardiovascular disease, the ancillary study examined the timing hypothesis from the perspective of cognition and mood.<sup>369</sup> In KEEPS, postmenopausal women within 3 years of the last menstrual period were randomized to oral versus transdermal estrogen versus placebo. Over a 4-year intervention period, 220 women received daily 0.45 mg oral conjugated equine estrogens (o-CEEs), 211 women received 50 µg/day transdermal estradiol (t-E2), and 262 women were assigned to placebo pills and patches. Women assigned to oral and transdermal estrogen additionally received micronized progesterone 200 mg/day for the first 12 days of each month. The primary outcomes for the Cognitive and Affective ancillary study included the Modified Mini-Mental State Examination, verbal learning/memory, auditory attention/working memory, visual attention/executive function, and speeded language/mental flexibility, and a mood measure (Profile of Mood States).<sup>369</sup> The KEEPS cognitive study failed to demonstrate any neuroprotective effects of menopausal hormone therapy on the studied cognitive outcomes. However, improvement in mood parameters (tension-anxiety, depression-dejection, anger-hostility, fatigue, vigor, and confusion-bewilderment) was observed in the subgroup of women assigned to o-CEE.<sup>369</sup> In a subsample of KEEPS subjects, the effect of hormone therapy on beta-amyloid protein deposition was studied using positron emission tomography (PET) scan. Of the 112 KEEPS eligible participants, 61 women with a median age of 60 were included in the analysis. While there were no differences in baseline characteristics of the subjects, carriers of the apolipoprotein e4 allele (a known risk factor for developing Alzheimer disease) who were assigned to transdermal estradiol arm of the clinical trial had evidence of reduced beta-amyloid protein deposition on PET scan.<sup>370</sup> While the

sample size is small, KEEPS data suggest that effects of estrogen on the brain may differ by route and formulation of hormone regimen.<sup>370</sup>

**The theme that emerges is that maintenance of health in target organs by estrogen requires normal tissue, a principle of timing that will also be discussed in regard to the heart later in this chapter under the section on Menopausal Hormone Therapy. Following the failure of secondary prevention trials to demonstrate a beneficial impact of hormone therapy on coronary disease in older women, it is increasingly argued that healthy cardiovascular endothelium is needed to respond to estrogen; that by the time, the endothelium is involved with excessive atherosclerosis, it is too late for estrogen to exert a beneficial effect. A similar argument is made for brain tissue, focusing on biochemical and signaling pathways that are progressively compromised with the neuronal involvement with disease.<sup>371</sup> The requirement for normal tissue, at least in the heart and in the brain, would explain the beneficial effects in studies of primary prevention and the lack of effect in secondary prevention trials.**

# CARDIOVASCULAR DISEASE

---

Diseases of the heart are the leading cause of death for women in the United States, followed by cerebrovascular disease and malignant neoplasms. In 2016, one in four female deaths were from CHD compared with one in eight women who develop breast cancer.<sup>372</sup> More female deaths in 2016 were caused by cardiovascular diseases than the combined total from cancer, chronic lower respiratory disease, Alzheimer disease, accidents, and diabetes mellitus.

Most cardiovascular disease results from atherosclerosis in major vessels. The risk factors are the same for men and women: family history of cardiovascular disease, high blood pressure, smoking, diabetes mellitus, an abnormal cholesterol/lipoprotein profile (Table 17.6), and obesity. However, when controlling for these risk factors, men prior to age 40 have a risk of developing CHD twice that of women. With increasing age, this advantage is gradually lost, and cardiovascular disease becomes the leading cause of death for both older women and older men.

Cardiovascular disease, especially atherosclerosis, is a consequence of multiple metabolic changes that interact with each other:

## TABLE 17.6 The Optimal Cholesterol/ Lipoprotein Profile

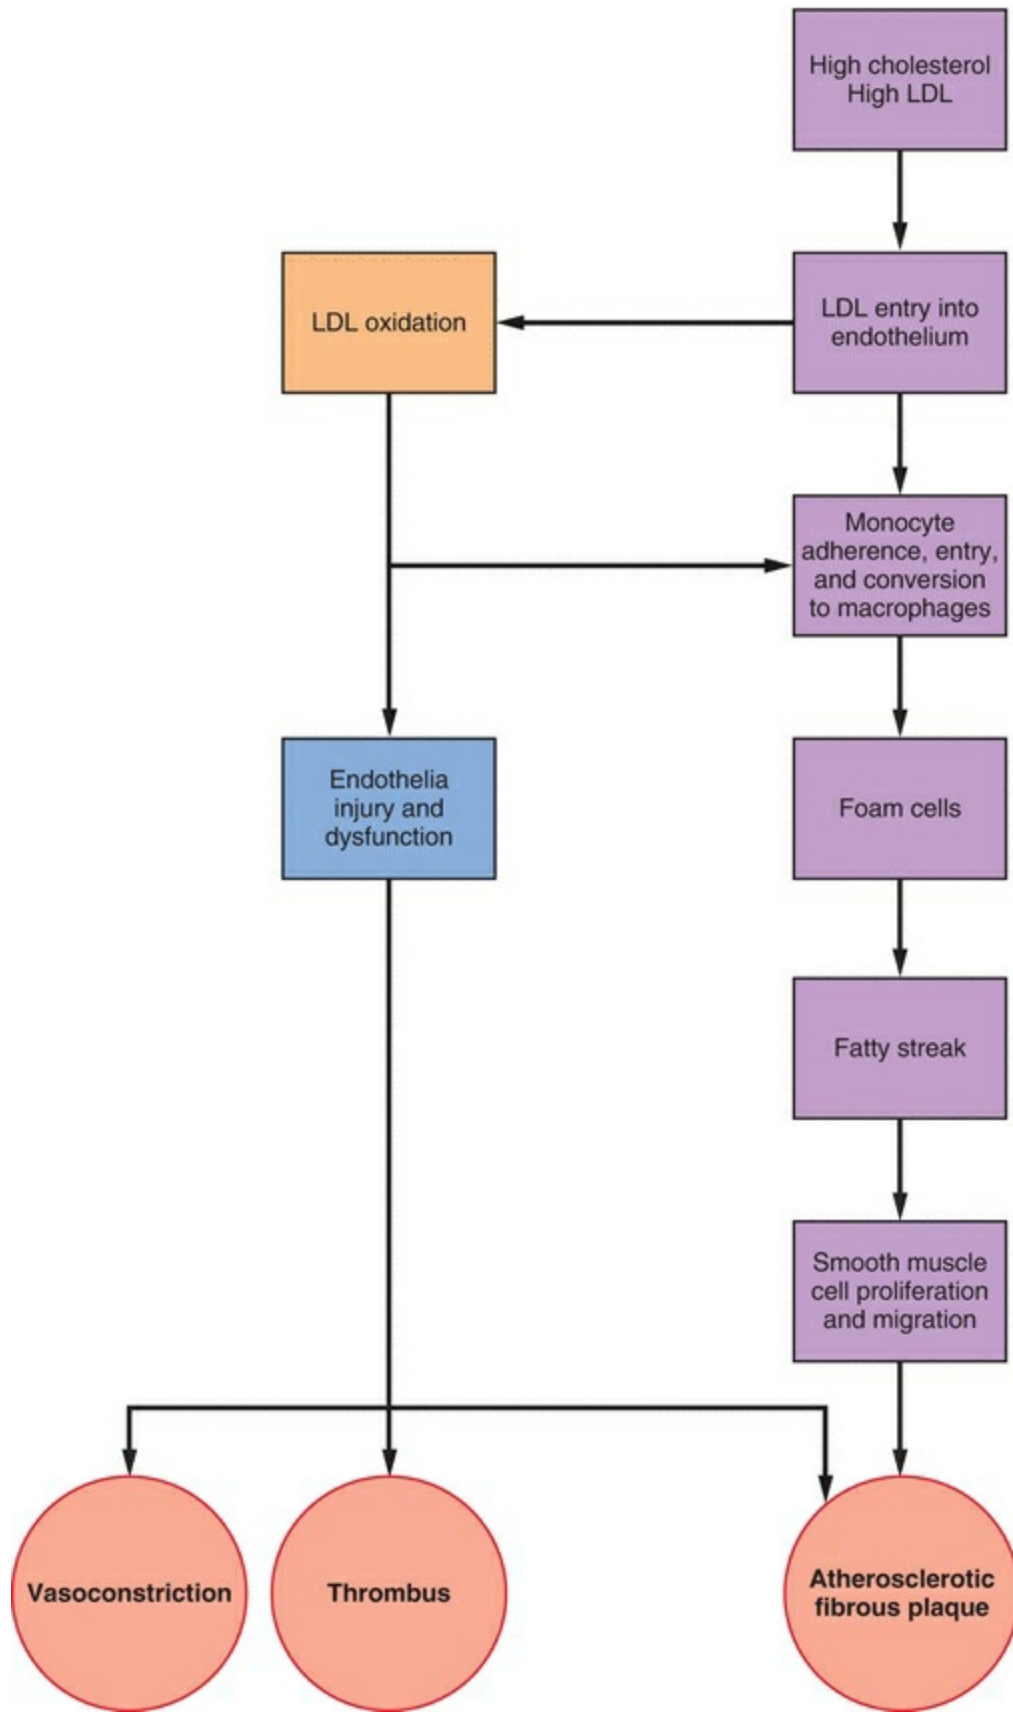

Total cholesterol	<200 mg/dL
HDL cholesterol	>50 mg/dL
LDL cholesterol	<100 mg/dL
Triglycerides	<150 mg/dL

- Adverse changes in the circulating lipid-lipoprotein profile.
- Oxidation of low-density lipoprotein (LDL), producing a modified LDL that is chemotactic for circulating monocytes and inhibits macrophage motility (thus trapping macrophages in the intima) and that causes cell injury and death in the endothelium.
- Endothelial injury and dysfunction affecting nitric oxide and prostacyclin production.
- Macrophage migration and functions, influenced by growth factors and cytokines.
- Proliferation and migration of smooth muscle cells, also influenced by growth factors and cytokines; these cells become the dominant cell type and the source of the connective tissue matrix in the atherosclerotic lesion, the fibrous plaque.
- Vasoconstriction and thrombogenic events.
- Remodeling of coronary arteries. An artery is able to respond to a developing atherosclerotic plaque by increasing its overall diameter in an attempt to maintain flow.<sup>373</sup>

The mechanism of this adaptive remodeling is not known, but the extent of this process must affect the risk of occlusion and infarction.

There is an established sequence of events leading to atherosclerosis (**Figure 17.10**). The process starts with endothelial dysfunction that leads to the fatty streak in arterial vessels, the precursor to clinically significant lesions. The fatty streak lesion, therefore, antedates the fibrous plaque, developing under the endothelial surface and dominated by fat-laden macrophages (the foam cells). The damaged endothelium expresses cytokines, adhesion molecules, and other inflammatory agents that are involved in the formation of atherosclerotic plaques. The formation of a plaque is initiated by the aggregation and adherence of circulating monocytes (macrophages) to a site on the arterial endothelium, stimulating an inflammatory response. When the

monocytes penetrate through the endothelium and enter the intima, they become loaded with lipids and converted to foam cells. Modification of LDL, especially oxidation, is crucial in this conversion of monocytes to foam cells. The adherence of monocytes to endothelium can be induced by elevated cholesterol and LDL cholesterol in the circulation. Most of the cholesterol that accumulates in atherosclerotic plaques is derived from circulating LDL cholesterol. As plaques become significant in size, they are prone to instability, rupturing, and creating a prothrombotic state. Matrix metalloproteinase enzymes are secreted by inflammatory cells and smooth muscle cells. These enzymes digest the proteins in the fibrous cap of an atherosclerotic plaque, making the plaque unstable and predisposed to rupture. **Estrogen induces matrix metalloproteinase production or activity, which digests the fibrous cap of a plaque exposing the underlying thrombogenic collagen, and this is believed to be the mechanism involved in the adverse thrombotic effects of estrogen in the presence of established atherosclerosis.**<sup>374</sup> In addition, 27-hydroxycholesterol, a cholesterol metabolite elevated in atherosclerotic lesions, competitively antagonizes estrogen receptor activity in cardiovascular epithelium.<sup>375</sup>

**FIGURE 17.10**

During the reproductive years, women are “protected” from CHD. For this reason, women lag behind men in the incidence of CHD by 10 years, and for myocardial infarction and sudden death, women have a 20-year advantage. The reasons for this are complex, but a significant contribution to this protection can be assigned to the higher high-density lipoprotein (HDL) levels in younger women, an effect of estrogen and lower levels of testosterone. Throughout adulthood, the blood HDL cholesterol level is about 10 mg/dL higher in women, and this difference continues through the postmenopausal years. Total and LDL cholesterol levels are lower in premenopausal women than in men, although the levels gradually increase with aging and after menopause they rise rapidly.<sup>376,377,378,379,380</sup> After menopause, the risk of CHD doubles for women as the atherogenic lipids at about age 60 reach levels greater than those in men. These changes can be favorably reduced by dietary modifications.<sup>381,382</sup> Of course, these lipid changes at menopause (whether natural or surgical) can be reversed with estrogen treatment.<sup>383</sup>

Prospective studies have documented the strong association between total cholesterol and CHD in women, although CHD risk appears at higher total cholesterol levels for women than for men.<sup>384,385</sup> Women with total cholesterol concentrations greater than 265 mg/dL have rates of CHD 3 times that of women with low levels. Even in elderly women, a high total cholesterol remains a significant predictor of heart disease, but the strength of the association between the cholesterol level and cardiovascular disease decreases with aging, and by age 80, the cost and benefits may not justify cholesterol intervention.<sup>386</sup> This is the reason for ceasing lipoprotein screening after age 75 in patients with normal lipids. However, this decision should be individualized, taking into account the vigor and health of the patient.

The strongest predictor of CHD in women is a low HDL cholesterol.<sup>384,385,387</sup> The average HDL cholesterol in women is approximately 55–60 mg/dL. A decrease in HDL cholesterol of 10 mg/dL increases CHD risk by 40–50%. In women (and men) who had normal total cholesterol and LDL cholesterol levels, but low HDL cholesterol levels, treatment with lovastatin reduced the risk of an acute major coronary event by approximately 37%.<sup>388</sup> High HDL cholesterol levels are uncommon in women with CHD, but even women with high levels do develop CHD.<sup>389</sup> **Because of the increased risk of CHD observed in individuals with low HDL, it is appropriate to be concerned when HDL cholesterol levels are less than 50 mg/dL.** It should be emphasized that modest elevations in blood pressure markedly increase the overall cardiovascular risk associated with an elevated LDL cholesterol or a low HDL cholesterol.

Keep in mind that low HDL cholesterol levels are a component of the metabolic syndrome related to insulin resistance. The metabolic syndrome is partly a result of

heredity but is also strongly influenced by obesity and physical inactivity. In the United States, the overall estimated prevalence of the metabolic syndrome is 24%, higher in women (40% by age 60) and increasing with age.<sup>390</sup> The prevalence increases with increasing body weight, from about 5% in normal-weight individuals to 60% in obese men and women, and the prevalence is highest in Mexican Americans and lowest in Blacks.<sup>391</sup>

# Metabolic Syndrome and Cardiovascular Disease

As defined by the National Heart, Lung, and Blood Institute and the American Heart Association, a diagnosis of metabolic syndrome requires the presence of any three of the following five clinical characteristics<sup>392</sup>:

1. Increased waist circumference (population specific, >88 cm for women in the United States)
2. Increased blood pressure ( $\geq 130$  mm Hg systolic;  $\geq 85$  mm Hg diastolic) or receiving medication for hypertension
3. Increased triglycerides ( $\geq 150$  mg/dL) or receiving medication for hypertriglyceridemia
4. Decreased HDL cholesterol ( $< 50$  mg/dL) or receiving medication for reduced HDL
5. Increased fasting glucose ( $\geq 100$  mg/dL) or receiving medication for hyperglycemia

An increasing prevalence of metabolic syndrome during the menopausal transition is correlated with increasing androgen dominance, as estrogen secretion declines.<sup>393,394</sup> Adiposity of the trunk is a risk factor for CHD in women and is associated with a relatively androgenic hormonal state, as well as hypertension, and disorders of lipid and carbohydrate metabolism.<sup>395</sup> Central fat distribution in women is positively correlated with increases in total cholesterol, triglycerides, and LDL cholesterol and negatively correlated with HDL cholesterol.<sup>396</sup> The atherogenic lipid profile associated with abdominal adiposity is at least partly mediated through an interplay with insulin and estrogen.<sup>397</sup> It is worth noting that there is a strong correlation between the magnitude of the worsening in cardiovascular risk factors (lipid and lipoprotein changes, blood pressure, and insulin levels) and the amount of weight gained during the menopausal transition.<sup>398</sup> Attention to weight gain during middle age is one of the most important components of good preventive health care. However, **weight gain at menopause is not an effect of hormonal changes, but rather it reflects aging-related alterations in lifestyle such as changes in diet and exercise that accompany aging.**<sup>398</sup>

Current recommendations regarding the optimal cholesterol/lipoprotein profile are more aggressive, urging more intensive treatment aimed at lowering LDL cholesterol levels; in the presence of CHD, the goal is to lower LDL cholesterol to less than 100 mg/dL.<sup>399</sup> Cholesterol-lowering drugs, specifically the statin family, have been repeatedly demonstrated in clinical trials to have a marked reduction in the risk of

clinical cardiovascular events in both men and women.<sup>400,401</sup>

Triglycerides are also an important risk factor for CHD in women, but are most commonly encountered in individuals with the metabolic syndrome.<sup>399</sup> If the triglyceride level is greater than 400 mg/dL and the HDL cholesterol is less than 50 mg/dL, the risk of heart disease is substantially increased. Patients with an elevated triglyceride level and a positive family history for heart disease most likely have an autosomal dominant disorder classified as familial combined hyperlipidemia. This disorder accounts for most myocardial infarctions in women less than 40 years old. Triglyceride levels of 150–200 mg/dL are considered borderline elevated. Triglyceride levels can be elevated because of obesity, smoking, and lack of exercise. Weight loss alone can return elevated triglyceride levels to normal.

Observational studies and clinical trials indicate that the major determinants of blood lipid levels are the same for both sexes. A diet high in saturated fatty acids and dietary cholesterol unfavorably increases blood lipids. Excess caloric intake and obesity decrease HDL cholesterol and increase total cholesterol, LDL cholesterol, and triglycerides. Smoking decreases HDL cholesterol (and also produces lower estrogen levels and an earlier menopause). Genetic defects of receptor-mediated cholesterol uptake account for only a small percentage of hyperlipidemia in men and women. There is also evidence that men and women who had impaired fetal growth have increased levels of cholesterol and LDL cholesterol in middle age.<sup>402</sup> The speculation is that impaired liver growth in utero produces a permanent adverse change in cholesterol and lipoprotein metabolism. Reduced fetal growth also leads in adulthood to insulin resistance and lower HDL cholesterol levels, most severe in those who become obese.<sup>403</sup>

# C-Reactive Protein and Cardiovascular Disease

The immune system (monocytes, cytokines, and cell adhesion molecules) and inflammatory processes both play an active role in the process of atherosclerosis.<sup>404</sup> Studies indicate that C-reactive protein (CRP) is a marker of cardiovascular risk in both men and women.<sup>405,406,407</sup> This risk is limited, however, to arterial disease; CRP levels are not linked to venous thrombosis or pulmonary embolus.<sup>405</sup> CRP predicts an increased risk of cardiovascular events even in individuals who have normal lipid levels, and, therefore, it is argued that both CRP and lipid profiles should be used for screening purposes.<sup>407,408</sup>

CRP is a protein synthesized in the liver and atherosclerotic arteries and was given its name because it reacts with the C-polysaccharide of *Streptococcus pneumoniae*. Thus, the circulating level of CRP increases in response to various inflammatory stimuli, but specifically bacterial infections and chronic inflammatory conditions such as systemic lupus erythematosus (SLE). Sensitive assays now detect small increases associated with low-grade inflammation in the vascular system.

Increased levels of CRP in patients with angina predict poor outcome, an increase in the relative risk of a coronary event. Prospective studies have documented an increased risk of cardiovascular events in patients without known cardiovascular disease who have high CRP levels, an association that is even greater in smokers.<sup>409</sup> Higher mean levels are found in both men and women who subsequently have myocardial infarctions. Stroke and peripheral vascular disease are also increased in men with higher CRP levels, and in women, CRP is also elevated in stroke.<sup>410</sup> In a meta-analysis of 14 prospective studies, individuals with CRP levels in the top third compared with individuals in the bottom third had a twofold increase in relative risk for CHD.<sup>411</sup> Thus, CRP levels have predictive value in both healthy individuals and individuals with cardiac disease. In addition, statin treatment lowers CRP levels,<sup>412</sup> and evidence indicates that statins and aspirin achieve greater benefits in individuals with high CRP levels.<sup>405,413</sup>

In general, studies have indicated that oral estrogen treatment (with or without progestin) increases CRP levels and raloxifene does not. In a double-blind, randomized trial, menopausal hormone therapy and raloxifene equally lowered homocysteine levels (a marker for vascular risk), but estrogen-progestin treatment increased CRP levels, whereas raloxifene had no effect.<sup>414</sup> These results were duplicated in a Dutch randomized study.<sup>415</sup> Tibolone (discussed later in this chapter under the section on Menopausal Hormone Therapy) increases CRP levels to the same degree as oral estrogen therapy.<sup>416</sup> A cross-sectional study found higher levels of CRP in healthy

postmenopausal women using hormone therapy.<sup>417</sup> In the PEPI randomized trial, hormone therapy increased CRP levels, but the levels of E-selectin, another marker of inflammation, were reduced.<sup>418</sup>

An estrogen-induced increase in CRP levels may be due to the known stimulant effects of estrogen on hepatic synthesis of proteins, especially because of the first-pass phenomenon with oral administration. For this reason, transdermal estrogen treatment does not change CRP levels.<sup>416,419,420</sup> Studies on multiple inflammatory markers report that oral estrogen therapy increases only CRP, the only marker synthesized in the liver. In fact, oral hormone therapy while increasing CRP reduces the circulating levels of other inflammatory markers (E-selectin, intercellular adhesion molecule-1, vascular cell adhesion molecule-1, monocyte chemoattractant protein-1, and tumor necrosis factor- $\alpha$ ) with inconsistent effects on interleukin-6 (IL-6).<sup>421,422</sup> Most importantly, it is not certain that the decrease in CRP levels with statins and the increase with estrogen are actually instrumental in clinical outcomes or reflect other effects. Thus, raising or lowering CRP levels will not necessarily increase and decrease the risk of clinical disease. A study from the WHI confirmed the correlation between baseline levels of CRP and an elevated risk of CHD, **but the increase in CRP induced by oral hormone therapy did not further increase this risk!**<sup>423</sup> **The uncertainties and questions regarding the clinical relevance of CRP levels make it premature to conclude that changes in CRP levels with hormone therapy have any direct clinical consequence. This does not detract, however, from the utility of CRP levels in quantifying the overall risk of cardiovascular disease in an individual patient.**

# Homocysteine and Cardiovascular Disease

Hyperhomocysteinemia is associated with an increase in risk for CHD.<sup>407</sup> Increasing folic acid intake and hormone therapy both reduce the circulating levels of homocysteine. In the WHI observation study, assessment of inflammation and hemostasis biomarkers for predicting stroke was undertaken in postmenopausal women, and homocysteine was not found to be of any value as a predictive biomarker in this population.<sup>410</sup> **The value of homocysteine measurements in a screening program and the efficacy of therapy directed to lowering homocysteine levels remain to be determined.**

# Lipoprotein(a) and Cardiovascular Disease

Lp(a) is composed of two parts, a lipoprotein particle that is similar to LDL and a glycoprotein component that resembles a clotting protein. Lp(a) is an independent risk factor for CHD. Menopausal hormone therapy has been associated with reduction in circulating Lp(a) levels.<sup>424</sup> Unlike other markers, the levels of Lp(a) are unaffected by lifestyle, and no clinical use has been established for Lp(a) measurements.

# Sex Steroids and Cardiovascular Disease

By a large margin, the leading cause of death among women continues to be CHD. Coronary atherosclerosis is a lifelong process that varies in its slope of development according to the presence or absence of risk factors. The landmark Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study documented the presence of fatty streaks in adolescents and an increasing prevalence with increasing age.<sup>425</sup> The PDAY study further established that abnormal lipid profiles early in life are a major factor in determining the extent and age of onset of atherosclerosis.<sup>426</sup> It is important for clinicians caring for women to appreciate the importance of premenopausal atherosclerosis and to understand that appropriate medical interventions can reduce the risk of later clinical events. Because atherosclerosis begins early in life, it is logical to conclude that the postmenopausal risk of coronary clinical events is influenced by the degree of coronary artery atherosclerosis already present at the time of menopause.

Women with POI (older terminology is “premature ovarian failure or POF”) are at increased risk for cardiovascular disease.<sup>427</sup> In other words, there is an inverse relationship between the risk of cardiovascular disease and the age of menopause.<sup>428</sup> Endothelial function in women with POI is impaired, as measured by dilation of the brachial artery in response to blood flow, a response known to be mediated by estrogen-modulated endothelial nitric oxide.<sup>429,430</sup> This association between endothelial dysfunction and hypoestrogenemia is reinforced by the observation that endothelial dysfunction in women with POF was improved by hormone therapy.<sup>429</sup>

An important contribution to the gender difference in cardiovascular disease prevalence and age of onset is the favorable effect of estrogen on important endothelial events. Vasodilatory and antithrombotic activities can be attributed to endothelial production of nitric oxide and prostacyclin, a process favorably influenced by estrogen. Hypercholesterolemia adversely affects this important endothelial process, and estrogen protects this important endothelial function in the presence of hypercholesterolemia.<sup>431</sup> Estrogen inhibits the oxidation of LDL and also protects against the toxic effects of oxidized LDL on the endothelium. Women in the SWAN study who complained of hot flushing had more evidence of subclinical cardiovascular disease, such as aortic calcification, compared to those without hot flushes.<sup>432</sup>

A Chinese comparison study concluded that Chinese men and women with angiographically determined coronary artery disease differ in the circulating sex steroid hormone milieu, compared with age-matched healthy individuals.<sup>433</sup> Straightforward reasoning has led investigators to connect the different prevalence of coronary artery disease in men and women to the obvious differences in circulating sex steroids determined by the testicles and ovaries. The newly appreciated importance of estrogen

in the premenopausal years has added strength to this connection. For many years, it has been generally believed that higher estrogen exposure in women protects against coronary artery disease, and the difference in coronary artery disease prevalence between men and women diminishes after menopause because of the loss of estrogen. At the heart of the matter is the gonadal difference between men and women.

Acute coronary events in premenopausal women occur more frequently when estrogen levels are the lowest during the menstrual cycle.<sup>434</sup> In the national SWAN study, cardiovascular risk factors were more favorable in women with higher levels of estrogen and less favorable in women with longer menstrual cycles.<sup>435</sup> Even amenorrheic athletes in good physical condition have demonstrated endothelial dysfunction, a condition that responded favorably to estrogen-containing oral contraceptives.<sup>436,437</sup>

In the WISE (Women's Ischemia Syndrome Evaluation) study, a study of premenopausal women undergoing coronary angiography for suspected myocardial infarction, coronary artery disease was more prevalent in those women who had low estrogen levels because of hypothalamic suppression.<sup>438</sup> These findings are similar to the pioneering studies in monkeys that demonstrated acceleration of atherosclerosis in animals with low estrogen because of stress-induced hypothalamic suppression, an effect that could be prevented by oral contraceptive treatment.<sup>439,440,441</sup> Postmenopausal women studied with coronary angiography in the WISE study who had used oral contraceptives in the past had less coronary artery disease.<sup>442</sup> In addition, premenopausal women with coronary artery disease have lower circulating levels of estrogen compared with normal women.<sup>443</sup>

Depression is a recognized risk factor for heart disease, but its contribution to premenopausal atherosclerosis is just beginning to be appreciated. Premenopausal monkeys that exhibit depressive behavior (induced by their lower social rank in a colony of animals) develop a more adverse lipid profile and an increasing degree of atherosclerosis when fed atherogenic diets.<sup>444</sup> Premenopausal women with a history of recurrent depression and without known coronary disease are more likely to have coronary and aortic calcification, a marker for early atherosclerosis.<sup>445</sup> The SWAN study found more aortic calcification in black women with depressive symptoms, although an association between coronary calcification and depression in black or white women could not be detected.<sup>446</sup>

Thus, hypoestrogenemia in the premenopausal years, whatever the cause, can increase the progression of atherosclerosis. This would include suppressed ovarian function associated with stress, depression, or intense athletic activity. The progressively deleterious effects of hypoestrogenemia include endothelial dysfunction,

lower levels of HDL cholesterol, an increase in central obesity, and possibly depression. **In monkeys and in women, lipid effects account for only 25–30% of the atheroprotective effects of estrogen.**<sup>447,448</sup>

A vast literature has documented multiple mechanisms favorably influenced by estrogen that would inhibit the development of atherosclerosis.<sup>449</sup> Clinicians tend to view testosterone as an estrogen opponent, and this is supported, for example, by studies such as lipid responses to testosterone that move in the opposite directions to those of estrogen.<sup>450</sup> Both beneficial and detrimental vascular actions of testosterone have been described in in vitro and animal studies. Clinical studies in women have in general supported an association between hyperandrogenism and an increase in risk for cardiovascular disease. The lipid and lipoprotein profile in androgenized women with polycystic ovaries (who are also exposed to relatively lower estrogen levels over time) is similar to the male pattern with higher levels of cholesterol, triglycerides, and LDL cholesterol and lower levels of HDL cholesterol, and this abnormal pattern is independent of body weight.<sup>451,452,453,454,455</sup> An adverse lipid and lipoprotein profile is a distinguishing feature of these patients even when body mass index (BMI), insulin, and age are controlled in case-control studies.<sup>456</sup> Subclinical atherosclerosis can be demonstrated by carotid ultrasonography to be prevalent in premenopausal women with a history of anovulation and polycystic ovaries.<sup>457</sup> In women undergoing coronary angiography, the prevalence of polycystic ovaries is increased, and women with polycystic ovaries have more extensive coronary atherosclerosis.<sup>458</sup> In the Nurses' Health Study, women with very irregular cycles compared to women with regular cycles had an adjusted increased risk of CHD.<sup>459</sup> **Thus, anovulatory women with polycystic ovaries develop risk factors for atherosclerosis and ultimately clinical disease comparable with that found in older postmenopausal women.**

Given the variability in circulating sex steroid levels between individuals, between sexes, and within individuals, we should not be surprised that random blood sampling does not always document meaningful differences in blood levels of gonadal steroids in men and women with coronary artery disease. Nevertheless, some cross-sectional studies have documented lower circulating testosterone levels in men with coronary artery disease and higher levels in men with a reduced risk of metabolic syndrome.<sup>460,461</sup> A prospective cohort study determined that lower testosterone levels were associated with an increased risk of developing metabolic syndrome in men.<sup>462</sup> Men with heart failure demonstrate improvements in symptoms and functional capacity when treated with testosterone.<sup>463</sup>

In healthy postmenopausal women, higher androgen levels are associated with increased metabolic markers for the risk of coronary artery disease, and increasing

testosterone levels during the perimenopausal transition correlated with an increasing prevalence of metabolic syndrome in the SWAN study.<sup>393,464,465</sup> Higher testosterone levels, although still in the normal range, have also been found to correlate with a reduction in atherosclerosis progression in naturally postmenopausal women.<sup>466,467</sup>

**In summary, existing data suggest that higher testosterone levels within the normal physiologic range may be protective against atherosclerosis (perhaps by target tissue aromatization to estrogens), whereas elevated androgen levels above the normal range, such as in anovulatory women with polycystic ovaries, are atherogenic.**

The important studies in women and monkeys reviewed above indicate that there exists an innate trajectory of atherosclerosis for each individual that can be modulated by various risk factors and that the slope of this process determines the age of onset for clinical events.<sup>468</sup> The contribution of premenopausal atherosclerosis to the development of clinical events highlights the important role for clinicians in aggressively promoting preventive interventions that can favorably change the slope of progression of atherosclerosis. An important risk factor is exposure to protective levels of estrogen at all stages of life. Conditions associated with hypoestrogenemia during the premenopausal years, therefore, require evaluation and treatment. There are many causes of hypoestrogenemia, and the treatments will vary according to the etiology. When indicated, appropriate hormone treatment can reduce the risk of cardiovascular disease later in life. In addition, appropriate interventions in insulin-resistant women with the metabolic abnormalities associated with polycystic ovaries can reduce the risks of both cardiovascular disease and diabetes mellitus.

A logical continuum of this reasoning is that hormone therapy in the early postmenopausal years likewise can provide primary prevention of clinical coronary disease. **The “timing hypothesis” proposes that adequate estrogen exposure prior to the onset of clinical events provides protection against cardiovascular disease (discussed in further detail under the section on Menopause Hormone Therapy).** A meta-analysis of 23 randomized hormone therapy trials concluded that treatment reduced the risk of CHD events in younger women compared with older women (10 or more years since menopause or >60 years of age).<sup>469</sup> This is a conclusion that is less firm now than when first proposed, because most of these trials were not designed to measure an endpoint of cardiovascular disease. However, another meta-analysis by the same authors concluded that hormone therapy reduced overall mortality in women with an average age of less than 60.<sup>470</sup>

## Cardiovascular Disease: Concluding Thoughts

In the last 30 years, mortality from CHD has declined substantially in the United States. Improvements in medical and surgical care can account for some of this decline, but 60–70% of the improvement is due to timely implementation of preventive measures. Excellent data from epidemiologic studies and clinical trials demonstrate substantial contributions from strategies such as smoking cessation, blood pressure reduction, and lowering of cholesterol toward a documented decline in stroke and heart disease–related morbidity and mortality.<sup>471,472,473</sup> The most effective means to lower CHD in a population is through primary prevention, especially smoking cessation and body weight reduction. While physiologic levels of estrogen are clearly relevant for maintenance of cardiovascular health, however, the impact of exogenous estrogen on cardiovascular risk in aging postmenopausal women who are remote from the FMP is not clearly delineated.<sup>474</sup> When attempting to understand the role of estrogens on cardiovascular risk, it is important to distinguish between endogenous and exogenous estrogens. In addition, more recent work has begun assessing the role of additional reproductive hormones (i.e., FSH) as well as the relevance of vasomotor instability in itself as predictors of cardiovascular risk.<sup>474</sup> While the loss of premenopausal estradiol levels is felt to contribute to the escalation in cardiovascular disease in postmenopausal years, the bulk of existing clinical data are “associative.” Appropriately designed studies are needed to better understand the spectrum of players (hormonal and nonhormonal) that may be relevant as causative to the processes that result in risk escalation for cardiovascular disease as women progress along the stages of reproductive aging.<sup>474</sup>

# MENOPAUSAL HORMONE THERAPY

---

There is little question that estrogen is the most effective of available remedies for women who suffer from bothersome vasomotor symptoms such as hot flashes and night sweats or from consequences of atrophy of reproductive tract tissues that naturally follows cessation of ovarian function; these benefits of estrogens have been long recognized. In the 1990s, however, based on accruing observational studies and a rationale that was driven by biologic plausibility, the focus of postmenopausal hormone therapy changed from short-term use in the management of symptom burden to long-term utilization as a preventative strategy against common diseases and disorders of aging including cardiovascular disease, dementia, and osteoporosis. HT was found to be very effective in treating vasomotor symptoms. Similarly, skeletal benefits in preventing osteoporosis were also clear. However, long-term use of HT for the sole purpose of targeting cardiovascular disease and dementia was challenged by a sequence of seminal clinical trial, with WHI being at the forefront. Not only did the clinical trial data indicate that HT did not protect against cardiovascular disease, nor mitigate the risk of aging-related dementia, but, on the contrary, raised concerns regarding the potential for harm as evident in an increased risk of thrombotic phenomenon, stroke, and breast cancer. In WHIMS (Women's Health Initiative Memory Study), incidence of cognitive deterioration was higher in the hormone-using postmenopausal women compared to those assigned to placebo. The ensuing decades following publication of WHI findings witnessed passionate and widespread quests attempting to unravel potential mechanisms that could explain HT-related harm; for a brief period, the field of menopause was rendered complex and decision-making by clinicians and patients very difficult. In this section of the chapter, we offer a comprehensive review of the literature, including more recent data and analyses, to help serve as a guide for the practicing clinician caring for menopausal women.

# History<sup>475,476,477,478</sup>

The existence of hormones was unknown 200 years ago. In the last half of the 19th century, a scattering of chemists and physiologists began to produce hormonally active extracts from glands, bile, and urine of animals. Adventurous clinicians used these extracts to treat patients, for example, supplying thyroid hormone to treat severely hypothyroid individuals, and the specialty of endocrinology was born. The word “endocrine” was adopted to designate the “glands of internal secretion,” the multiple sources of hormones.

Charles-Édouard Brown-Séquard, the son of a French woman and an American sea captain, was born on the island of Mauritius. Speaking fluent English and French, he practiced medicine and lectured in London and New York before settling in Paris. Brown-Séquard reported in 1889 that he was rejuvenated by the self-administration of extracts from dog testicles, most likely a placebo effect considering the scant amount of testosterone he could have extracted using his aqueous method, and he suggested that ovarian extracts would have the same revitalizing effect in women. Efforts to treat women around the end of the 19th century were largely unsuccessful, but in 1897, ovarian extract was reported to be effective for menopausal hot flushing.<sup>479</sup>

The first American attempt to treat menopausal symptoms is attributed to E.L. Severinghaus and J. Evans of Madison, Wisconsin, who in 1929 administered a derivative from the amniotic fluid of cattle.<sup>476,480</sup> In the 1930s, the ovarian hormones were isolated, and the “estrin” products and the synthetic estrogens, stilbestrol and ethinyl estradiol, were administered to menopausal women. Edgar Allen and Edward Doisy were the first to isolate the ovarian hormone, estrogen. Allen was born in Colorado, educated at Brown University, and served in France during World War I. In 1933, he became the chairman of the Department of Anatomy at Yale University. He died of a heart attack while on patrol off Long Island for the U.S. Coast Guard in February 1943. Doisy was born in Illinois and educated at the University of Illinois and Harvard. During World War I, he was assigned to the Rockefeller Institute in New York City and then to the Walter Reed Hospital in Washington. Doisy was the first chairman of biochemistry at the St. Louis University School of Medicine. He received the Nobel Prize in Medicine, along with Henrik Dam, in 1943 for his isolation and synthesis of vitamin K. Doisy died in 1986 at the age of 92.

In 1919, Allen and Doisy, both discharged from the army after World War I, joined the faculty at the Washington University School of Medicine in St. Louis. They became friends playing on a faculty baseball team and planned their first experiments while driving to work together. In 1922, Allen moved to the University of Missouri to be professor of anatomy, and Doisy went to St. Louis University, but they continued their

collaboration. Doisy prepared ovarian extracts and mailed them to Allen for experiments. In 1923 and 1924, Allen and Doisy reported the isolation from pig ovaries and the administration to animals of “an ovarian hormone.”

In 1926, Sir Alan S. Parkes and C.W. Bellerby coined the basic word “estrin” to designate the hormone or hormones that induce estrus in animals, the time when female mammals are fertile and receptive to males. Doisy and his students Veler and Thayer in St. Louis isolated a few milligrams of estrogen in crystalline form in 1929 from large amounts of urine from pregnant women. The terminology was extended to include the principal estrogens in humans, estrone, estradiol, and estriol, in 1932 at the first meeting of the International Conference on the Standardization of Sex Hormones in London, although significant amounts of pure estradiol were not isolated until 1936. At this same meeting, the pioneering chemists were bemoaning the problem of scarcity that limited supplies to milligram amounts when a relatively unknown biochemist, A. Girard from France, offered 20 g of crystalline estrogen derived by the use of a new reagent to treat mare’s urine.<sup>481</sup>

In the 1920s, George W. Corner at the University of Rochester invited Willard Myron Allen, an organic chemist who was then a medical student, to join him in the study of the corpus luteum. Within 2 years, they had a pure extract, but it was not until 1934 that crystalline progesterone was isolated almost simultaneously in several countries. It took the corpora lutea of 50,000 pigs to yield a few milligrams. At the Second International Conference on the Standardization of Sex Hormones in London, Corner and Allen proposed the name progestin. Others proposed luteosterone, and, at a cocktail party, the various biochemists agreed to call the chemical progesterone.<sup>481</sup>

Hormones were being administered to patients in the 1940s, but supplies were very limited. And with a scarce supply, hormones were incredibly expensive. Progesterone, for example, cost \$200 per gram. “To secure barely enough androsterone to cover the head of a pin, Adolph Butenandt had had to start with nearly four thousand gallons of urine; to obtain less than one hundredth of an ounce of pure testosterone crystals, Ernst Laqueur had had to process nearly a ton of bulls’ testicles. It took a full ton of cholesterol, from the spinal cords or brains of cattle or from the grease of sheep’s wool, to yield just twenty pounds of the starting material from which progesterone ultimately could be obtained. Edward Doisy had had to process the ovaries of more than 80,000 sows to get just 12,000ths of a gram of estradiol.”<sup>482</sup>

In the 1930s, the Ayerst Company was extracting estrogens from the urine of pregnant women. Limited by the problems of supply, low activity, and bad taste and odor, Gordon A. Grant, head of biochemistry for Ayerst, suggested in 1939 that they use urine from horses. The process produced sodium salts from the sulfate esters of the various estrogens, yielding a water-soluble conjugate. Premarin (conjugated estrogens)

was approved in Canada in 1941 and in the United States in 1942 for the treatment of symptoms associated with menopause.<sup>483</sup> The tablets were and are still designated as variations of 1.25 mg, based on the equivalent amounts of Premarin and estrone (1.25 mg) that could produce the same effect in the Allen-Doisy bioassay (amount required to produce an increase in rat uterine weight). It was not until 1972 that the first quantitative analysis of Premarin was performed, based on gas chromatography. Modern studies indicate that there is a large number of steroids in Premarin, even androgens and progestins, but only the 10 estrogens are present in sufficient quantity to have clinical effects ([Table 17.7](#)).

## **TABLE 17.7 Postmenopausal Hormone Therapy**

## Composition of Conjugated Estrogens (Premarin)

Sodium estrone sulfate	49.3%
Sodium equilin sulfate	22.4%
Sodium 17 $\alpha$ -dihydroequilin sulfate	13.8%
Sodium 17 $\alpha$ -estradiol sulfate	4.5%
Sodium $\Delta$ 8,9-dehydroestrone sulfate	3.5%
Sodium equilenin sulfate	2.2%
Sodium 17 $\beta$ -dihydroequilin sulfate	1.7%
Sodium 17 $\alpha$ -dihydroequilenin sulfate	1.2%
Sodium 17 $\beta$ -estradiol sulfate	0.9%
Sodium 17 $\beta$ -dihydroequilenin sulfate	0.5%

# **ESTROGEN FORMULATIONS AND ROUTES OF ADMINISTRATION**

---

## Oral Administration

The relative potencies of commercially available estrogens are of great importance when prescribing estrogen, and the clinician should be familiar with the following potencies ([Table 17.8](#)).

### **TABLE 17.8 Relative Estrogen Potencies**

<b>Estrogen</b>	<b>FSH Levels</b>	<b>Liver Proteins</b>	<b>Bone</b>
Conjugated estrogens	1.0 mg	0.625 mg	0.625 mg
Micronized estradiol	1.0 mg	1.0 mg	1.0 mg
Estropipate (piperazine estrone sulfate)	1.0 mg	1.25 mg	1.25 mg
Ethinyl estradiol	5.0 µg	2–10 µg	5.0 µg
Estradiol valerate	—	—	1.0 mg
Esterified estrogens	—	—	0.625 mg
Transdermal estradiol	—	—	50 µg

Data from **Dennerstein L, Lehert P, Burger HG, Dudley E**, Mood and the menopause transition, *J Nerv Ment Dis* 187:685, 1999; **Smith-DiJulio K, Woods NF, Mitchell ES**, Well-being during the menopausal transition and early postmenopause: a within-stage analysis, *Womens Health Issues* 18:310, 2008; **Woods NF, Mitchell ES, Percival DB, Smith-DiJulio K**, Is the menopausal transition stressful? Observations of perceived stress from the Seattle Midlife Women's Health Study, *Menopause* 16:90, 2009; **Avis NE, McKinlay SM**, A longitudinal analysis of women's attitudes toward the menopause: results from the Massachusetts Women's Health Study, *Maturitas* 13:65, 1991; **Morse CA, Smith A, Dennerstein L, Green A, Hopper J, Burger H**, The treatment-seeking woman at menopause, *Maturitas* 18:161, 1994; **Defey D, Storch E, Cardozo S, Diaz O, Fernandez G**, The menopause: women's psychology and health care, *Soc Sci Med* 42:1447, 1996.<sup>9,10,11,12,13,14</sup>

The 17 $\alpha$ -ethinyl group of ethinyl estradiol (by resisting metabolism) enhances hepatic effects, because no matter by which route it is administered, liver function is affected.<sup>484</sup> The same is true for CEEs. Contrary to the case with estradiol, the liver appears to preferentially extract ethinyl estradiol and CEEs regardless of the route of administration. Thus, the route of administration appears to influence the metabolic responses only in the case of specific estrogens, most notably estradiol.

A major factor in the potency differences among the various estrogens (estradiol,

estrone, estriol; **Figure 17.11**) is the length of time that the estrogen binds to its receptor. The higher rate of dissociation with the weak estrogen (estriol) can be compensated for by continuous application to allow prolonged binding and activity. Estriol has only 20–30% affinity for the estrogen receptor compared with estradiol; therefore, it is rapidly cleared from a cell. However, if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.<sup>485</sup> However, at least two studies have been unable to demonstrate prevention of bone loss with the administration of 2 mg estriol daily, suggesting that target organ response may vary.<sup>486,487</sup> In pregnancy, where the concentration of estriol is very great, it can be an important hormone not just a metabolite. Because estriol protects the rat against breast tumors induced by various chemical carcinogens,<sup>488</sup> it has been hypothesized that a higher estriol level protects against the more potent effects of estrone and estradiol. But, antagonism of estradiol occurs only within a very narrow range of the ratio of estradiol to estriol, a range that is rarely encountered either physiologically or pharmacologically.<sup>489</sup> Below this range, estradiol is unimpeded; above this range, estriol itself exerts estrogenic activity. Commercial preparations containing estriol, estradiol, and estrone comprise sufficient amounts of estrone and estradiol to produce standard clinical effects.<sup>490</sup>

**FIGURE 17.11**

Esterified estrogens are synthetically prepared from plant precursors and are composed mostly of sodium estrone sulfate with a 6–15% component of sodium equilin sulfate. Estradiol valerate is rapidly hydrolyzed to estradiol; therefore, the pharmacology and effects are comparable at similar dosages.<sup>491</sup>

# Transdermal Estrogen Administration

Transdermal estradiol can also be administered by a patch, gel, emulsion, or spray. The patches first used for transdermal administration of estrogen contained an alcohol reservoir; estrogen was released through a semipermeable membrane attached to the skin with an adhesive. In the current generation of estrogen patches, the hormone is dissolved and distributed throughout the adhesive matrix. In a study of women who had previously discontinued hormone patches because of skin irritation (contact dermatitis), skin reactions were less common with the newer matrix patches.<sup>492</sup> In addition, the matrix patches are better tolerated in tropical environments.<sup>493</sup> The patches are designated according to the amount of estradiol delivered per day with formulations delivering as little as 14 to as much as 100  $\mu\text{g}$  daily and are available in varying doses and various trade names (Climara and Vivelle are commonly available in the United States). The gel is similarly available under various trade names (Divigel, EstroGel, Estreva Gel) and in varying doses and can be applied once daily on an arm, anywhere from the wrist to the shoulder, or the thigh, without rubbing or massaging and alternating sides.<sup>494,495</sup> The emulsion, Estrasorb, is packaged in foil pouches; usually two packets are applied daily, one to each thigh, and rubbed in thoroughly. Evamist is the transdermal spray, and the usual dose is one spray daily to the forearm (if more than one dose is required daily, each spray is on a separate site).<sup>496</sup> Elestrin is available in a metered dispenser. Simultaneous use of sunscreen on the site of administration should be avoided. If dosage is being monitored by blood estradiol levels, blood should be drawn from a site where transdermal estradiol has not been applied for several days. **The ideal dose of estrogen is that which allows for systemic symptom relief.**

## Circulating Estradiol Levels in Users of Oral Versus Transdermal Estrogen

The concentration of estrogen in the hepatic portal system after oral administration is 4 to 5 times higher than that in the periphery.<sup>497</sup> Because of first-pass metabolism in the liver, oral estradiol results in a circulating estrone to estradiol ratio of approximately 5; with transdermal administration, the ratio is 1. The first-pass effect has important lipoprotein effects. For example, studies have demonstrated an increase in HDL and decrease in LDL and cholesterol with oral estrogens (discussed earlier in this chapter), an effect that is less prominent with transdermal estrogen administration.<sup>498,499</sup> However, English data indicate that the transdermal administration of 50  $\mu\text{g}$  estradiol twice a week is as effective as 0.625 mg oral conjugated estrogens, when combined with a progestin in sequential regimens, on bone mineral density (BMD) and lipids over a duration of 3 years.<sup>500</sup> Standard doses of estrogen administered transdermally (50  $\mu\text{g}$ )

protect against fractures as do standard doses of oral formulations.<sup>501</sup> While lower doses of estrogens can provide effective suppression of vasomotor symptoms as well as improve BMD, data on fracture risk reduction with low-dose regimens are lacking.<sup>502</sup>

Studies comparing circulating estradiol levels in women receiving oral or transdermal estrogen reveal that while estradiol levels are in therapeutic range for bone protection, there exists substantial variation among individuals.<sup>503</sup> Furthermore, due to the chemical components of CEEs (which are not measurable in serum samples on routine assays), it is difficult to measure a therapeutic level of estrogen in CEE users. In addition, individual women metabolize estrogen differently, depending on the route of administration, liver function, body composition, body size, potential medication interactions, skin absorption (for transdermal preparations), and the presence of binding proteins; all these can contribute to individual variations in serum estradiol levels.<sup>504</sup> The only way to accurately compare clinical effectiveness of oral and transdermal estrogen delivery is to determine if the two methods of administration yield comparable blood levels; however, the first-pass hepatic effect may account for differences in clinical effectiveness and this is difficult to quantify. The first-pass effect is particularly pronounced with oral estrogen formulations and raises SHBG levels such that total serum estradiol levels are greatly affected. A potential advantage of transdermal treatment because it has minimal to no effect on SHGB levels is the absence of a reduction in free, unbound testosterone levels (which may have implications for sexual function in a subset of users) as are observed with oral estrogen therapy.<sup>503</sup>

## **Systemic Effects of Hormone Therapy**

### **Clotting Factors**

First-pass hepatic metabolism affects the synthesis of clotting proteins, markers of coagulation and fibrinolysis that can influence the risk of thrombosis and CHD events. Oral estrogen increases factor VII and prothrombin 1 and 2 fragment, whereas transdermal estrogen decreases factor VII.<sup>505,506,507,508</sup> Oral estrogen also increases circulating levels of matrix metalloproteinases, MMP-2 and MMP-9, enzymes that are associated with a tendency for clotting.<sup>509</sup> However, what is important is to understand the different effects of oral and transdermal delivery on clotting factors and how they translate into clinical differences and cardiovascular risk.

### **Activated Protein C (APC) Resistance and Risk of Venous Thromboembolism (VTE)**

Resistance to APC is an important marker for venous thrombosis in individuals with

inherited thrombogenic mutations and even in the absence of these mutations. Oral estrogen increases APC resistance, whereas transdermal estrogen has no significant effect on this marker.<sup>510,511</sup> Based on this difference, one would predict that transdermal delivery of estrogen would be less likely than oral delivery of estrogen to be associated with VTE.

A French case-control study (epidemiologic studies of the link between the transdermal route of administration and a relatively rare event are possible in France because of the popularity of the transdermal method) reported no increased risk of VTE in users of transdermal estrogen, as compared with a fourfold increase in oral estrogen users.<sup>512,513,514</sup> Estrogen users who carried a factor V Leiden mutation or a prothrombin mutation had a 25-fold higher risk of VTE than did women who did not use estrogen and did not have either mutation. The women with a prothrombotic mutation who used transdermal estrogen had a VTE risk that was similar to that of women with a prothrombotic mutation who did not use estrogen. The French E3N prospective cohort study also reported an increased risk of VTE with current users of oral therapy, a hazard ratio of 1.7 (CI = 1.1–2.8), a ratio that is similar to the usual twofold increase repeatedly documented in the literature, and no increase with transdermal estrogen.<sup>515</sup> Analysis of the WHI trials noted that despite an increase in APC resistance, this did not explain the increase in ischemic stroke noted in oral HT users.<sup>516,517</sup> Venous thrombosis is discussed in more detail in the hormone therapy section of this chapter.

## **Lipids and Hepatic Enzymes**

Both oral and transdermal estrogens reduce total cholesterol, LDL cholesterol, and lipoprotein(a). Compared with transdermal estrogen, oral estrogen produces significantly greater elevations in HDL cholesterol and increases triglycerides, whereas transdermal estrogen decreases triglyceride levels.<sup>505,507,518,519,520</sup> Indeed, triglyceride levels markedly elevated in response to oral therapy return to normal when treatment is changed to transdermal administration.<sup>521</sup> In addition, oral estrogen therapy is associated with an increased risk of gallstones.<sup>522</sup> This risk is present in current and former estrogen users and is somewhat attenuated with the addition of progestin to estrogen therapy.<sup>522</sup>

## **Inflammatory Markers**

Women on oral estrogen have increased levels of CRP, whereas those taking transdermal estrogen do not.<sup>421,422,505,507,518,523,524</sup> In fact, oral hormone therapy while increasing CRP reduces the circulating levels of other inflammatory markers (E-selectin, intercellular adhesion molecule-1, vascular cell adhesion molecule-1, monocyte chemoattractant protein-1, and tumor necrosis factor- $\alpha$ ) with inconsistent

effects on IL-6.<sup>421,525</sup> Transdermal estrogen does not affect levels of these inflammatory markers. It is not certain that the decrease in CRP levels with statins and the increase with oral estrogen are instrumental in clinical outcomes or reflect other effects.

A longitudinal study of 346 postmenopausal women taking oral HT reported that elevated CRP was a strong predictor of future cardiac events, but only in those with increased IL-6 levels.<sup>523</sup> An increase in CRP alone was not associated with an excess of events. **The difference in CRP levels between users of oral versus transdermal therapy, especially in younger postmenopausal women, is of little clinical significance.** In fact, in the Estrogen Replacement on Progression of Coronary Atherosclerosis trial, estrogen-induced increases in CRP had no effect on disease progression, as measured by serial angiograms.<sup>524</sup> A study from the WHI confirmed the correlation between baseline levels of CRP and an elevated risk of CHD, **but the increase in CRP induced by oral hormone therapy did not further increase the risk.**<sup>423</sup> While CRP may cause endothelial inflammation and subsequent atherosclerosis, it may also very well be elevated secondary to first-pass hepatic metabolism (i.e., pharmacologic effect); unlike IL-6, its elevation has an overall proinflammatory effect.<sup>517</sup>

## Myocardial Infarction Risk

Both oral and transdermal administration of hormone therapy are associated with a decrease in myocardial infarction risk in observational studies.<sup>526</sup> However, the WHI trials and postintervention data offer additional insight and will be discussed in further detail later in this chapter.

## Metabolic Syndrome

The menopausal transition itself is associated with increased likelihood of metabolic dysfunction. However, in a review of several RCTs, it was noted that overall effects on markers of the metabolic syndrome, including insulin resistance, suggested a neutral or improved metabolic profile.<sup>527</sup> Despite this favorable effect, in women with the metabolic syndrome, caution is recommended given the increased risk of cardiovascular events, as noted in a nested case-control study of CHD in the WHI trials.<sup>527,528</sup> Transdermal estradiol has minimal effects on inflammation, coagulation, and insulin sensitivity.<sup>528,529</sup>

## Effects in Smokers

Limited evidence suggests that postmenopausal women who smoke may have a better response to transdermal estrogen than to oral estrogen, including greater reductions in

total peripheral resistance, vascular sympathetic tone, and norepinephrine levels, and increased vascular responsiveness.<sup>530</sup> Smokers receiving transdermal estradiol have decreased plasma viscosity and thromboxane B<sub>2</sub> levels.<sup>530</sup> These results raise the possibility, although the data are limited, that smokers may represent a group of women for whom transdermal estrogen would be an advantage.

## **Carbohydrate Metabolism**

There is little difference between the oral and transdermal methods of delivery on carbohydrate metabolism. Both methods have a beneficial impact on central abdominal fat content, glucose levels, and insulin resistance, associated with a reduced risk of developing adult-onset diabetes mellitus.<sup>531,532,533,534,535,536</sup> The effect of hormone therapy on carbohydrate metabolism/diabetes risk will be discussed in further detail in the hormone therapy section of this chapter.

## **Skeleton**

Effects of menopausal hormones on bone metabolism and BMD are discussed later in this chapter in the section on osteoporosis.

## Estradiol Implants

Estradiol pellets are available in doses of 25, 50, and 75 mg for subcutaneous administration twice yearly. The 25-mg pellet provides blood levels in the range of 40–60 pg/mL, levels that are comparable with those obtained with standard oral doses.<sup>537,538</sup> However, the effect of subcutaneous regimens is cumulative, and after several years, the blood levels are 2 to 3 times higher and can persist for up to 2 years following last insertion. We believe that estradiol pellets do not confer any advantage over the standard hormone regimens. We recommend that women receiving estradiol pellets be monitored with blood levels of estradiol. In women in whom serum estradiol levels are greater than 200 pg/mL (or even >100 pg/mL), prolonging intervals between insertions should be considered.

## Oral Versus Transdermal Administration

It is difficult to draw conclusions about clinical differences between oral and transdermal hormone delivery based on secondary markers. Epidemiologic studies on clinical events are needed. However, this is a challenge because of the relatively small number of women receiving transdermal estrogen. In addition, the studies must adjust for individual variability of dosing to ensure that circulating estrogen levels in the patients being studied are similar.

Given that transdermal route of delivery is suggested to lessen the risk for thrombotic events linked with exogenous estrogen use, it often is preferred by patients and, when applicable, allows monitoring of serum estradiol levels. Although comparison studies have not been performed, it is reasonable to expect similar pharmacokinetics for all transdermal methods—more stable/constant estradiol levels, less fluctuation, and theoretical benefits over oral therapy. Furthermore, because of lack of effects of transdermal delivery on serum SHBG levels and thereby with minimal effect on free androgen levels, transdermal method for estradiol delivery may be preferable in women with impaired sexual function.

## Key Points

- **Based on the evidence to date, transdermal estrogen therapy seems a preferred option for women who are deemed eligible for HT use after taking into account individual woman's personal and family histories and after ruling out absolute and relative contraindications to HT use.**
- **Sufficient evidence suggests that transdermal route of estrogen**

**administration be preferentially considered if decision for initiating HT is made after detailed counseling and weighing of risks versus benefits of HT for the following patients:**

- **Women deemed at risk for VTE**
- **Women with spontaneous or estrogen-induced hypertriglyceridemia**
- **Obese women with metabolic syndrome**
- **Diabetic and hypertensive women**
- **Smokers**
- **Transdermal route for estrogen therapy should be preferentially considered in women with complaints of hypoactive sexual desire or decreased libido.**

# Vaginal Administration of Estrogen

## Very-Low-Dose Method

Some patients do not gain full relief from the symptoms of vaginal atrophy with oral or transdermal administration of estrogen. Local vaginal administration makes sense for these patients. Vaginal treatment is especially helpful when a rapid response is desired. In addition, there are many women who desire the genitourinary effects of estrogen, but either must or wish to avoid systemic therapy. Overall, there is no evidence that one method or preparation is superior to the others in achieving clinical response. **Measurement of vaginal pH from the lateral vaginal wall is a simple and inexpensive way to assess adequate treatment of the vagina. It has been impressive in our experience and others how an acidic pH (<4.5) obtained from the lateral, outer third of the vagina correlates well with good estrogen effects. In a recent randomized controlled trial, it was also found to correlate with vaginal maturation index, symptomatic vulvovaginal atrophy, and visual inspection of vaginal epithelium.**<sup>241,242,539</sup>

Estrogen in the form of vaginal creams is absorbed very readily from a vagina with immature, atrophic mucosa.<sup>540</sup> Indeed, the initial absorption is rapid, and relatively high circulating levels of estrogen are easily reached. As the vaginal mucosa matures, absorption decreases.<sup>541</sup> This decline takes approximately 3–4 months, after which lesser but still significant absorption takes place.<sup>542</sup> Effective treatment of vaginal atrophy with minimal absorption can be achieved with the administration of 0.3 mg conjugated estrogens, 2 to 3 times per week.<sup>543,544</sup> Typically, addition of a progestogen is not indicated with low-dose therapy; however, data regarding endometrial safety for  $\geq 1$  year are not available. **We believe that treatment with a vaginal cream longer than 12 months requires endometrial surveillance.**

The amount of estradiol delivered in low-dose tablet form or a ring is not sufficient to treat menopausal symptoms, but effectively improves local urogenital atrophy and reduces recurrent urinary tract infections. This has been accepted as a method to relieve atrophic vaginal symptoms in women with contraindications to estrogen treatment; however, systemic effects do occur, although not deleterious effects.<sup>6</sup>

**Estring** is a 55-mm-diameter silicone ring that contains 2 mg estradiol, with a release rate of 7.5  $\mu\text{g}/\text{day}$  for 90 days.<sup>545</sup> European studies have demonstrated that vaginal maturation can be achieved with this ring that can be left in place for 3 months, with a low level of systemic absorption.<sup>546,547</sup> The subjective symptoms associated with vaginal atrophy are rapidly relieved. No change in endometrial thickness was observed

after 1 year of treatment.<sup>548</sup>

**Vagifem** is a vaginal formulation that is currently available in the United States as a tablet that contains 10 µg estradiol (was previously also available in a higher strength of 25 µg); the initial dose of one tablet daily provides relief from atrophic symptoms within 2 weeks.<sup>549</sup> After the first 2 weeks, the maintenance dose is twice weekly, and endometrial thickness has been reported to not change from baseline; however, the study was only 6 months in duration.<sup>550</sup> One 2-month study found no evidence of endometrial stimulation; another reported one case of vaginal bleeding with endometrial proliferation.<sup>551,552,553</sup>

The systemic absorption of estrogen from vaginally administered formulations (low-dose estradiol ring or tablet) is very low, especially after the vagina achieves estrogen-induced maturation (about 3 months). Is this low level of absorption free of the risk of endometrial hyperplasia? The problem is that all studies have been too short (all 1 year or less, except one 2-year study) to determine long-term endometrial safety. Although systemic absorption occurs, the circulating estradiol levels with these low-dose methods remain in the normal postmenopausal range.<sup>548,550,554,555,556,557</sup> But, because the small increase in circulating estradiol levels causes distant target tissue responses (e.g., an increase in bone density or an improvement in the lipid profile<sup>558,559</sup>), clinicians cannot assure patients that these methods are totally free of systemic activity.<sup>560</sup> **Although the change in blood levels is very slight and for that reason not effective for the relief of vasomotor symptoms, we believe long-term treatment requires ultrasonographic monitoring of endometrial thickness with biopsy when indicated. This ultrasonographic approach is more preferable than complicating the treatment regimen with the addition of a progestational agent. We further suggest that each patient titrate her dose and schedule of treatment to balance an effective response with minimal dosing. For women who are breast cancer survivors and are considering this treatment, decisions should involve patients' oncologist, given the potential risk of increased systemic estrogen levels.**<sup>561</sup> Of note, postmenopausal women taking an AI in particular require special consideration given their lower estradiol levels. In a recent nested case-control study assessing the risk of breast cancer recurrence in women on tamoxifen or AI receiving vaginal estrogen therapy, there was no increase in breast cancer recurrence; caution with interpretation for the AI group however as statistical power was lacking.<sup>562</sup>

## Standard Dose Method

A vaginal ring (Femring, estradiol acetate) that releases estradiol acetate provides 50 or 100 µg estradiol per day over a 3-month time span.<sup>563,564</sup> Estradiol acetate is a

prohormone, which is rapidly hydrolyzed to estradiol that is reflected in blood estradiol levels similar to those achieved with oral and transdermal methods. The systemic levels achieved effectively suppress hot flushing, and a beneficial impact on bone is to be expected. Endometrial protection requires the addition of a progestin in the presence of a uterus.

# Role of Monitoring Blood Levels of Estradiol in Estrogen Users

Monitoring the estradiol blood level in postmenopausal women does not have a role in routine management. However, in women not responding to standard HT dosing, it may be beneficial to assess serum estradiol levels. Monitoring however is not as straightforward as it would seem. There are two primary difficulties. First, the clinical assays available differ considerably in their technique and quality (laboratory and antibody variations). Second, the various commercial products represent a diverse collection of estrogenic compounds, ranging from estradiol to unique equine estrogens. Although the body interconverts various estrogens into estrone and estradiol, is this process relatively consistent within and between individuals? A highly specific assay for estradiol will detect very low levels of estradiol in women receiving 0.625 mg CEEs; nevertheless, most clinical assays will report a level of 40–100 pg/mL in these women.

We find measurement of blood estradiol levels very useful in selected patients, such as the patient who requests ever-increasing doses of estrogen for the treatment of symptoms, which in the presence of very high blood levels of estradiol can be confidently diagnosed as psychosomatic. What each clinician must do is learn what blood level of estradiol as performed by the local laboratory is associated with the standard doses of hormone therapy (0.625 mg conjugated estrogens, 1 mg estradiol, 50 µg transdermal estradiol) and consistently use the same laboratory. This range is 40–100 pg/mL estradiol when the estrogen is taken the evening before the office visit (with transdermal administration, blood sampling should be obtained the day before new patch placement); the range reflects individual variation including the variability from peak to nadir values. **Remember that because FSH is also regulated by a factor other than estrogen (i.e., inhibin), FSH levels cannot be used to monitor estrogen dosage.** Postmenopausal hormone therapy will produce only a 10–20% decrease in FSH and LH, and there is great individual variability in the responses.<sup>565</sup>

**Products containing ethinyl estradiol (commonly used in combined hormonal contraceptives) will not affect the measurement of circulating estradiol levels.** Ethinyl estradiol circulates without being changed, and the antibodies in the immunoassays for estradiol will not recognize it. It is for this reason that women on oral contraceptives have very low measurements of estradiol. This problem for the postmenopausal use of ethinyl estradiol is not a major handicap because ethinyl estradiol is slowly metabolized, and blood levels are relatively stable with less variation from individual to individual compared with the other estrogen formulations.

# Menopausal Hormone Therapy: Sequential and Continuous Regimens

Postmenopausal hormone therapy initially consisted only of sequential regimens that were logical reflections of the cyclic estrogen and progesterone patterns in a premenopausal menstrual cycle. Clinical trials established the doses and durations for progestin administration that would effectively protect the endometrium against unchecked estrogen-driven proliferation.<sup>566</sup> Progestin withdrawal bleeding occurs in 80–90% of women on a sequential regimen.<sup>567,568,569</sup> The continuous combined method of treatment evolved to improve patient continuance that was adversely affected by bleeding and other symptoms triggered by the cyclic hormonal changes. The addition of a daily dose of a progestin to the daily administration of estrogen allowed the progestin dose to be smaller, provided effective protection against endometrial hyperplasia, and resulted in amenorrhea within 1 year of treatment in 80–90% of patients.<sup>568,570,571,572</sup>

In the sequential regimen, estrogen is administered daily and progestins for 2 weeks of every month, using the comparable doses of the following progestogens noted below and listed in [Table 17.9](#)<sup>569,570,573,574</sup>:

## TABLE 17.9 Progestins Available Worldwide

**Estimated  
Comparable  
Oral Doses**

Progesterone	Oral peanut oil tablet	200 mg
21-Carbon derivatives	Medroxyprogesterone acetate	5.0 mg
	Megestrol acetate	5.0 mg
	Cyproterone acetate	1.0 mg
	Dydrogesterone	10.0 mg
	Chlormadinone acetate	5–10.0 mg
	Medrogestone	10.0 mg
19-Norpregnanes	Trimegestone	0.0625–0.50 mg
	Promegestone	0.5 mg
	Nomegestrol	5.0 mg
	Nomegestrol acetate	3.75–5.0 mg
	Demegestone	
	Nestorone (nonoral)	0.05–0.1 mg
19-Nortestosterone family		
Ethinylated	Norethindrone	0.7–1.0 mg
	Norethindrone acetate	1.0 mg
	Levonorgestrel	0.075 mg
	Desogestrel	0.15 mg
	Norgestimate	0.09 mg
	Gestodene	0.20 mg
	Norethynodrel	
	Lynestrenol	
	Ethinodiol diacetate	
Nonethinylated	Dienogest	2.0 mg
Derived from spironolactone and nonethinylated	Drospirenone	2.0 mg

- 5 mg medroxyprogesterone acetate
- 1.0 mg norethindrone acetate
- 200 mg micronized progesterone

In the daily continuous, combined regimen, progestins are combined with estrogen in the following comparable doses<sup>571,572,575</sup>:

- 1.5 or 2.5 mg medroxyprogesterone acetate
- 0.35 mg norethindrone
- 0.5 or 1.0 mg norethindrone acetate
- 100 mg micronized progesterone
- 2 mg drospirenone
- 2 mg dienogest

# Menopausal Hormone Therapy: Estrogen Dose

There has been a progressive decrease in estrogen doses in postmenopausal hormone therapy regimens. For many years, the standard dose of estrogen was 0.625 mg conjugated estrogens, 1–2 mg micronized estradiol, 1–2 mg estradiol valerate, or equivalent doses of other estrogens such as 5 µg ethinyl estradiol. Lower doses have been proven on the average to be as effective as these “standard” doses, providing clinicians and patients with more options. Conjugated estrogens in a dose of 0.3 or 0.45 mg effectively produce a gain in bone density when combined with 1.5 mg medroxyprogesterone acetate, and a dose of 0.5 mg micronized estradiol produces comparable effects.<sup>576,577,578,579</sup> The 0.45/1.5 mg and 0.3/1.5 mg conjugated estrogens/medroxyprogesterone acetate combinations improve vaginal atrophy, reduce hot flushing, and improve measures of sexual function in a pattern that is quantitatively and qualitatively similar to the 0.625/2.5 mg combination with less mastalgia.<sup>580,581</sup> These lower-dose combinations are associated with less breakthrough bleeding and a higher rate of cumulative amenorrhea compared with older standard doses and retain the favorable changes in the lipid profile.<sup>582,583</sup> At these lower doses of conjugated estrogens, the combination with progestin produces an additive effect; therefore, when these lower doses of estrogen are used without progestin, the effect on hot flushing will not be as great. In a dose-response study, the most efficacious dose of oral micronized estradiol was 1 mg/day.<sup>584</sup> The lower-dose combination of ethinyl estradiol and norethindrone acetate (2.5 µg/0.5 mg) is nearly as effective in treating hot flushes as the higher-dose combination (5.0 µg/1.0 mg).<sup>585</sup> **Vigilance is advised in assessing response with lower doses as there will be more women who respond poorly, probably because of a greater rate of metabolism and clearance.**

# Menopausal Hormone Therapy: Progestational Component

Many women do not tolerate treatment with progestational hormones. Typical side effects include breast tenderness, bloating, and depression. These reactions are significant detrimental factors with continuance. Breast discomfort associated with postmenopausal hormone therapy can be attributed largely to progestins. Comparison studies have not been performed to address whether this symptom is minimized by particular progestins. Can the progestational agent be administered less frequently? We are secure in our position, supported by clinical data, that a daily combination program effectively prevents endometrial hyperplasia. A sequential regimen that incorporates progestin exposure for less than 14 days has over time an increased risk of endometrial hyperplasia.<sup>586,587</sup> Sequential regimens with less than 14 days of progestin monthly or even long-term use of recommended schedules do not match the protection offered by the daily, continuous method of estrogen-progestin treatment.

Two metabolites of progesterone, allopregnanolone and pregnanolone, are believed to be responsible for progesterone's unique sedative effect. Treatment regimens with micronized progesterone should be taken at bedtime, and these estrogen-progesterone combinations are a good choice for women with sleep difficulties. A study in a sleep laboratory has demonstrated a significant improvement in sleep quantity and quality in women using a sequential regimen of estrogen and micronized progesterone in contrast to no effect in the group using medroxyprogesterone acetate.<sup>588</sup>

Some patients are very sensitive to medroxyprogesterone acetate. One can consider a trial of norethindrone instead. In a sequential regimen, the dose of norethindrone is 0.7 mg (available in the progestin-only, minipill oral contraceptive; each pill contains 0.35 mg norethindrone). In the continuous, combined regimen, the dose of norethindrone is 0.35 mg daily. Commercial combination products are available containing estradiol and norethindrone acetate.

Progesterone can also be administered vaginally. A vaginal gel allows the delivery of very low doses that can effectively protect the endometrium with low systemic levels because of a first-pass effect on the uterus.<sup>589</sup> The administration of 90 mg every 2 days produces secretory changes in the endometrium.<sup>590</sup> An application of the 4% commercial preparation (Crinone) twice weekly protects the endometrium and is associated with amenorrhea in most patients. In a sequential regimen, the 4% preparation should be applied daily for at least 14 days each month; however, long-term data on endometrial safety are lacking.<sup>591</sup> The application of a 100-mg vaginal tablet (Endometrin) every other day is also effective, with long-term follow-up of 3 years

demonstrating no endometrial hyperplasia.<sup>592</sup>

The transdermal estrogen-progestin combinations incorporate norethindrone acetate in a daily dose of 0.140 or 0.250 mg; or levonorgestrel in daily doses of 0.007, 0.015, 0.030, and 0.040 mg/day; and, in a sequential regimen, norethindrone acetate, 0.250 mg, or levonorgestrel, 0.010 mg.<sup>593,594,595</sup>

## **Infrequent Progestational Exposure: Long Sequential Regimens**

Such regimens are increasingly being considered, either for the convenience of lesser frequency of withdrawal bleeding episodes associated with cyclic progesterone use or for those wishing to minimize progestin exposure duration. Experience with extended-cycle regimens, however, is very limited. The administration of medroxyprogesterone acetate every 3 months was associated in one study with longer, heavier menses and unscheduled bleeding and a 1.5% incidence of hyperplasia at 1 year, whereas in another study, overall bleeding was less, but the incidence of hyperplasia was approximately 4%.<sup>596,597</sup> In a Dutch study that was only 12 weeks in length, simple endometrial hyperplasia was encountered at the end of the unopposed estrogen phase.<sup>133,598</sup> In yet another study, there was no endometrial hyperplasia encountered by 143 women who completed 2 years of treatment; however, the progestin administered every 3 months was of high dosage, 20 mg medroxyprogesterone acetate daily for 14 days.<sup>599</sup> In Finland, the addition of progestin at 3-month intervals was associated with a striking increase in the risk of endometrial cancer when this regimen was used for many years.<sup>600</sup> Most impressively, the Scandinavian Long Cycle Study, a clinical trial scheduled to last 5 years, was canceled after 3 years because of a 12.5% incidence of endometrial pathology and 1 case of endometrial cancer.<sup>575,601</sup> Given the lack of long-term data on safety of extended regimens, if a patient chooses such an approach, endometrial monitoring is advised. **Any program that differs from the standard regimen should consider periodic surveillance of the endometrium (as discussed earlier in this chapter). Even the long-term use of standard sequential regimens is subject to a small increase in the risk for endometrial cancer, and endometrial surveillance should be considered in women using this method.**

**We caution against long regimens in women who may be at an innately higher risk for endometrial hyperplasia and cancer, such as those with a personal history of endometrial hyperplasia, those who are obese, those who are insulin-resistant, and diabetic women.**

## **The Progestin Intrauterine Device**

The levonorgestrel-releasing IUDs (such as the Mirena or Skyla) are increasingly being used in estrogen-taking postmenopausal women to confer endometrial protection.<sup>602,603,604,605,606</sup> The intrauterine presence of the progestin effectively protects the endometrium against hyperplasia and cancer.<sup>209</sup> The local site of action provides endometrial protection while minimizing systemic progestin side effects; for example, estrogen's favorable lipid effects are not attenuated with intrauterine progestin.<sup>607</sup> As with the oral continuous, combined regimens, irregular breakthrough bleeding may occur in the first 6 months, and after 1 year, approximately 60–70% of the women are amenorrheic. The levonorgestrel system has the advantage of a 5- to 7-year duration of use. These methods provide treatment options that minimize substantially the systemic effects of progestins.

## Special Considerations for Progestin Use

Inclusion of progestational agent in menopausal hormone therapy regimen is exclusively for endometrial benefit. Thus, use of estrogen-alone hormone formulations reflects the standard of clinical care in managing menopausal symptoms in women without a uterus. However, there are some special conditions that warrant consideration of a combined estrogen-progestin regimen even in hysterectomized women.

### Key Points

- In women in whom hysterectomy and bilateral salpingo-oophorectomy is undertaken for management of endometriosis, we recommend a combination of estrogen plus progestogen. In general, following hysterectomy estrogen-only HT is required, if needed. However, given the role of estrogen in endometriosis growth/progression, this is one situation where combined HT is indicated following hysterectomy. Cases of adenocarcinoma have been reported in patients with pelvic endometriosis treated with unopposed estrogen.<sup>151,152,153,154,155,156</sup>
- Patients who have undergone procedures that have the potential to leave residual endometrium (e.g., a supracervical hysterectomy) should be treated with an estrogen-progestin combination. Responsive endometrium may be sequestered in patients who have undergone endometrial ablation,<sup>423,526</sup> and combined estrogen-progestin treatment is also recommended for these women.
- In women undergoing hysterectomy for management of early stage endometrial adenocarcinoma, if HT is being considered for symptom control, a combination regimen is advised given the potential protective action of the progestational agent.
- The combined estrogen-progestin approach makes sense for patients previously

treated for endometrioid tumors of the ovary.<sup>608</sup>

# ROLE OF ANDROGENS IN MENOPAUSE MANAGEMENT

---

The total amount of testosterone produced after menopause is decreased because the amount of the primary source, peripheral conversion of androstenedione, is reduced. The early postmenopausal circulating level of androstenedione decreases approximately 62% from young adult life.<sup>157</sup> Nevertheless, the menopausal decline in the circulating levels of testosterone is not great, from no change in many women to as much as 15% in others.<sup>59,153,157,163</sup> Testosterone therapy has been shown to improve sexual interest and overall psychological well-being in menopausal women. In an excellent longitudinal Australian study from 5 years before menopause to 7 years after menopause, the circulating levels of testosterone did not change.<sup>158</sup> Indeed, because of a decrease in SHBG, this Australian study calculated an increase in free androgens. The total amount of testosterone produced per day, however, is slightly decreased because the primary source, the peripheral conversion of androstenedione, is reduced. Because of this decrease, some argue that androgen treatment is indicated in the postmenopausal period.

The potential benefits of androgen treatment include improvement in psychological well-being and an increase in sexually motivated behavior. **Hypoactive sexual desire disorder is defined as a decrease in sexual activity sufficient to cause distress.** Beneficial effects of androgen treatment have been reported with the administration of relatively large doses of androgen.<sup>609</sup> In a well-designed, placebo-controlled study, lower doses of androgen (but still very pharmacologic, 5 mg methyltestosterone) contributed little to actual sexual behavior, although an increase in sexual fantasies and masturbation could be documented.<sup>610</sup> The transdermal testosterone treatment of women improved sexual function compared with a placebo group only in the dose that raised circulating testosterone levels to about 100 ng/dL (the upper limit of normal for reproductive-age women is 80 ng/dL in most laboratories).<sup>611</sup>

Any benefit must be balanced by the unwanted effects, in particular, virilization (acne, alopecia, and hirsutism) and a negative impact on the cholesterol-lipoprotein profile. In a short-term study comparing a product with estrogen and a relatively low oral dose of testosterone (1.25 mg methyltestosterone) to estrogen alone, a negative impact on the lipid profile was apparent within 3 months.<sup>612</sup> Over a 2-year period, the administration of estrogen (1.25 mg) combined with 2.5 mg methyltestosterone produced a significant overall adverse impact on the cholesterol-lipoprotein profile.<sup>613</sup> In addition, 30% of the patients experienced acne, and 36% developed facial hirsutism. A lower dose of this combination (0.625 mg esterified estrogens and 1.25 mg methyltestosterone) also significantly lowered HDL cholesterol.<sup>614</sup> The adverse impact

on the lipid profile is less (and may even be avoided) by the parenteral administration of testosterone.<sup>615</sup> Of course, the clinical effects of these metabolic changes are not known.

**It should be remembered that androgens do not protect the endometrium, and the addition of a progestin is still necessary.** It is uncertain (and unstudied) how much aromatization, especially local aromatization in target tissues, of the administered testosterone increases the estrogen impact and whether this might increase the risk of endometrial and/or breast cancer. The addition of androgen does not reduce the amount of breakthrough bleeding women experience with a continuous combination regimen.<sup>616</sup> Adding testosterone to an estrogen therapy program has been reported to provide no additional beneficial impact on the bone or on relief from hot flashes.<sup>613,617</sup> On the other hand, others have demonstrated a greater increase in bone density with an estrogen-androgen combination compared with estrogen alone, although the blood levels achieved were higher than those associated with standard postmenopausal hormone therapy.<sup>615</sup> In another study, only a very pharmacologic dose of methyltestosterone added to the bone density achieved with estrogen alone.<sup>618</sup> A greater effect on bone associated with androgen treatment may be indirect, reflecting higher free estrogen levels because of a reduction in SHBG and/or androgen-induced changes in muscle mass.

There is no doubt that pharmacologic amounts of androgen can increase libido, but these same doses result in supraphysiologic levels and produce unwanted effects.<sup>619</sup> In addition, patients on high doses of androgens often are somewhat addicted to this therapy. Small amounts of androgen supplementation can be provided in situations in which the patient and clinician are convinced that a depressed libido cannot be explained by psychosocial circumstances. In these cases, the lipid profile should be carefully monitored. Any positive clinical response may well be a placebo effect. The products that are available in various parts of the world include testosterone undecanoate (used orally), sublingual micronized testosterone, intramuscular injections, subcutaneous implants, and transdermal preparations (Intrinsa, applied twice a week).<sup>620</sup> For example, the testosterone transdermal gel marketed for use in men (AndroGel), 5 g/day, can be used at a starting dose of about 1 g/day. Testosterone undecanoate produces very high testosterone levels with great variability and is not recommended.<sup>621</sup> **If testosterone use is considered, our preferred method is to use a product that will allow dose to be titered by measuring the total testosterone blood level with the goal of maintaining concentration in the range of 20–80 ng/dL.**

The initial clinical trials concluding that the 300 µg transdermal dose of testosterone was effective for low libido consisted of women with either surgical (1,172 women) or natural menopause (549 women) who were being also treated with

estrogen.<sup>622,623</sup> A 1-year, randomized, placebo-controlled clinical trial of 814 women with hypoactive sexual desire disorder and not on estrogen therapy from 65 centers in the United States, Canada, Australia, the United Kingdom, and Sweden assessed the impact of transdermal testosterone that delivered 150 or 300 µg/day.<sup>624</sup> The higher dose of testosterone increased sexuality (including desire, arousal, orgasm, and pleasure) by 1.4 episodes per month compared with placebo. This increase appeared as early as the second month of treatment. The lower dose did not differ from placebo. In the higher-dose group, 30% reported unwanted androgenic effects (essentially an increase in facial hair). In addition, one woman in the low-dose group and three women in the high-dose group developed clitoral enlargement (the enlargement resolved in the woman receiving the low dose, but not in the high-dose women). The frequency of acne, alopecia, and voice deepening was the same in all groups. It is certainly plausible that with longer exposure to the high dose, more and more women would develop androgenic side effects. There were four cases of breast cancer in the treatment groups and none in the placebo group; however, one was diagnosed after only 4 months of treatment and one had a bloody nipple discharge before the trial started, making it difficult to determine if these were preexisting or de novo cancers.

In the Nurses' Health Study, the risk of invasive breast cancer associated with the use of combined estrogen and testosterone was nearly twofold increased.<sup>625</sup> This report from the Nurses' Health Study is complicated by the same problem in other breast cancer reports from this cohort: the hormone users (in this case, estrogen and testosterone) differ substantially from never-users. This requires multiple statistical adjustments, a process that is further influenced by the number of cases involved. The analysis is limited by relatively small numbers; there were only 29 cases of breast cancer among the estrogen-testosterone users. Nevertheless, the results should raise caution regarding the postmenopausal use of androgens.

If testosterone affects breast tissue, does it do so directly or is it aromatized locally into estrogen? The majority of studies indicate that testosterone inhibits proliferation of breast cancer cell lines in vitro, as well as in vivo markers of breast epithelial proliferation in animals and women,<sup>626,627</sup> suggesting that aromatization is of greater concern. Testosterone preparations such as implants and transdermal applications do carry the risk of target tissue aromatization, perhaps raising local estrogen levels to high levels in breast tissue. Perhaps, an argument against this possibility was the failure to demonstrate any increase in breast density associated with transdermal testosterone treatment, even with the higher dose.<sup>628</sup> However, the mean age of the women in this study was 54.6, and an increase in breast density with estrogen-progestin therapy is largely observed in women over age 55; in younger women, it is difficult to find any differences between hormone users and nonusers.<sup>629</sup>

In the transdermal testosterone trial with women not on estrogen treatment, there was a 10.6% incidence of vaginal bleeding in the women who had not undergone hysterectomy and were receiving the higher dose, compared with 2.6% in the placebo group and 2.7% in the low-dose group.<sup>624</sup> Was this due to aromatization of testosterone in the endometrium? There were no cases of endometrial hyperplasia or cancer in this trial, but again, a longer duration of exposure might have unwanted consequences. This issue cannot be resolved without long-term data. In addition, the long-term effects on the cardiovascular system are unknown.

Response in the clinical trials with transdermal testosterone did not correlate with testosterone levels at baseline, and higher levels during treatment did not predict androgenic side effects. This is not surprising because measurement of free and bioavailable testosterone is subject to considerable inaccuracy and variability. For this reason, testosterone levels cannot be used to diagnose the hypoactive sexual desire disorder.<sup>630</sup> The transdermal clinical trials have reported that all testosterone levels remained within the premenopausal ranges. However, the mean level of free testosterone was relatively high at 6.8 pg/mL, although within the reference range. According to the data in the supplemental appendix, available only online, the mean levels were at or above the upper end of the reference age. In addition, because of individual variability, there was a wide range of testosterone levels, with a significant number of values elevated above normal. For many women, these are not physiologic levels. We do not know if it is possible to avoid unwanted consequences by careful monitoring of blood levels.

The only testosterone formulation approved for exclusive use in female population in the United States is of a combination of esterified estrogen with methyltestosterone—a higher (2.5 mg methyltestosterone) and lower (1.5 mg methyltestosterone) dose combination formulation is available.<sup>631</sup> Compounded testosterone formulations in the form of gels, pellets, and injectable testosterone (decanoate, enanthate, cypionate) have been varyingly utilized, but are not FDA approved. With gels, 5 mg (1%) is recommended.<sup>632</sup> Varying doses have been used for injectable testosterone with currently no adverse effects noted; however, outcomes have only been measured over a 6-month period.<sup>633</sup> Exercising extreme caution when considering testosterone pellet therapy is warranted given concern for supraphysiologic doses achieved. Furthermore, in women with breast cancer, uterine cancer, cardiovascular disease, or liver disease, testosterone use is generally contraindicated.<sup>631</sup>

There is little doubt that the pharmacologic amounts of testosterone can produce favorable effects on sexuality, but it remains doubtful that maintaining testosterone levels within the normal physiologic range can have a beneficial impact on well-being and health. Some women receiving pharmacologic amounts of testosterone develop very

high circulating levels. The fundamental problem is that the long-term consequences of pharmacologic amounts of testosterone are unknown. **If a clinician and a patient choose to use supplemental androgens, our advice is to select a treatment that can be monitored with measurements of total testosterone in serum.** The choices include the testosterone transdermal patch, a testosterone skin gel (on the market for use in men), and testosterone compounded for individual use by a pharmacist. We are left with this question: is a modest increase of one or two episodes per month sufficient to offset the unanswered question of long-term safety? Some women would say yes, but the clinician has an obligation to avoid excessive doses and to educate the patient regarding the unanswered questions. **Prior to initiation, we recommend obtaining baseline lipid, and liver function tests and periodic surveillance (3 months following initiation and yearly thereafter) are recommended to ensure safety.** The free testosterone index can be used to monitor testosterone levels (goal of physiologic levels) with all testosterone formulations. Of note, oral methyltestosterone cannot be measured, as it is not detected in existing testosterone assays.<sup>631</sup> As long-term safety data are limited, it is highly recommended that a discussion for treatment discontinuation be made with patients at 6 months following initiation.<sup>631</sup>

**While a role of testosterone therapy in women's health remains somewhat controversial, in the setting of reduced libido, particularly in surgically menopausal women, testosterone may be beneficial for some menopausal women not responding to traditional HT.**

# Dehydroepiandrosterone

Adrenal androgen production decreases dramatically with aging. The mechanism is not known, but it is not due to the loss of estrogen at menopause nor can it be reversed with estrogen treatment.<sup>634</sup> The impressive decline (75–85%) in circulating levels of DHEA that occur with aging (greater in men than in women) has stimulated a search for a beneficial impact of DHEA supplementation.<sup>635</sup>

The only proven function of DHEA and its sulfate, DHEA-S, is to provide a pool of prohormone for conversion to androgens and ultimately estrogens. By age 70 or 80, the circulating levels in men and women are about 10% of peak levels that occur between 20 and 30 years of age. Systemic DHEA supplementation does not produce improvements in menopausal symptoms, mood, libido, cognition, or memory, but it does increase testosterone and decrease HDL cholesterol.<sup>636</sup> The acute administration of DHEA did produce a modest effect on sexual response in postmenopausal women, but the dose was enormous, 300 mg.<sup>637</sup>

Although low levels of DHEA and DHEA-S have been reported to be associated with increased risk of cardiovascular disease in men, in women conflicting results are found in cross-sectional data. In a longitudinal study of 236 women, higher levels of DHEA and DHEA-S in middle-aged women correlated with an increased risk of cardiovascular disease.<sup>638</sup>

DHEA supplementation, 50 mg/day, produced reproductive levels of DHEA-S in elderly men, did not change levels of testosterone and dihydrotestosterone, and raised estradiol and estrone levels, although still within normal range.<sup>639</sup> In women, 25 or 50 mg/day increased testosterone levels, decreased SHBG levels, and produced adverse effects on the lipid profile.<sup>640,641</sup> Exogenously administered DHEA is converted to potent androgens and estrogens. Potential long-term effects include hirsutism, alopecia, voice changes, prostate and breast effects, and an increased risk of CHD. Supplementation with DHEA requires titrating of dosage using the circulating level of total testosterone and keeping the concentration below 80 ng/dL. This is difficult because the U.S. Food and Drug Administration measured the DHEA content of 45 commercial products, and assayed values varied from 0% to 109.5%!<sup>642</sup>

In contrast to systemic DHEA formulations, a prospective, randomized, placebo-controlled trial of daily intravaginal use of DHEA (trade name Prasterone) in a dose of 0.5% (6.5 mg) demonstrated significantly improved symptoms of vaginal atrophy, with little change in the serum levels of DHEA, estradiol, and testosterone.<sup>643,644,645,646,647</sup> Presumably, the vaginally administered DHEA is converted locally to estrogen and testosterone within the vaginal tissue. In clinical trials comparing DHEA to 0.3 mg CEE

or 10 µg E2 daily, DHEA was found to be at least as effective as CEE and/or estradiol in improving vulvovaginal symptoms.<sup>648</sup> There was no effect of vaginal DHEA on the following tissues: the endometrium and liver; the effects on the bone are not yet known.

# SELECTIVE ESTROGEN RECEPTOR MODULATORS

---

A greater understanding of the estrogen receptor mechanism ([Chapter 1](#)) allows us to understand how mixed estrogen agonists/antagonists can have selective actions on specific target tissues. New agents are continuously being developed in efforts to isolate desired actions (vasomotor symptom benefit and bone effect) from unwanted side effects (endometrial and breast tissue effects). Indeed, in time, we can expect to see new products with progressively better agonist/antagonist profiles, yielding increasingly user-friendly drugs.

# Raloxifene

Raloxifene exerts no proliferative effect on the endometrium but produces favorable responses in bone and lipids.<sup>649,650,651,652</sup> The MORE (Multiple Outcomes of Raloxifene Evaluation) study of raloxifene administration to osteoporotic women reported results from 8 years of follow-up.<sup>653,654</sup> Women with low T-scores had approximately a 50% reduction in vertebral fractures with raloxifene treatment and with previous vertebral fractures, approximately 35%. However, **there has been no evidence of a reduction in hip or wrist fractures.** The major side effect was about a threefold increase in VTE. Raloxifene (and tamoxifen) shares with estrogen an increased risk for VTE.<sup>655</sup> The size of the risk is comparable for all three drugs, and nearly all the cases occur in the first 1 or 2 years of exposure. A small number of women experience hot flushing with raloxifene. Raloxifene treatment in the MORE trial had neither a positive nor a negative effect on cognition.<sup>656</sup>

Women who received raloxifene in the MORE trial had about an 80% reduction in the incidence of estrogen receptor–positive breast cancers. The CORE study, the Continuing Outcomes Relevant to Evista trial, was designed to measure the impact of four additional years of raloxifene (60 mg/day), beginning during the fourth year of the MORE trial.<sup>657</sup> Of the 7,705 participants initially randomized in the MORE trial, 3,510 women elected to continue raloxifene treatment (2,336 completed the CORE trial) and 1,703 continued on placebo (1,106 completed the trial). During the 4-year CORE study, raloxifene treatment was associated with a 66% (HR = 0.34; CI = 0.18–0.66) reduction of estrogen receptor–positive invasive breast cancer in the treated group. There was no difference in estrogen receptor–negative tumors. Over the entire 8-year period, the reduction in estrogen receptor–positive cancers reached 76%. In the 8-year period, there was no difference in the number of deaths in the two groups.

The Study of Tamoxifen and Raloxifene (STAR) trial enrolled 19,747 women at increased risk of breast cancer who were randomized to treatment with either raloxifene, 60 mg daily, or tamoxifen, 20 mg daily, in more than 500 centers in the United States, Canada, and Puerto Rico.<sup>658</sup> After an average treatment period of almost 4 years, the numbers of invasive breast cancers were identical in the two groups of women. It was estimated that these results were equivalent to about a 50% reduction (based on the previous results in the tamoxifen prevention trial),<sup>659,660</sup> but without a placebo arm, an accurate assessment was impossible. Thus, raloxifene appears to achieve the same reduction as tamoxifen in invasive breast cancers with a lesser increase in venous thrombosis and perhaps no increase in cataracts and uterine cancer. Fractures, as well as strokes and heart attacks, were equally prevalent in the two groups. “Quality of life” was said to be the same for both drugs.

Tamoxifen has been demonstrated to reduce the incidence of both lobular carcinoma in situ and ductal carcinoma in situ.<sup>659,660</sup> In the 7-year follow-up report of the tamoxifen for prevention study, the risk for breast cancer was 0.57 (CI = 0.46–0.79), a 43% reduction, not the 50% cited in the results above, and the risk for in situ disease was 0.63 (CI = 0.45–0.89), a 37% reduction.<sup>659</sup> Not only did raloxifene not yield a reduction in in situ cancers, the number with raloxifene in the STAR trial was greater. If raloxifene is truly preventing breast cancer, this should produce a reduction in in situ disease. Perhaps, with longer follow-up, a difference between the two treatment groups will no longer be apparent.

In a 2-year randomized trial in monkeys, raloxifene exerted no protection against coronary artery atherosclerosis despite changes in circulating lipids similar to those achieved in women.<sup>661</sup> The Raloxifene Use for The Heart (RUTH) study included more than 10,000 women from 26 countries, either at high risk for myocardial infarction or with known CHD.<sup>662,663</sup> The participants were randomized to placebo or raloxifene, 60 mg daily, and followed for up to 7 years. There was no effect of raloxifene treatment on CHD events; however, there was a small increase in stroke mortality. The results of the RUTH trial are not surprising. The known favorable impact of raloxifene on the cholesterol-lipid profile was not robust enough to prevent coronary events.

Because the Nurses' Health Study reported a reduction in coronary events associated with estrogen therapy administered to young postmenopausal women, the RUTH trial performed a post hoc analysis of the impact of raloxifene according to age of the women at entry to the study as well as subgroups such as the use of medications, including statins.<sup>663</sup> Overall, raloxifene did not increase or decrease coronary events in either of the treated groups. The only category demonstrating a significant difference, a 40% reduction in coronary events, consisted of women less than 60 years of age. Despite the statistically significant reduction in coronary events in women under age 60, there was no relationship in any subgroup according to years since menopause, even in the group less than 10 years postmenopausal. The women who were less than 60 years of age were an average of 9.9 years since menopause, compared with 19.4 years for the overall study population. A decision to use raloxifene should not be influenced by its effects on the cardiovascular system. This is a bone and breast decision.

**In our view, raloxifene is an option for prevention of osteoporosis-related spinal fractures, especially for patients reluctant to use hormone therapy or in those wanting to combine some bone protection with a reduction in the risk of breast cancer. We recommend, however, periodic evaluation of bone density at the hip, and if bone loss occurs, patient and clinician should consider another treatment option.**

# Ospemifene

Ospemifene (Ophena), the newest of these agents, has been approved by the FDA in the United States and Europe for its beneficial effects on vaginal tissue. It is being primarily given in a dose of 60 mg/day given orally for the treatment of vulvar and vaginal atrophy, sites where ospemifene exerts a significant estrogenic impact.<sup>664</sup> Ospemifene suppressed the development of breast cancer in the drug-induced mouse model, and post hoc analysis of safety data is reassuring in terms of effects on the breast, endometrium, and bone; vasomotor symptoms can worsen, however.<sup>665</sup> More recently, improvements in urinary urge incontinence and in sexual function were observed following a 12-week treatment with ospemifene in postmenopausal women with symptoms of overactive bladder syndrome.<sup>666</sup>

# Effect of SERMs on the Skeleton

These effects are discussed later in the chapter, in the section on osteoporosis.

## Tissue-Selective Estrogen Complex

The combination of an estrogen combined with a selective estrogen receptor modulator (SERM) is called a TSEC (tissue-selective estrogen complex). The idea is to gain the benefits of estrogen (improved vasomotor symptoms and improved BMD and reduced fracture risk) while mitigating potential for adverse effects of estrogen on certain end organs (such as the endometrium and the breast). A series of randomized controlled trials (SMART) have paired conjugated estrogen with a SERM, bazedoxifene (BZA), with the goal of achieving symptom benefit without the need for adding progestational agent to HT regimen in women who have a uterus, while allowing synergy of both agents on certain end organs such as the bone.<sup>667</sup> BZA belongs to the estrogen agonist-antagonist family of drugs. It has favorable effects on the bone and lipids, but does not affect the endometrium or the breast.<sup>668,669</sup> BZA in a dose of 20 mg daily decreased the risk of all clinical fractures in randomized clinical trials, with a potency comparable to other antiresorptive agents in postmenopausal women at high risk for fractures.<sup>670,671</sup> In a subgroup of women at higher risk for fractures, BZA had a reduced risk of nonvertebral fractures (50% reduction with 20 mg), compared with both raloxifene and placebo. Treatment for 2 years had no effect on mammographic breast density.<sup>672</sup> Furthermore, in the Selective Estrogens, Menopause, And Response to Therapy (SMART)-5 trial (using BZA paired with CEE), there was no increased incidence of breast density or tenderness when compared to CEE/MPA.<sup>673</sup> The results of these trials indicate that the effect of BZA on the bone should be comparable to that of estrogen and bisphosphonates.

BZA combined with conjugated estrogens effectively suppresses hot flashes, improves vaginal atrophy, prevents bone loss, and does not stimulate the endometrium or cause breast tenderness.<sup>668,673,674,675,676,677</sup> The combination of 20 mg BZA with CEE prevents endometrial hyperplasia and has an extremely high rate of amenorrhea (at least 80%).<sup>678,679</sup> Given BZA's antiestrogenic effects specific to the endometrium (even in the presence of CEE), the TSEC approach may be the future of HT given that it maximizes the benefits of HT and also minimizes harm. It also allows for the avoidance of a progestational agents. **The first TSEC to be approved by the FDA in the United States is Duavee.**

# TIBOLONE

---

Tibolone is marketed for menopausal HT in many countries throughout the world, but is not approved in the United States. It was first introduced in the Netherlands, the home country of its manufacturer Organon (now Schering-Plough), which initiated research on this product in the 1960s. Although tibolone was specifically developed as a drug to treat osteoporosis, the clinical performance of tibolone led rapidly to its approval for the treatment of menopausal symptoms as well as prevention of osteoporosis. Because of its unique metabolism, tibolone can exert different hormonal activities at different sites. It has beneficial effects on bone density, improves vasomotor symptoms, and does not have estrogenic effects on the endometrium.<sup>680</sup> However, there are concerns regarding its safety. Adverse effects of tibolone on breast tissue and increased stroke risk are described with its use, and overall it is felt to be less effective than estrogen-based HT.<sup>681</sup> Given these concerns, we do not recommend it as a first-line management approach to menopause.

# The Chemistry of Tibolone

Tibolone is structurally related to the 19-nortestosterone progestins that are used clinically in oral contraceptives; however, its activity depends on its metabolism. Tibolone {7- $\alpha$ ,17- $\alpha$ -17-hydroxy-7-methyl-19-norpregn-5(10)-en-20-yn-3-one} is metabolized among human and nonhuman primates into three biologically active metabolites (**Figure 17.12**); the 3 $\alpha$ -hydroxy (3 $\alpha$ -OH) metabolite and the 3 $\beta$ -hydroxy (3 $\beta$ -OH) metabolite have estrogen agonist properties, whereas the  $\Delta$ -4 ketoisomer has progestogenic and androgenic effects.<sup>682,683</sup> Although tibolone itself binds to the estrogen receptor, in vivo the activity of the 3-hydroxymetabolites is 100 times greater, with a greater affinity for the estrogen receptor-alpha than for estrogen receptor-beta.<sup>683</sup> The loss of the hydroxyl group at position 3 of the A ring eliminates estrogenic activity in the  $\Delta$ -4 isomer. The  $\Delta$ -4 isomer exerts its androgenic effects primarily in the liver and brain.

**FIGURE 17.12**

The conversion of tibolone into metabolites occurs chiefly in the liver and intestine. The metabolism of the parent compound is rapid and very near total, yielding mainly the 3 $\alpha$ -OH and the 3 $\beta$ -OH metabolites in the circulation; the level of the 3 $\alpha$ -OH metabolite is

threefold higher compared with the  $3\beta$ -OH metabolite.<sup>684,685</sup> Tibolone and the  $\Delta$ -4 isomer can be detected only at peak levels 2 hours after ingestion, and, even then, the levels are very low, at the limit of detection. The half-life of the metabolites that predominate in the circulation (the  $3\alpha$ -OH and  $3\beta$ -OH metabolites) is approximately 7–8 hours, and a steady state is attained by day 5.<sup>686</sup> Eating does not affect the metabolism, and tibolone can be taken at any time of the day.<sup>684</sup> The pharmacokinetics of tibolone are not affected by impaired renal function. There is a very weak effect of the metabolites on cytochrome P450 enzymes, and no interference is to be expected with coadministered drugs.<sup>685</sup> After the initial metabolism of tibolone, the products are rapidly sulfated, and more than 75% of the metabolites circulate as the sulfates to be activated by tissue sulfatases.<sup>685</sup>

Tibolone is available in two daily doses, 1.25 and 2.5 mg. There is considerable variability (about 30–40%) within and between subjects, but the 1.25- and 2.5-mg doses produce the same bioequivalence as measured by maximum levels and areas under the curve for the  $3\alpha$ -OH and  $3\beta$ -OH metabolites.<sup>684</sup> However, there are differences in clinical responses, which influence the choice of dose.

The metabolism of tibolone is not limited to the liver and intestine. Important effects are explained by specific local tissue metabolism. For example, the  $\Delta$ -4 isomer is primarily produced within the endometrium, binds to the progesterone receptor, and protects the endometrium from the agonist effects of the two estrogenic metabolites.<sup>685,686,687,688,689,690</sup>

# Effect of Tibolone on Menopausal Symptoms

Menopausal symptoms provide the main motivation for women to use postmenopausal hormonal therapy. Tibolone must perform well in this category in order for it to be an attractive option for clinicians and patients. Clinical studies have established without question that tibolone exerts an estrogenic beneficial impact on hot flushing and vaginal dryness. Appropriate studies have documented that tibolone in a daily dose of 2.5 mg is as effective as standard postmenopausal hormone regimens in treating hot flushing.<sup>691,692,693,694,695,696,697</sup> The 1.25-mg dose takes longer to be effective, and this dose also has a higher incidence of persistent flushing.<sup>698</sup> In addition, tibolone effectively treats the side effect of hot flushing associated with GnRH agonist therapy.<sup>699</sup> Fortunately, tibolone treatment provides an estrogenic effect on the vagina. Tibolone, 2.5 mg daily, relieves vaginal dryness and dyspareunia, and in most studies, tibolone is as effective as estrogen treatment.<sup>693,694,695,696,697,700,701,702,703</sup>

A decided advantage for tibolone can be found in studies examining sexuality. In prospective, randomized trials comparing tibolone with estrogen or estrogen-progestin therapy, tibolone has been associated with a better sexual response.<sup>694,697,704,705,706,707</sup> An increase in libido has been reported in studies comparing tibolone with placebo,<sup>703,708</sup> and the response has been greater than that with estrogen therapy, comparable to that associated with androgen treatment.<sup>709</sup> The overall effect has included an increase in sexual interest and sexual performance, specifically fantasies, arousal, and orgasm.

There are two possible mechanisms for tibolone's effect on sexuality: a direct androgenic effect of the  $\Delta$ -4 isomer and/or an increase in the circulating level of free testosterone. Tibolone is associated with a profound change in the circulating levels of SHBG, about a 50% decrease.<sup>703,710</sup> This is undoubtedly due to the  $\Delta$ -4 isomer and an androgenic effect on the liver. Tibolone treatment, therefore, produces a decrease in the concentration of total testosterone (bound and unbound) but a substantial increase in the amount of free, unbound testosterone. This hormonal profile is a striking contrast to that associated with estrogen therapy, which increases SHBG and decreases both total and free testosterone levels. The androgen side effects of acne and hirsutism, however, have not been reported with tibolone treatment.

When women who had been on tibolone for 10 years were compared with a matched group, the treated women were less clumsy, were less anxious in response to mild stress, and demonstrated better memory for facts, although there was no difference in memory for events and worse performance on sustained attention and planning.<sup>711</sup> Overall, tibolone exerts a positive effect on mood that is modest in impact.<sup>710,712</sup> However, this is an area in which it is not easy to achieve consistent effects, a problem

often due to the differences in measurement tools and definitions. The study of cognition is difficult because of the need to match treated and control groups for intelligence, age, occupation, education, and mental state (e.g., depression). Because of this difficulty, the literature reporting the effects of hormone therapy on cognition provides an inconsistent picture. This is further complicated by the sensitivity and appropriateness of the assessment tools that are used. This is an area that requires standardization and new approaches for research, not only for tibolone but for all pharmacologic treatments that affect the central nervous system.

# Effect of Tibolone on the Cardiovascular System

Consistent with reports of tibolone's effects on HDL cholesterol in postmenopausal women, tibolone-treated monkeys have much lower HDL cholesterol compared with control monkeys.<sup>713,714</sup> Although tibolone treatment resulted in lower circulating HDL cholesterol, coronary artery atherosclerosis extent in monkeys was not significantly different from the control group. Similar results were observed in the carotid arteries.<sup>714</sup> That observation prompted the question of whether the HDL cholesterol reductions noted among the animals treated with tibolone were associated with physiologically meaningful reductions in HDL cholesterol function. HDL cholesterol has a critical role in reverse cholesterol transport, the mechanism by which cell cholesterol (i.e., artery wall cholesterol) can be returned through the plasma to the liver for excretion.<sup>715</sup> Further, it has been found that cholesterol efflux capacity predicts the severity and extent of coronary artery disease in human patients.<sup>716</sup> Postmenopausal monkeys treated with tibolone had no reduction in cholesterol efflux.<sup>717</sup> This disassociation between reductions in circulating concentrations of HDL cholesterol and the lack of change in HDL cholesterol function suggests the likelihood that this may account in large part for the finding that coronary artery atherosclerosis was not increased or decreased in the monkey model.

Short-term clinical studies uniformly document that tibolone treatment, 2.5 mg/day, reduces HDL cholesterol levels in women by about 20%; however, there is also a reduction in total cholesterol (about 10%) and triglycerides (about 20%) and a slight decrease or no change in LDL cholesterol levels.<sup>705,718,719,720,721,722,723,724</sup> In women, therefore, tibolone does not increase LDL cholesterol, and the reduction in HDL cholesterol is less than that recorded in monkeys. In addition, tibolone decreases LDL cholesterol oxidation and produces a shift away from small dense LDL cholesterol (which is more atherogenic); both changes would be beneficial.<sup>724</sup> The potential harmful effects associated with reductions in HDL cholesterol are further balanced by tibolone-associated reductions in endothelin and lipoprotein(a), anti-ischemic effects detected in women with angina, and an improvement in insulin sensitivity.<sup>723,725,726,727,728</sup> In longer-term studies, HDL cholesterol levels did not come back to baseline at the end of 2 years of treatment, but did return to baseline at the end of 3 years.<sup>723,729,730,731</sup> And other studies have found that the decrease in HDL cholesterol is statistically insignificant.<sup>732,733</sup>

The recognition that reductions in HDL cholesterol are potentially harmful is based on the important roles for HDL cholesterol in the mediation of cholesterol movement from lipid-laden cells and inhibition of LDL cholesterol oxidation. However, the experimental results in the monkey model indicate that reductions in HDL cholesterol

concentrations are not directly paralleled by reductions in important HDL cholesterol functions. At least one reason for this lack of direct correlation is the complex nature of HDL cholesterol lipoproteins, a heterogeneous collection of particles that differ in their activities.<sup>734</sup> The overall change in HDL cholesterol levels will not reflect specific changes in particles that can affect specific biologic activities. Similar to results in the monkey model, a randomized trial in women demonstrated that significant reductions in HDL cholesterol levels (average 27%) caused by tibolone treatment, 2.5 mg/day, were due to a decrease in one subclass of HDL cholesterol particles, and measures of HDL cholesterol antiatherogenic functions (reverse cholesterol transport and inhibition of LDL cholesterol oxidation) were not impaired.<sup>728</sup> The study was limited by the short, 12-week duration of treatment; however, the findings are consistent with those obtained in the 2-year monkey experiment. These human results were confirmed and strengthened by a study of 68 postmenopausal women randomized to daily treatment for 3 months with either 2.5 mg tibolone or placebo.<sup>735</sup> Changes in HDL cholesterol were associated with an increase in hepatic lipase activity, an androgenic effect, again without impairing the ability of plasma to maintain cholesterol efflux.

Results in the monkey model are consistent with an overall neutral impact on the cardiovascular system.<sup>714</sup> A long-term (average of 7.5 years) follow-up of women treated with tibolone found no increase in carotid artery intimal-medial thickness and the number of atherosclerotic plaques, results that are consistent with the monkey model.<sup>736</sup> This neutral impact is further supported by failing to find any effect of tibolone on experimentally induced brachial artery dilation or on vascular resistance measured in the carotid and middle cerebral arteries.<sup>732,737</sup> On the other hand, a method studying venous dilation in the hand found an improvement in endothelium-dependent responses after tibolone treatment.<sup>738</sup> Myocardial infarction and heart failure have been reported to be associated with overactivity of the sympathetic component of the cardiac autonomic nervous system, and tibolone treatment decreases plasma levels of free fatty acids, an effect that results in an improved ratio of cardiac sympathetic tone to parasympathetic tone.<sup>739</sup> Another favorable effect connected to tibolone and its metabolites is a direct impact on endothelial cells that results in a beneficial decrease in endothelial-leukocyte adhesion molecules, another human finding similar to that in the monkey trial.<sup>740</sup>

The OPAL (Osteoporosis Prevention and Arterial effects of tibolone) study was a 3-year, randomized, double-blind trial in six U.S. centers and five European centers, treating 866 postmenopausal women with either 2.5 mg tibolone daily, 0.625/2.5 mg daily of conjugated estrogens/medroxyprogesterone acetate, or placebo.<sup>741</sup> The arterial endpoint of the study was carotid intima-media thickness measured by ultrasonography every 6 months. Both the tibolone-treated group and the estrogen-progestin-treated

group demonstrated an increase in intima-media thickness over the time period of the study, at a rate significantly greater than the placebo group, leading to the conclusion that both tibolone and estrogen/progestin treatment increased atherosclerosis compared with the placebo group.

In the OPAL trial, European women differed from American women in multiple ways: higher lipids, higher blood pressure levels, and more smokers. Hysterectomized women were excluded in the United States but not in Europe (28% of the study population). The overall mean results, indeed, indicated a difference comparing both treatment groups to placebo. But in the European women, atherosclerosis, measured by intima-media thickness, improved in the placebo group, making it easy to calculate a significant difference compared to the treated groups. In American women, there were no differences comparing the three treatment groups; all demonstrated progression of thickness. Thus, the overall conclusion was inordinately influenced by the results in the European women. The investigators could not explain these differences. Unfortunately, the OPAL trial did not achieve its goal of providing robust data on cardiovascular effects, due to the older age of the women and the notably different results in American and European women. There continues to be good reason to believe that tibolone has a neutral effect on the cardiovascular system. In addition, tibolone does not adversely affect the blood pressure in women with established hypertension.<sup>721</sup>

A case-control study assessed the risk of VTE in a very large population of postmenopausal women (23,505 cases and 231,562 controls) derived from the U.K. General Practice Research Database.<sup>742</sup> No increase in risk was observed with the current use of either tibolone or transdermal estrogen compared with a significant increase associated with the current use of oral estrogen.

# Effect of Tibolone on Diabetes

The administration of tibolone, 2.5 mg/day, to older women with type 2 diabetes mellitus produced no significant changes in the lipid profile.<sup>743</sup> Tibolone treatment is associated with an increase in insulin sensitivity in women with insulin resistance, although some have reported no effect in normal women.<sup>720,728,744,745</sup> Therefore, tibolone is an attractive option for postmenopausal women with diabetes mellitus.

## Effect of Tibolone on the Uterus

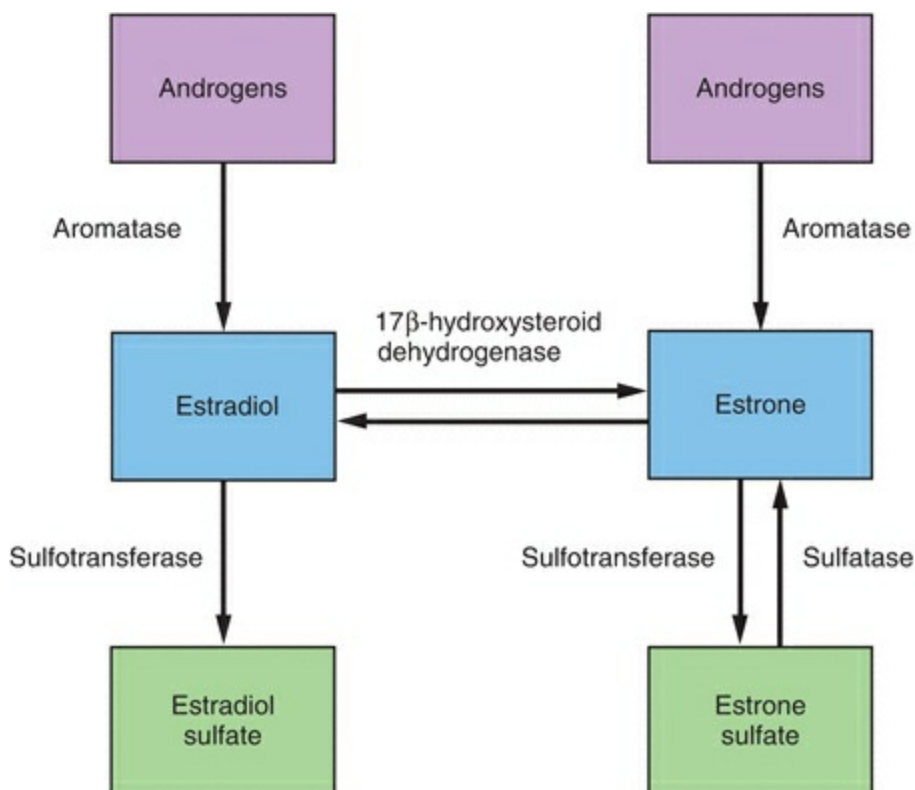

Tibolone does not stimulate endometrial proliferation. This is because the predominant if not exclusive tibolone metabolite produced within the endometrium is the  $\Delta$ -4 isomer, which binds to the progesterone receptor and protects the endometrium from the agonist effects of the two estrogenic metabolites.<sup>687,688,689,690</sup> This protective effect has been documented in long-term (up to 8 years) human studies.<sup>689,690,693,701,702,746,747,748</sup> Isolated cases of endometrial proliferation have been reported, for example, 4 of 150 women treated with 2.5 mg daily for 2 years.<sup>749</sup> In a 5-year follow-up, 47 of 434 women experienced bleeding, and of these, 11 had endometrial polyps or fibroids, but there were 2 with simple hyperplasia and 2 with endometrial carcinoma in situ.<sup>750</sup> This underscores the standard clinical principle to investigate persistent vaginal bleeding in any postmenopausal woman. In the major U.S. clinical trial, three cases of endometrial cancer were observed, but, in each case, preexisting carcinoma was later detected when the initial biopsy samples were more extensively examined.<sup>723</sup> Nevertheless, a second large 2-year trial was conducted, the THEBES study, and no endometrial hyperplasia or cancer occurred in the tibolone-treated groups.<sup>751</sup>

The reported breakthrough bleeding rates with tibolone treatment have been comparable to treatment with combined, continuous estrogen-progestin therapy,<sup>694,696,719,746</sup> but well-designed comparison clinical trials indicate that the rate is less with tibolone.<sup>695,697,703,752,753</sup> In addition, amenorrhea is achieved more rapidly; 90% of tibolone-treated women are amenorrheic by 6 months.<sup>695,750,754</sup> Bleeding is less in older women and can be greater with the 2.5-mg dose compared with the 1.25-mg dose, but the difference is too small to be detected in some studies.<sup>698,723,755</sup> Importantly, a lack of correlation has been observed between bleeding and endometrial thickness measured by ultrasonography.<sup>755,756</sup> **This again emphasizes the need to biopsy tibolone-treated women with persistent bleeding.**

Careful evaluations of women with fibroids who have been treated with tibolone have revealed no evidence of myoma growth, with up to 3 years of follow-up.<sup>757,758,759</sup> Furthermore, add-back treatment with tibolone effectively prevents flushing and bone loss and does not impair the fibroid response to therapy with GnRH analogs.<sup>760</sup>

# Effect of Tibolone on the Breast

The breast is a complicated estrogen factory. The breast tissue, normal and abnormal, contains all the enzymes necessary for the formation of estrogens (sulfatase, aromatase, and  $17\beta$ -hydroxysteroid dehydrogenase) and the conversion of estrogens into their sulfates (sulfotransferase) (Figure 17.13). Estrone sulfate concentrations are high in the breast (higher than in plasma) and even higher in cancer tissue. This state is achieved in postmenopausal women with very low systemic levels of estrogen, indicating that a local mechanism is operative.

**FIGURE 17.13**

The major pathway of estrogen synthesis in human breast tumor cells is by conversion of estrone sulfate to estrone by estrone sulfatase, a pathway that is more important than the aromatase pathway.<sup>761</sup> Aromatase is an enzyme complex that produces the irreversible conversion of androgens to estrogens. The location of aromatase activity is predominantly in the stromal tissue of the breast. Comparing normal to tumor tissue, the levels of estrone sulfate and estradiol were higher in the tumor tissue.<sup>762</sup> Sulfatase activity is higher (130–200 times) than aromatase activity in all breast tissues examined, and the sulfatase and aromatase activity was higher in the tumor tissue than in normal

tissue. Thus, estrogen concentrations in the breast are higher in women with breast cancer, and formation of estradiol from sulfated estrogen is the primary pathway. Most importantly, this increase in estrogen activity is independent of the estrogen receptor status of the tissue.

Tibolone and its metabolites inhibit estrone sulfatase and 17 $\beta$ -hydroxysteroid dehydrogenase in normal stromal cells and in hormone-dependent breast cancer cells (MCF-7 and T-47D).<sup>763,764,765,766</sup> This inhibits conversion of estrone sulfate to estradiol. In addition, tibolone and its 3-hydroxymetabolites increase the conversion of estrone back to estrone sulfate by increasing the activity of sulfotransferase.<sup>767</sup> Tibolone and all three metabolites inhibit the conversion of estrone to estradiol by 17 $\beta$ -hydroxysteroid dehydrogenase.<sup>764</sup> Although these effects resemble progestin activity, tibolone is more potent. Tibolone increases aromatase activity in stromal cells but only at high concentrations that are beyond in vivo levels.<sup>765</sup> These tibolone-induced enzyme changes would lower the active estrogen concentrations in breast tissue.

In the rat and mouse breast cancer models (cancer induced by 7,12-dimethylbenz[a]anthracene, DMBA), tibolone exerts protective effects to the same degree as tamoxifen.<sup>768</sup> However, tibolone is not antiestrogenic and does not inhibit aromatase. Therefore, the mechanism is explained by the enzyme effects summarized previously, inhibition of sulfatase and 17 $\beta$ -hydroxysteroid dehydrogenase and stimulation of sulfotransferase to increase the production of inactive sulfates.<sup>765</sup> In addition, tibolone increases cellular differentiation and stimulates apoptosis, at least with normal breast cells in vitro.<sup>769</sup> An increase in apoptosis is an action of the parent tibolone and its  $\Delta$ -4 isomer. Thus, tibolone acts like progestins and weak androgens in breast cell line studies examining proliferation, differentiation, and apoptosis.

Tibolone and its metabolites do not display the same activity directed toward the sulfatase enzyme in all tissues. Strong inhibition of sulfatase is a major feature in breast cells, but tibolone and its metabolites inhibit sulfatase only moderately in the endometrium (contributing to an antiestrogenic action) and provide no inhibition in the bone (allowing a greater estrogenic impact).<sup>770</sup>

Postmenopausal hormone therapy increases breast density on mammography in about 10–20% of estrogen users and about 20–35% of estrogen-progestin users, an effect that occurs within the first months of treatment. In contrast, tibolone does not increase breast density and causes far less mastalgia than that seen with estrogen treatment.<sup>695,707,723,753,771,772,773,774,775</sup> It is logical to conclude that these favorable responses are a consequence of the tibolone effects on the breast tissue enzymes involved in local estrogen production.

The Livial Intervention following Breast cancer: Efficacy, Recurrence, And

Tolerability Endpoints (LIBERATE) trial was a multinational, placebo-controlled, randomized study of women with vasomotor symptoms who had had breast cancer surgically treated within the previous 5 years.<sup>776</sup> The study was designed to demonstrate that tibolone was superior to placebo, but when the drug monitoring safety board notified the sponsor that there appeared to be an excess of breast cancers in the treated group, the trial was canceled on July 31, 2007, 5 months before its scheduled end. The median duration of participation and treatment was about 3 years, with a wide range from a few weeks to almost 5 years. The participants used a variety of adjuvant treatments, mostly tamoxifen, 66.8%; 6.5% used aromatase inhibitors. The dose of tibolone was 2.5 mg daily. Final numbers for analysis were 1,556 women in the treated group and 1,542 in the placebo group. The women ranged in age from under 40 to 79, with a mean age of 52.7 years. 57.8% had positive lymph nodes and 70% had a tumor stage of IIA or higher. Estrogen receptor status was known in 2,808 women in whom the tumors were estrogen receptor positive in 77.8%. In the intent-to-treat analysis, the hazard ratio for recurrent breast cancer in the tibolone-treated women was 1.40 (CI = 1.14–1.70). The absolute risk for tibolone was 51 cancers per 1,000 women per year and 36 in the placebo group. The increase occurred only in women with estrogen receptor–positive tumors. There was no difference in mortality rates between the two groups during the 5-year study period. There were no differences in cardiovascular events or gynecologic cancers, and not surprisingly, vasomotor symptoms, quality of life measures, and bone density improved with tibolone treatment.

How do the LIBERATE results that indicate an estrogenic action of tibolone in breast cancer survivors jibe with the literature indicating that tibolone exerts a nonestrogenic effect on breast tissue? Indeed, it was realistic to expect tibolone to have a salutary effect on the breast. It is well documented that the breast responds to tibolone with less stimulation compared with estrogen, judged by changes in mammographic breast density and the characteristics of tissue obtained by fine-needle aspiration. In the LIFT clinical trial (discussed under bone) that had vertebral fractures as the primary endpoint and breast cancer as a secondary endpoint, the risk of breast cancer after 3 years was significantly 68% reduced with tibolone treatment, although the dose was lower, 1.25 mg daily.<sup>777</sup>

The previous literature documenting beneficial actions of tibolone on the breast reflected, however, the impact of tibolone on normal breast tissue, and tibolone's activity to lower local bioactive estrogen levels in target tissues might be lost in cancer cells. The contrary results in the LIFT trial could reflect its older population of women at high risk for fractures, a population that also differed by having lower body weights, no history of tamoxifen treatment, and lower risk factors for breast cancer.

Although the LIBERATE trial may apply to all breast cancer survivors, speaking strictly in a scientific sense, the results were derived mainly from tamoxifen users with

10-fold fewer users of aromatase inhibitors. The possibility that estrogen or tibolone would interfere with the beneficial effects of tamoxifen or aromatase inhibitors has always been one of the objections to treating breast cancer survivors with estrogenic hormones. In a subgroup analysis of the LIBERATE trial, the group of women who had used aromatase inhibitors had a greater risk of recurrent breast cancer compared with tamoxifen; however, the confidence interval was wide because of relatively small numbers. Possibly, the estrogenic effect of tibolone would be more pronounced on an occult breast cancer in estrogen-depleted tissue compared with tissue where tamoxifen was bound to the estrogen receptor and prevented estrogenic stimulation. We don't know if the LIBERATE data are meaningful for future treatment regimens. Nevertheless, **until there are new data, the use of tibolone in women with a history of breast cancer remains relatively contraindicated.**

# Effect of Tibolone on the Bone

These effects are discussed later in the chapter in the section on osteoporosis.

## Key Points: Tibolone

- Tibolone is an appropriate choice for hormonal therapy, suitable for many postmenopausal women.
- The standard dose of tibolone for many years was 2.5 mg daily, but the clinical trials support the use of the lower dose, 1.25 mg daily, with no major loss of efficacy.
- Because of its unique and varied metabolism, tibolone has different actions in different tissues, which provide an overall favorable risk-benefit profile.
- Tibolone treats menopausal symptoms, including hot flushes and vaginal dryness, as effectively as estrogen therapy and, most importantly, improves sexual response.
- Endometrial safety and prevention of bone loss (discussed in under the section on osteoporosis of this chapter) are comparable to that achieved with continuous, combined estrogen-progestin regimens and with a lower rate of breakthrough bleeding.

The sum of the various biologic effects of tibolone and its metabolites on the cardiovascular system should neither increase nor decrease the risk of coronary artery disease. Thus far, there has been no indication for an increased risk of VTE, but this is a potential side effect that requires further epidemiologic studies. Tibolone does not stimulate the proliferation of breast cells and affects enzyme activity in the breast to lower breast tissue concentrations of active estrogen. Tibolone does not increase breast density on mammography and does not increase the frequency of mastalgia. The reported increased risks of breast cancer and endometrial cancer in observational studies very likely represent “preferential prescribing” of tibolone in Europe.<sup>778,779</sup> Women prescribed tibolone in Europe more often had chronic breast disease, a personal history of breast cancer, previous dysfunctional uterine bleeding, hypertension, and previous uterine operations. Most importantly, more women prescribed tibolone had a history of previous treatment with unopposed estrogen. Thus, clinicians were more likely to prescribe tibolone to women they believed were at higher risks for these two cancers, and this would

**yield higher rates in treated groups compared with control groups.**

# NON-HORMONAL TREATMENT OPTIONS FOR VASOMOTOR SYMPTOMS

---

The treatment of choice for vasomotor symptoms (hot flashes and night sweats) is hormone therapy (HT). However, there exist a substantial number of women who either cannot, should not, or will not accept HT. Pharmacologic non-hormonal options for managing vasomotor symptoms are listed in [Table 17.10](#).

## TABLE 17.10 Drugs for Hot Flushing—Randomized Clinical Trial Results

<b>Drug</b>	<b>Dose</b>	<b>Reduction in Flushing</b>
Citalopram (Celexa) placebo	20 mg/day	50%, same as placebo
Fluoxetine (Prozac)	20 mg/day	50%, same as placebo
Sertraline (Zoloft)	50,100 mg/day	40%, same as placebo
Paroxetine (Paxil)	12.5 mg/day	62%
	25 mg/day	65%
Venlafaxine (Effexor)	37.5 mg/day	37%
	75 mg/day	61%
	150 mg/day	61%
Desvenlafaxine succinate (Pristiq)	100 mg/day	64%
Gabapentin (Neurontin)	900 mg/day	50%
Pregabalin (Lyrica)	150 mg/day	65%

Clonidine, bromocriptine, and naloxone given orally are only partially effective for the relief of hot flushes and require high doses with a high rate of side effects such as drowsiness and dry mouth. Bellergal treatment (a combination of belladonna alkaloids, ergotamine tartrate, and phenobarbital) is slightly better than a placebo and a potent

sedative in the short term; however, one study documented a similar response with Bellergal and placebo after 8 weeks.<sup>780,781</sup> Veralipride, a dopamine antagonist that is active in the hypothalamus, is relatively effective in inhibiting flushing at a dose of 100 mg daily, but is associated with major side effects, including mastodynia and galactorrhea.<sup>782,783,784</sup> Vitamin E, 800 IU daily, is barely more effective than placebo.<sup>785</sup> Dong quai, ginseng, black cohosh, isoflavones (including soy protein), yoga, and acupuncture all have little clinical difference compared with placebo treatment.<sup>786,787,788,789,790,791,792,793,794,795,796</sup> Clonidine (given as a patch or orally at 0.1 mg/day) is only partially effective for the relief of hot flushes and has a high rate of side effects such as drowsiness and dry mouth.<sup>797,798</sup> Medroxyprogesterone acetate (10–20 mg daily) and megestrol acetate (20 mg daily) are also effective (as effective as estrogen), but concerns regarding exogenous steroids, especially in patients who have had breast cancer, would apply to progestins as well.<sup>799,800,801</sup>

In the last few years, SSRIs (Selective Serotonin Reuptake Inhibitors), and SNRIs (Selective Norepinephrine Reuptake Inhibitors) have gained a reputation for significant efficacy in treating hot flushing. The drugs that have been studied include citalopram (Celexa), fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil, Brisdelle), and SNRIs, venlafaxine (Effexor) and desvenlafaxine succinate (Pristiq). In addition, antiseizure medications, gabapentin (Neurontin) and pregabalin (Lyrica), have been demonstrated to reduce vasomotor symptoms (see [Table 17.10](#)).

Paroxetine is FDA approved for the treatment of hot flushes. In a randomized control trial comparing low-dose paroxetine to placebo for treatment of hot flushes, treatment with paroxetine had a statistically significant reduction in vasomotor symptoms compared to placebo.<sup>802</sup> However, it is less effective than HT in relieving vasomotor symptoms and should be reserved for use in those women who have a contraindication to HT.

Venlafaxine was studied in breast cancer survivors; although the optimal dose was 75 mg, an appreciable response with 37.5 mg indicated that it would be worthwhile to begin treatment with the lower dose.<sup>803,804,805</sup> The response was very rapid, within days, and therefore the dose can be increased in 1–2 weeks. The main side effects were mouth dryness, anorexia, nausea, and constipation. The efficacy of venlafaxine was demonstrated to be the same in women taking or not taking tamoxifen. Desvenlafaxine succinate is a metabolite of venlafaxine and equally effective as the parent compound.<sup>806,807</sup> **The effects of citalopram, fluoxetine, and sertraline are no more effective than placebo, about a 50% reduction in short-term trials.**<sup>808,809,810,811,812</sup>

Gabapentin (Neurontin) is a  $\gamma$ -aminobutyric acid analog that has been used for seizures since 1994. It is also effective for migraine headaches, tremors, and panic

disorder. In a gabapentin clinical trial, 67% of the treated women experienced more than a 50% reduction in flushes at week 12, compared with 38% in the placebo group.<sup>813</sup> The most common side effects were somnolence (20%) and dizziness (13%). Peripheral edema occurs occasionally because of an induced decrease in serum protein. The potency of this agent appears to be more modest than the SSRIs in a dose of 900 mg/day.<sup>814,815</sup> Side effects are common at higher doses, and further studies are needed to compare gabapentin to HT.<sup>816,817</sup>

Pregabalin (Lyrica), a more potent form of gabapentin, is an anticonvulsant drug that has been used in doses of 150–300 mg daily to treat anxiety and neuropathic pain, for example, diabetic neurogenic pain, pain after shingles, and fibromyalgia. Side effects include dizziness, drowsiness, visual disturbances, tremor, weight gain, and a decrease in libido. In a phase III randomized trial, a dose of 75 mg b.i.d. (the recommended dose because of more side effects with higher doses), hot flushing was reduced by 65% after 6 weeks of treatment, an impact that was only 15% greater than placebo.<sup>818</sup> Although the data are limited to this short-term, small clinical trial, the effect of pregabalin appears to be comparable to gabapentin.

**The SSRIs are a logical choice if HT is contraindicated or not accepted by patients, although the reduction in hot flushing is considerably less than what can be achieved with estrogen treatment.** It is worth trying to titer the dose down to its lowest effective level because of a bothersome incidence of decreased libido. In addition, clinical experience indicates that it is best to slowly titrate upward to the recommended dose and, likewise, to wean the patient slowly when discontinuing treatment. SSRIs are effective for flushing secondary to both tamoxifen and hypoestrogenemia, and the efficacy is similar in women with and without breast cancer.<sup>819</sup> **An added advantage of the SSRIs is the fact that the clinical studies have also reported improvements in depression, anxiety, and sleep. Gabapentin is useful in those with difficulty sleeping, while clonidine may be more beneficial in women who also have hypertension.**

**Caution is advised when considering SSRIs in women with a history of breast cancer being treated with tamoxifen.** Tamoxifen is converted to an active metabolite by enzymes that are inhibited by certain SSRIs. Paroxetine coadministration decreases plasma concentrations of the active tamoxifen metabolite.<sup>820,821</sup> A lesser effect is associated with fluoxetine and sertraline. In a retrospective cohort study, only paroxetine use during tamoxifen therapy was associated with an increased risk of death due to breast cancer.<sup>822</sup> **Paroxetine, fluoxetine, and sertraline are therefore best avoided in women with a history of breast cancer who are being treated with tamoxifen.**

# BIOIDENTICAL HORMONES

---

Publication of the WHI Hormone Trials was followed by a period of much confusion and concern regarding safety of prescription HT. In the wake of both prescriber and patient distrust of HT, an upsurge of interest in bioidentical hormones occurred. Bioidentical hormones have since garnered much interest from the lay public, as well as generated much political, financial, and legal conflict. Bruce Patsner, research professor in the Health Law and Policy Institute at the University of Houston Law Center, has written what is, in our view, a masterful analysis of the problem, with suggestions for its resolution.<sup>122</sup>

# The History of the Conflict

The operations of a pharmacy are regulated in the individual states by state boards of pharmacy, in a system similar to the regulation of medical practice. The first federal law regulating drugs, the Federal Food, Drug, and Cosmetic Act, was passed in 1938, at a time when most drugs were compounded according to a doctor's prescription. The American Pharmacists Association defines pharmacy compounding as the preparation of a prescription drug that is "individualized" to the needs of the patient. This changed after World War II with the development and growth of the pharmaceutical industry. The Kefauver-Harris Amendment in 1964 extended the role of the Food and Drug Administration (FDA) to include safety and efficacy.

In the 1990s, the FDA began to regard the drugs coming from compounding pharmacies as falling under the "new drug" regulations, and therefore, the FDA had jurisdiction over the marketing and promotion of those drugs. The pharmacy world was immediately challenged; there was no way that an individual pharmacy could carry out the kind of clinical studies required for the approval of new drugs. Thus, the pharmacists immediately realized that all compounded drugs would be illegal. At the same time, the FDA was a bit ambivalent, acknowledging that there were examples where the individual needs of a patient required the compounding of a drug, for example, the creation of a liquid preparation when none was available. This was before compounding took to the Internet for marketing and promotion.

In 1992, the FDA issued its Compliance Policy Guide on Compounding, reserving a right for "selective enforcement," as a compromise between believing it was correct in assuming that compounded drugs represented new drugs and admitting that some patients required compounding. The pharmacy profession immediately rejected the idea that the FDA had any regulatory jurisdiction over pharmacies. The 1997 Food and Drug Modernization Act attempted to clarify the situation. An amendment was added to the existing laws stating that compounded drugs were not "new drugs," but at the same time, the 1997 act prohibited the marketing of compounded drugs.

The pharmacy profession sued the FDA, arguing that a restriction on advertising and promotion of compounded drugs was unconstitutional, a restriction of free speech. The District Court ruled against the FDA in 1999. The FDA appealed and lost again in the ninth Circuit Court of Appeals, which further invalidated the entire 1997 act. In 2002, the U.S. Supreme Court upheld the Circuit Court decision.

The FDA issued a new Compliance Policy Guide in 2002, stating that selective enforcement would hinge on three major factors: (1) a potential adverse effect of a drug, (2) whether drugs were compounded from non-FDA-approved components, and (3) whether compounded drugs were similar to drugs already removed from the market for safety reasons. At this point, the FDA affirmed that it did not want to infringe on the

traditional practice of compounding, the preparation of a drug according to a doctor's prescription to fit an individual patient's requirements.

Wyeth Pharmaceuticals filed a Citizen Petition with the FDA in October 2005 requesting that the FDA take action against several compounding pharmacies that were primarily Internet-based. The Petition's major allegation was that these pharmacies were essentially manufacturing new drugs and should be subject to new drug regulations. On January 9, 2008, the FDA announced it would take action against seven pharmacies providing prescription bioidentical hormones and issued warning letters that potentially could be followed by seizures of drugs and injunctions against production.

The FDA would like to regard compounded drugs as "new drugs," but the legal precedent has now been set by the courts: compounded drugs are not "new drugs." This was reaffirmed in a 2006 decision in the U.S. District Court for Texas. The FDA would further like to regard the giant compounding pharmacies, especially those operating over the Internet, as manufacturers, like pharmaceutical companies, but again, the court decisions have prevented the FDA from requiring compounding pharmacies to meet "new drug" standards. The "new drug" argument doesn't work.

"Bioidentical" and "natural" are often used in concert. Strictly defined, to meet the definition of bioidentical, the hormones must reflect the endogenous milieu (i.e., the right balance of estrone, estradiol, and estriol, the three endogenous estrogens) and natural progesterone (the progestational agent synthesized by the ovarian corpus luteum after ovulation) and right levels and ratio of circulating androgens (testosterone, androstenedione, and DHEA). The formulations that are available as bioidentical are created in compounding pharmacies and can contain several of the aforementioned hormones, but neither the regimens nor the formulations are standardized. Furthermore, batch-to-batch variability in dosage is inherent.<sup>561</sup> The term bioidentical holds marketing value, erroneously implying greater safety and better efficacy. The situation is further complicated because consumers assume that the marketed formulation offers better efficacy and safety. This, however, is not the case as these compounded hormones are not subject to the same regulations as approved HT nor are there studies that have demonstrated long-term safety or better efficacy in comparison to the approved "natural" formulations.<sup>823</sup> The problem is that compounding pharmacies are not required to compare the formulation with the performance of an approved product, nor is there any way for a patient to be assured that the dosage is correct (that the drug contains what it is supposed to contain). Thus, there are no randomized controlled trials demonstrating safety and efficacy, let alone superiority to the approved formulations.<sup>823</sup>

Lay proponents of bioidentical compounded hormones often propose testing of salivary hormone levels to guide dosing of compounded formulations. Assessments of

this approach by researchers, as well as organizations such as the American College of Obstetricians and Gynecologists and the Endocrine Society, have concluded that the variations in salivary sex steroid levels from individual to individual and from specimen to specimen preclude clinical interpretation.<sup>561,824,825,826</sup> For the majority of patients, laboratory testing is not necessary in hormone decision-making. Furthermore, given the lack of scientific data demonstrating safety, the use of bioidentical hormones over approved HT regimens is not recommended.<sup>827</sup>

# A Better Approach

The American Pharmacists Association and the National Association of Boards of Pharmacies define compounding as the steps required in order to provide a drug in response to a clinician's prescription according to an individual patient's needs and the preparation of drugs in anticipation of a demand. Therefore, there are three people involved: the patient, the clinician, and the pharmacist. This is in contrast to the production of large amounts of a drug for a national market of unknown users. **The American Pharmacists Association says that if an FDA-approved product is commercially available that meets a patient's needs, it should be the drug provided.**

The key to the position of the pharmacists is the contention that there are circumstances, decided by the patient, that make the use of commercial products not a good choice. This seems reasonable, but it is also reasonable that this decision requires the involvement of the clinician because ultimately a prescription is still required. The traditional view of compounding, therefore, is one of personal relationships with patient, clinician, and pharmacists. This becomes a totally different story when a large Internet pharmacy responds to thousands of prescriptions with no knowledge of the patients. What happened to the "individualization" aspect of compounding? Is it practicing medicine by the pharmacy to have a registered clinician employed by the pharmacy to interpret hormone levels and adjust doses?

Clinicians are appropriately frustrated by the claims made that bioidentical compounded drugs have greater efficacy and safety. Bruce Patsner argues that it should be accepted that bioidentical drugs from the big compounding pharmacies do not meet the definition of compounding supported by the pharmacist's own organization, the American Pharmacists Association—a personal relationship of patient, clinician, and pharmacist addressing an individual's needs.<sup>828</sup> The FDA can argue that the big operations are not legitimate compounding, but big commercial operations directed to unknown consumers.

Patsner also argues that the most vulnerable point is the false safety and efficacy claims. The contention should not be that the safety and efficacy claims are inaccurate, because the pharmacies can always compose their words to avoid legal assaults. The point of emphasis should go back to the pharmacist's published credo: if a commercial, approved product is available to meet the patient's needs, a compounded product is not indicated. Replacing a commercial product with a "natural," untested, unregulated product is not the same thing as prescribing a compounded product when no commercial product will meet the individual's needs.

Patsner summarizes his argument by saying that the large compounding pharmacies are not true compounders because they advertise and promote their products as

replacements for commercially available, approved, and tested drugs and that the attempt at “individualization” uses an unsubstantiated method that marginalizes clinicians.<sup>828</sup>

The bioidentical hormones and the various commercial female hormone products are produced by pharmaceutical companies using similar methods that start from the same raw material, usually soy or yams. Some of the commercial products available consist of estradiol, testosterone, and progesterone, the exact same steroid drugs provided by compounding pharmacies. A major difference between the commercial products and products from compounding pharmacies is the important fact that commercial products are federally regulated and tested for purity and potency; compounding pharmacies have not been regulated in this fashion.

The compounded estrogen formulations that contain combinations of estrone, estriol, and estradiol contain sufficient estradiol to produce the same biologic effects associated with commercial preparations. There are no clinical studies documenting that these combinations confer better results or safety. Whether the presence of estriol reduces the risk of breast cancer has not been tested in appropriate clinical studies. Case-control data indicate that estriol used without a progestational agent increases the risk of endometrial cancer; thus, its biologic behavior is similar to that of other estrogens.<sup>829</sup>

**Custom-compounded formulations have not been proven to be safer or better and therefore should not be regarded as having similar risks and benefits as commercial products. Claims for custom-compounded products have not been scientifically tested. Tailor-making a hormone therapy regimen according to salivary testing is an appealing idea that has not been addressed scientifically, and given the variability in salivary hormone levels, it is unlikely that clinical studies would yield useful information. Recommendations promoting customized compounded formulations individualized to salivary sex steroid hormone profiles thus should be viewed with cynicism as the salivary hormone levels vary widely between individuals and from measurement to measurement within the same individual. Books and pharmacies promoting their own products should similarly be viewed with caution. Patients who wish to use products similar to endogenous hormones should be made aware of the content of available commercial formulations and reassured that marketed and approved 17 $\beta$  estradiol and micronized progesterone formulations are indeed reliable bioidentical representatives. Books and pharmacies promoting their own products should be viewed with caution; don't confuse marketing with science.**

# ALTERNATIVE THERAPIES

---

The business of selling alternative therapies is now a worldwide phenomenon. The promotion of many of these treatments relies on a network of alternative providers, authors, and compounding pharmacies. Why are herbs and botanicals not regulated? In the United States, the Dietary Supplement Health and Education Act of 1994 deregulated the industry by classifying dietary supplements as neither foods nor drugs. Thus, manufacturers of dietary supplements are not required to demonstrate that they are safe or effective. In addition to a lack of regulation, there are many other problems associated with herbs and botanicals. The products vary in the amount and purity of active ingredients; indeed, products on the shelf often are adulterated and contaminated with drugs or metals.<sup>830</sup> And very importantly, there is enormous variation in the plants themselves because of genetic, harvest year, and processing differences and in individual metabolism of the products.

# Alternative Therapies for Vasomotor Symptoms: Phytoestrogens

“Phytoestrogens” is a descriptive term applied to nonsteroidal compounds that have estrogenic activity or are metabolized into compounds with estrogen activity. Phytoestrogens are classified into three groups: isoflavones, lignans, and coumestans.<sup>831,832</sup> They are present in about 300 plants, especially legumes, and bind to the estrogen receptor. Soybeans, a rich source of phytoestrogens, contain isoflavones, the most common form of phytoestrogens, mainly genistein and daidzein, and a little glycitin.

Examples of phytoestrogens:

- **Isoflavones (genistein, daidzein, glycitin): soybeans, lentils, chickpeas (garbanzo beans), and red clover**
- **Lignans: flaxseed, cereals, vegetables, and fruits**
- **Coumestans: sunflower seeds and bean sprouts**

Isoflavones exist in plants bound as glycoside conjugates attached at the 3 position, called glycones. The carbohydrate component requires gut bacteria to remove the sugar moiety to produce active compounds, the aglycones. Individual variability in gastrointestinal microflora, as well as absorption, influences the bioavailability of isoflavones. Biochanin and formononetin are methylated precursors that are metabolized to genistein and daidzein. Red clover and lentils contain significant amounts of these precursors. The isoflavones are in the active, deconjugated forms in fermented soy foods like miso and tempeh. The concentration of isoflavones in tofu is highly variable.

The phytoestrogens are characterized by mixed estrogenic and antiestrogenic actions, depending on the target tissue and local estrogen concentration. Variations in activity may also be due to the fact that the soy phytoestrogens have a greater affinity for the estrogen receptor- $\beta$  compared with estrogen receptor- $\alpha$ , although the affinity for the beta-receptor is still only 35% that of estradiol.<sup>833</sup> Despite a low affinity for the alpha-receptor, circulating levels many times that of steroidal estrogens produce the potential for biologic activity.

You can eat soybeans every day and never see a bean. Soybeans are defatted to produce soy flour. Soy flour is then prepared to remove the carbohydrates. Ninety-five percent of soy flour is toasted and used as animal feed. Alcohol washing is used to get a taste-free product, but alcohol extraction removes the phytoestrogens.<sup>834</sup> SUPRO, known as “isolated soy protein,” from Protein Technologies International, the major supplier for commercial products and research, is extracted by aqueous washing and

retains the isoflavones.

The reason why most of the soybean crop is devoted to animal feed is because what is left after removing lipids is totally bland. The solution is to mix soybeans with other foods, for example, beans and soups. Unfortunately, they require standing in water for about 12 hours and simmering for 2–3 hours to be cooked. The average Japanese intake of isoflavones is about 50 mg/day.<sup>835</sup> The rest of Asia has an average consumption of about 25–45 mg/day, and Western consumption is less than 5 mg/day.<sup>836,837</sup>

Equol is the active metabolite in all phytoestrogens. Interestingly, not all individuals have the ability to convert phytoestrogens into their active metabolite.<sup>797</sup> Given conflicting results, regarding efficacy, routine use is not recommended, especially with data from a Cochrane review demonstrate no conclusive evidence.<sup>797,838</sup> Furthermore, phytoestrogens are **generally** contraindicated in women with hormone-dependent **cancers**, thromboembolic disease, or **cardiovascular** disease, as the amount of estrogen from consumption of these products is not known.<sup>797</sup>

## Other Alternative Therapies for Flushing

### Red Clover

Promensil is an extract of red clover (*Trifolium pratense*) containing formononetin, biochanin, daidzein, and genistein. Formononetin and biochanin are metabolized to daidzein and genistein, respectively. Red clover is a legume used to enrich nitrogen levels in soils. Promensil is produced by Novogen in Australia and marketed by Solvay in the United States. A 500-mg tablet contains 200–230 mg of dried extract, which contains 40 mg of isoflavones. Two randomized, placebo-controlled studies of the effect of Promensil on hot flushes were reported in 1999.<sup>839,840</sup> Neither demonstrated a significant difference compared with the placebo group. In one of the reports, 4 times the recommended dose (four tablets daily) also had no effect.<sup>840</sup> On the other hand, an appropriately designed Dutch study, two tablets daily, detected a significant reduction of flushing in a 12-week period of time.<sup>841</sup> A large placebo-controlled trial randomized 252 women with severe hot flushing to either Promensil (two tablets daily) or another red clover extract Rimostil (two tablets daily for an intake of 57 mg isoflavones).<sup>842</sup> The quantitative reduction in flushing (about 41% in 12 weeks) was identical in the Promensil, Rimostil, and placebo groups, although Promensil had a very slightly faster response. In another randomized clinical trial, the effect of red clover (a daily intake of 128 mg isoflavones) on vasomotor symptoms was no better than placebo treatment.<sup>843</sup> The best evidence indicates that the impact of red clover on vasomotor symptoms is the same as placebo treatment.

**Why do these randomized, blinded, and placebo-controlled trials lack agreement? One reasonable explanation is that isoflavones have a mild impact on hot flushing, detectable only in women with frequent and severe flushing. A major clinical response should not be expected. Another possibility is the role of equol (see later discussion).**

## **Don Quai, Ginseng, and Vitamin E**

One randomized, placebo-controlled trial examined the effect of dong quai on hot flushing.<sup>786</sup> No estrogenic effects could be detected on flushing, endometrium, or vagina; furthermore, it could have potential adverse effects including light sensitivity and increased bleeding risk in those taking warfarin.<sup>786</sup> Ginseng has the same impact on menopausal symptoms as placebo treatment.<sup>787</sup> Similarly, vitamin E supplementation is ineffective for VMS.<sup>785</sup>

## **Evening Primrose**

Evening primrose is often recommended for mastalgia, PMS, and menopausal symptoms. Evening primrose oil is extracted from the seed of the evening primrose; it provides linoleic and gamma-linoleic acids (precursors of prostaglandin E). Appropriately blinded and controlled studies have failed to find any differences comparing primrose oil with placebo.<sup>844,845,846</sup>

## **Black Cohosh**

Black cohosh (*Cimicifuga racemosa*) is also called black snakeroot and bugbane. It has been widely promoted to treat hot flashes. Unfortunately, most of the early reports supporting the efficacy of black cohosh were case series or studies without placebo control groups, or the studies did not directly and quantitatively measure hot flushing.

Overall, black cohosh has been reported to contain formononetin, a methylated precursor that is metabolized to the two primary phytoestrogens, genistein and daidzein. More sophisticated analysis, however, using liquid chromatography methods, has failed to detect the presence of formononetin in various black cohosh preparations, nor in black cohosh roots and rhizomes.<sup>847</sup>

An older clinical trial was noteworthy and alone in finding a similar impact on hot flushing with black cohosh and placebo treatment.<sup>788</sup> Well-designed trials are confirming that early study and providing us with a uniform story. The Herbal Alternatives for Menopause (HALT) Study is centered in Seattle, Washington. This double-blind trial randomized 351 women to placebo or one of the four treatment groups: (1) black cohosh 160 mg daily (note the higher dose); (2) a multibotanical

treatment containing 50-mg black cohosh, alfalfa, chaste tree, dong quai, false unicorn, licorice, oats, pomegranate, and Siberian ginseng, four capsules daily; (3) the multibotanical plus counseling to increase dietary soy intake; and (4) conjugated estrogens 0.625 mg with or without 2.5 mg medroxyprogesterone acetate.<sup>848</sup> After 1 year, no differences were observed in hot flushing comparing any of the three herbal treatment groups to placebo.<sup>848</sup> The herbal remedies also had no effect on sleep quality as reported after 3 months.<sup>849</sup>

A randomized trial in Chicago compared black cohosh, 128 mg, and red clover, 120 mg, to standard hormone therapy and placebo treatment.<sup>843</sup> Over a period of 1 year, only hormone therapy reduced vasomotor symptoms greater than placebo. In this same clinical trial, neither black cohosh nor red clover had an impact on measures of cognition.<sup>850</sup> A Mayo Clinic study reported the results of a double-blind, randomized, crossover clinical trial to assess the efficacy of black cohosh for the treatment of menopausal hot flashes.<sup>792</sup> The dose was 20 mg b.i.d., the dose of the most commonly marketed black cohosh product in the United States. The similarity of the studied product with Remifemin was confirmed by high-performance liquid chromatography and proton nuclear magnetic resonance analysis. One hundred and thirty-two patients were treated for two 4-week crossover periods. Black cohosh reduced hot flushing scores by 20% in the fourth treatment week compared with 27% in the placebo group, and frequency was reduced 17% on black cohosh and 26% on placebo. A randomized trial in Australia found no difference between placebo and a combination of black cohosh with Chinese herbs.<sup>851</sup>

**Black cohosh is not estrogenic, and black cohosh has no effect on menopausal symptoms.**

An expert committee of the U.S. Pharmacopoeia concluded that black cohosh may be associated with hepatotoxicity; however, a European review of cases with hepatotoxicity emphasized the difficulty in establishing a cause-effect relationship.<sup>852,853</sup> Hepatotoxicity remains a concern, awaiting the accumulation of definitive data.

# Ginkgo Biloba

Ginkgo biloba is an extract prepared from the leaves of the G. biloba tree. It contains flavonoids and unique terpene lactones. Ginkgo biloba is a multimillion-dollar herb sold in the United States for the preservation of memory. In vitro studies suggested that ginkgo had antioxidant (from the flavonoids) and antiamyloid (from the lactones) effects. Indeed, the biologic studies provided a rationale for the use of ginkgo to prevent dementia.

A randomized, double-blind, placebo-controlled trial comparing Ginkgo biloba with placebo for the prevention of dementia enrolled 3,069 elderly individuals (over age 75) in five academic centers in the United States.<sup>854,855</sup> The participants were randomized to b.i.d. doses of 120-mg ginkgo or placebo (45% female in the ginkgo group and 47% female in the placebo group). The ginkgo formulation and dosage were that used in many of the brands sold in the United States. The dementia rate steadily increased in both groups over a 7-year period of follow-up, accumulating 277 cases (17.9%) in the treatment group and 246 cases (16.1%) in the placebo group. The rate of dementia did not differ between the two groups, nor did the rate of Alzheimer disease. In addition, treatment with Ginkgo biloba did not produce less cognitive decline in either adults with normal cognition or with mild cognitive impairment. Other randomized trials have failed to demonstrate any beneficial effects on Alzheimer's, learning, memory, attention, verbal fluency, or concentration.<sup>856,857</sup> Caution is warranted however when considering treatment in those with cardiovascular disease as it may be proarrhythmic; further studies in those with cardiac disease are needed.<sup>858</sup>

**The American trial robustly demonstrated that Ginkgo biloba in the tested and commonly used dose did not delay the onset of dementia or cognitive decline.**<sup>854,855</sup> The concept of “delay” is important. A treatment that could delay the onset of dementia by 5 years would reduce the number of dementia cases by 50%. In fact, this clinical trial found a statistically significant increase in the risk for developing dementia with ginkgo treatment in the 25% of participants who had cardiovascular disease prior to enrollment. However, the authors appropriately urged caution in interpreting this subgroup analysis. **A Cochrane review in 2007 of 35 clinical trials with 4,247 participants concluded that there was no convincing evidence that ginkgo treatment benefited individuals who already had dementia or cognitive impairment.**<sup>859</sup>

# St. John's Wort

St. John's wort has been reported to be comparable to tricyclic antidepressants in treating mild to moderate depression, based on eight appropriate trials.<sup>860</sup> This is the conclusion of two meta-analyses.<sup>861,862</sup> All studies were short term, about 4–6 weeks in duration, and with small numbers. The treatment consisted of a 300-mg plant extract in tablet form, administered t.i.d. However, two large, American 8-week trials found no difference between treatment and placebo.<sup>863,864</sup>

The U.S. Food and Drug Administration (FDA) issued an alert in February 2000 that St. John's wort may interact with drugs known to be metabolized by the cytochrome P450 pathway: theophylline, digoxin, immune suppressants, and oral contraceptives.<sup>865,866</sup> St. John's wort activates an orphan receptor that induces the expression of metabolic enzymes.<sup>867</sup> In clinically depressed individuals being treated with prescription antidepressants, manic reactions can result (the central serotonergic syndrome).

# Phytoestrogens and Cardiovascular Disease

The cardiovascular story with phytoestrogens received a large boost in 1995, when a meta-analysis concluded that an intake of an average of 47 g soy protein/day lowered total cholesterol and LDL cholesterol.<sup>868</sup> This was supported by studies in the monkey indicating that isoflavone increased HDL cholesterol, enhanced vasodilation, and decreased atherosclerosis.<sup>869</sup>

Only intact soy protein has a beneficial effect on lipids. Separation of the protein component from dietary soy protein loses the effect. This effect depends on the inhibition of cholesterol absorption by the nonisoflavone protein.<sup>870,871</sup> The mechanism involves up-regulation of the LDL cholesterol receptor and catabolism of LDL cholesterol, leading to an increase in bile excretion. The soy peptide binds bile acids and prevents resorption. Alcohol extraction removes the isoflavones from soy protein and causes a loss of the beneficial effect on atherosclerosis in monkeys.<sup>872</sup> Thus, both the isoflavone portion and the protein component are required for a full cardiovascular effect. Non-alcohol-washed soy protein extract has been extensively studied in monkeys. This preparation lowers total cholesterol and LDL cholesterol and raises HDL cholesterol,<sup>873,874</sup> produces coronary artery vasodilation,<sup>875</sup> inhibits reduction in coronary flow after collagen induced platelet aggregation and serotonin release,<sup>876</sup> and inhibits atherosclerosis but not as robustly as estrogen.<sup>869,874</sup>

In women, soy protein reduces total and LDL cholesterol and does not affect triglycerides or HDL cholesterol; ethanol-extracted soy protein has no effect.<sup>877,878,879,880</sup> The minimal dose is about 60 mg isoflavones daily, which is present in 25 g soy protein/day.<sup>881</sup> LDL cholesterol must be above 130 mg/dL in order to have an effect. Studies of healthy men and women could detect no effect of phytoestrogens (25–80 mg isoflavones per day) on lipids or brachial vasodilation.<sup>882,883,884</sup> In a 12-week study of women with type 2 diabetes mellitus, dietary supplementation of 30 g soy protein (132 mg isoflavones) daily improved insulin resistance and glucose control in addition to lowering total cholesterol and LDL cholesterol levels.<sup>885</sup> In addition, soy intake prevents LDL cholesterol oxidation in hyperlipidemic men and women even when circulating LDL cholesterol levels are unaffected.<sup>886</sup> Promensil, in a 10-week study, had no effect on lipids (it only contains isoflavones, no protein) but did improve arterial compliance.<sup>887</sup>

The U.S. FDA, in October 1999, authorized the use in food labeling of health claims related to the association between soy protein and reduced risk of CHD, “based on the totality of publicly available scientific evidence, soy protein included in a diet low in saturated fat and cholesterol may reduce the risk of CHD by lowering blood cholesterol

levels.”<sup>888</sup>

Remember that both protein and isoflavones are needed for a cardiovascular effect. Isoflavones by themselves have no effect on lipids.<sup>887,889,890</sup> Protein without isoflavones has no effect on vasodilation and atherosclerosis.<sup>872</sup> The FDA has stated that there is insufficient evidence to allow them to exclude alcohol-washed products from the health claim, but it makes sense that a combined protein-isoflavone product is best. Even in older women with moderate hypercholesterolemia, a high intake of soy phytoestrogens (purified isoflavones without protein) had no effect on the lipid profile.<sup>891</sup> And also remember that there is no effect on the lipids in individuals who already have a normal profile. Even in individuals with high cholesterol levels, the beneficial impact of soy protein intake is modest and likely to have little clinical effect.

It will require appropriate clinical trials to determine how phytoestrogens compare in the cardiovascular system with estrogens and to determine the efficacy, safety, and correct dosage (studies thus far recommend a daily intake of 60 g soy protein). In addition, the intake of sufficient soy to produce a clinical response is not easy; intake is handicapped by gastrointestinal symptoms, a major alteration in diet or the use of an unpalatable supplement, and great variability in plant contents and products (due to processing). A dietary intake to match the isoflavone dose used in the studies on the lipid profile, for example, would require about 1 lb daily of tofu! In addition, individuals demonstrate great variability in absorption and metabolism. A user-friendly preparation must be developed that minimizes individual variability in response. **Despite the abovementioned observations, there is no clinical evidence that supports a preventative role for soy intake against cardiovascular disease.**

# Phytoestrogens and Cognition

Phytoestrogens up-regulate cognition markers and improve memory in rats equally when compared with estrogen.<sup>892,893</sup> Soy supplementation has been suggested to improve measurements of memory and attention in postmenopausal women.<sup>894,895</sup> On the other hand, randomized trials detected no effects of soy protein, red clover, or black cohosh on tests of memory, executive function, language, visual perception, cognition, or measures of quality of life.<sup>850,884,896,897</sup> On the contrary, there is one human study involving men that is disturbing. In a National Institutes of Health study that began in 1965, men reported their tofu consumption.<sup>898</sup> Cognition was tested in 1991–1993 between the ages 71 and 93. Higher midlife tofu consumption (two or more servings per week) was associated with poor cognitive test performance, enlargement of ventricles, and low brain weight.

**At the present time, there is no role for phytoestrogens for cognitive benefit.**

# Phytoestrogens and the Breast

In the parts of the world where soy intake is high, there is a lower incidence of breast, endometrial, and prostate cancers.<sup>899</sup> For example, a case-control study concluded that there was a 54% reduced risk of endometrial cancer, and another case-control study indicated a reduction in the risk of breast cancer in women with a high consumption of soy and other legumes.<sup>900,901</sup> Daidzein and genistein urinary excretion is lower in Australian women who develop breast cancer.<sup>902</sup> High soy and tofu consumption, and high urinary excretion of isoflavones have been reported to be associated with a lower risk of breast cancer in Singapore, China, and Australia. There is even a lowered risk of breast cancer in American women consuming a diet rich in isoflavones.<sup>901,903,904,905,906,907</sup> These studies have supported the belief that high phytoestrogen intake protects against breast cancer. It is by no means certain, however, that there is a direct effect of soy intake.<sup>908</sup> Indeed, a 6-month study of the impact of administered soy protein on breast secretions in premenopausal and postmenopausal women revealed increased breast secretions with the appearance of hyperplastic epithelial cells.<sup>909</sup> Epithelial hyperplasia based on cytology in breast secretions was demonstrated in 7 of 24 (29.2%) of the subjects. Swedish and English cohort studies could not detect a relationship between dietary phytoestrogens and the risk of breast cancer.<sup>910,911</sup>

Genistein increases epidermal growth factor in immature rat mammary tissue, and it has been hypothesized that earlier exposure to genistein promotes early cell differentiation leading to breast glands that are more resistant to the development of cancer.<sup>912</sup> On the other hand, using the chemically induced rat breast cancer model, no evidence of isoflavone inhibition on tumor development has been detected.<sup>913</sup> In the monkey, treated for 6 months, no proliferation was reported in either endometrium or mammary tissue.<sup>914,915</sup>

One hypothesis speculates that phytoestrogens protect the breast by decreasing exposure to the more potent endogenous estrogens. The evidence does not support this idea. High-dose treatment (100 mg of daidzein plus 100 mg genistein) does lower estradiol and DHEA-S levels in premenopausal women and increases cycle length.<sup>916</sup> However, these are extremely high doses. One study reported that treatment with Asian soy foods (approximately 32 mg isoflavones per day) was associated with a 9.3% significant decrease in luteal serum estradiol levels, but there were no other changes, including follicular phase estradiol, progesterone levels, and SHBG levels, or cycle length.<sup>917</sup> Interestingly, the reduction in luteal estradiol was observed only in Asian participants in whom urinary excretion of isoflavones was higher than non-Asians.<sup>917</sup> These same investigators reported that a high intake of the soy protein alone (with the

isoflavones removed) reduced estradiol and progesterone levels throughout the cycle.<sup>918</sup> Other studies have found no effects on estradiol, FSH, LH, or SHBG in premenopausal women<sup>919</sup> and, most importantly, no effects on circulating hormones in postmenopausal women.<sup>920,921</sup> The lack of an effect on gonadotropin and steroid levels is important, depriving the clinician of a method to assess dosage.

Catechol estrogens (2-hydroxy- and 4-hydroxyestrogens) have long been proposed as a metabolite pathway that could be protective or at least antiestrogenic. Hydroxylation in the 2 or 4 position produces inactive metabolites. In one study, eight premenopausal women treated with a soy milk supplement increased their urinary excretion of 2-hydroxyestrone by an average of 47%.<sup>922</sup> Another study could detect no change in 2-hydroxyestrogens.<sup>919</sup> A study limited to Asian American women also was unable to identify an impact of soy intake on overall estrogen metabolite excretion; however, an increase in catechol estrogens was observed with greater soy intake, balanced by a decrease in 16-hydroxylation.<sup>923</sup>

In response to soy, no significant increase in nipple aspirate levels of genistein and daidzein could be detected.<sup>924</sup> However, an indication of estrogenic stimulation occurred, as measured by pS2 (a protein up-regulated by estrogen) levels, but there was no evidence of an effect on epithelial cell proliferation, estrogen and progesterone receptors, apoptosis, or mitosis. Thus, no antiestrogenic effect could be detected, and at best, there was a very weak estrogen effect. In another study, 48 women with normal breasts received a 60 g soy supplement for 14 days, and in these women, lobular epithelial proliferation and progesterone receptor expression increased, an indication of estrogen stimulation.<sup>925</sup> Some argue that the key to a beneficial impact on the breast may be early exposure, and a sudden increase late in life of dietary phytoestrogens may be harmful. On the other hand, a Chinese cohort study of 5,042 breast cancer survivors documented a reduced risk of recurrence and death associated with increasing levels of soy intake, evident among women with either estrogen receptor–positive or receptor–negative disease and among either tamoxifen users or nonusers.<sup>926</sup> In an American cohort of 1,954 breast cancer survivors, a 60% greater decrease in breast cancer recurrence was observed in postmenopausal women using tamoxifen comparing the highest level of soy intake with the lowest.<sup>927</sup> **Most of the evidence indicates that a high intake of phytoestrogens is associated with a reduced risk of breast cancer, including recurrence in breast cancer survivors. It is not known whether this effect is a marker for beneficial metabolic responses to phytoestrogens or whether there is a direct impact on breast tissue. The evidence also indicates that phytoestrogen consumption does not adversely interfere with tamoxifen’s mechanism of action.**

There is agreement that phytoestrogens have no effects on the uterus or

vagina.<sup>786,839,840,889,920,921,928,929,930,931,932</sup> A beneficial effect on vaginal dryness and dyspareunia cannot be expected; however, the lack of a proliferative stimulus on the endometrium is a wanted consequence of phytoestrogen supplementation (Table 17.11).

## **TABLE 17.11 Summary of Phytoestrogen Clinical Effects**

Flushes	Insignificant effect
Coronary heart disease	Weak impact
Bone	No effect
Cognition	Unknown
Breast	May be protective
Endometrium	No effect
Vagina	No effect

**Currently, the recommended intake expected to have some effect on CHD is 50–60 mg isoflavones per day, an amount that is in 25 g of soy protein aqueous extract. A beneficial impact on CHD in women with abnormal lipid profiles is to be expected, a consequence of a decrease in total and LDL cholesterol and an increase in vascular reaction, but the actual clinical effect is unknown. Excess intake can cause gastrointestinal upset and flatulence, inhibition of enzymes necessary for the digestion of proteins, possibly obstruction of mineral uptake, and weight gain.**

# The Role of Equol

Equol is a bacterial metabolite and the only hormonally active metabolite of the soy phytoestrogen, daidzein. It is one of the estrogenic compounds in pregnant mare's urine, hence its name. At least in vitro, equol stimulates gene transcription with both estrogen receptors and with a greater potency than any other isoflavone.<sup>933</sup> Equol formation is totally dependent on intestinal microflora; therefore, strictly speaking, it is not a phytoestrogen. To be accurate, equol is a nonsteroidal estrogen, a member of the isoflavone family, and exclusively a metabolic product of intestinal bacteria.

The most important observation regarding equol is that 30–50% of adults do not produce equol, even when challenged with high doses of soy.<sup>934</sup> This is in contrast to nonhuman primates and other animals; all that have been studied produce high levels of equol. Thus, there are two human populations: equol producers and equol nonproducers. The key question is whether equol producers receive greater clinical effects from phytoestrogens than nonequol producers. As noted, thus far, the clinical effects of isoflavones on the bone have not been impressive. In a 2-year randomized trial of postmenopausal women, isoflavone-rich soy milk increased spinal bone mass in the 45% of the subjects who were equol producers, with essentially no effect in equol nonproducers.<sup>935</sup> More profound beneficial effects on the lipid profile have been reported in equol-producing women.<sup>934</sup> Therefore, the population destined to receive a benefit from soy intake may be limited to equol producers. Studies need to be repeated measuring the responses in individuals who are identified as equol producers or equol nonproducers. If the population destined to receive a benefit from soy intake is limited to equol producers, a convenient, inexpensive method must be developed to identify equol production. It may be possible to convert nonproducers to producers.

An emerging approach is to administer equol itself. Daidzein yields two forms of equol, the R-equol inactive isomer and S-equol, the active isomer that binds to estrogen receptor- $\beta$ . S-equol has been synthesized and its administration is effective for the treatment of menopausal symptoms.<sup>936</sup> Another alternative is the S-equol supplement made by incubating equol-producing bacteria with soy isoflavones.<sup>937,938</sup> S-equol also blocks the activity of dihydrotestosterone, and thus, it has potential to treat androgenic effects such as acne, hirsutism, male pattern baldness, and prostate cancer.<sup>939</sup>

# Estriol

Interest in estriol can be traced to Lemon's report in 1975 that estriol limited the growth of breast tumors in the chemical-induced rat tumor model. However, it is usually overlooked that estradiol worked equally well in that model. Estriol treatment of postmenopausal women has no overall effect on lipids and no effect in the prevention of myocardial infarction.<sup>940,941</sup> Estriol, without concomitant progestin treatment, does increase the risk of endometrial cancer with the long-term oral use of 1–2 mg/day.<sup>829</sup> At least two studies have been unable to demonstrate prevention of bone loss with the administration of 2 mg estriol daily.<sup>486,487</sup> And one case-control study found no reduction in hip fractures with estriol compared with a lower risk with estradiol.<sup>941</sup> There is no evidence indicating any beneficial effects unique to estriol.

# Transdermal Progesterone

Transdermal (or percutaneous) compounded progesterone cream has been erroneously promoted to have multiple benefits. In order to achieve widespread effects, absorption must yield adequate blood levels. Two English randomized, blinded, placebo-controlled studies used 2 to 4 times the recommended dose and reported blood levels of about 1 ng/mL, supported by very low urinary pregnanediol levels.<sup>942,943</sup> An American study achieved progesterone blood levels of 2–3 ng/mL with application twice daily.<sup>944</sup> An Italian 1-year study did not measure blood levels but could detect no effects on bone density, lipid profiles, or depression scores.<sup>945</sup>

These studies indicate very little systemic absorption of progesterone from the cream product (the levels do not reach normal luteal phase concentrations), and there is great variability.

An English randomized clinical trial using transdermal doses of 5, 20, 40, and 60 mg progesterone cream could detect no differences in measures of psychological, somatic, and vasomotor symptoms compared with placebo.<sup>946</sup> An Australian study of 16, 32, or 64 mg transdermal progesterone cream administered daily could detect no significant absorption and, most importantly, no endometrial response and no effect on flushes, lipids, bone, moods, or sexuality.<sup>947,948</sup> Incidentally, this study found salivary progesterone levels to be so variable that they had no meaning. Progesterone cream can produce high salivary levels, without a significant change in serum or urinary levels (the mechanism is unknown).<sup>949,950</sup> Red cell levels reflect serum levels and do not indicate preferential transport or sequestration.<sup>950</sup> Wild yam creams are marketed as progesterone precursors or “balancing” formulas. Yam contains diosgenin, a plant steroid that can be converted to progesterone in a chemical laboratory but not in the human body. Predictably, a wild yam cream has no effects on a wide range of measurements in postmenopausal women.<sup>930</sup> Some do contain progesterone, added by the manufacturer. Creams with less than 0.016% progesterone can be sold over the counter. There is no evidence to indicate that these preparations produce systemic effects.

Better absorption is provided by progesterone gels, an alcoholic solution with hydroxypropyl methylcellulose and water.<sup>931</sup> With a 100-mg dose of a progesterone gel, serum progesterone levels are well into the luteal phase range, but clinical use awaits studies documenting the impact on the endometrium.<sup>951</sup>

**Clinicians and patients should be aware that transdermal progesterone cream will not reduce hot flashes more than a placebo response, but most importantly, this treatment will not protect the endometrium against the risk of endometrial cancer**

**associated with estrogen therapy.**

Lastly, for women with VSMs, additional nonpharmacologic options include environmental and lifestyle changes. Remaining in a cool environment and weight loss have been shown to decrease the number of hot flashes. Complementary and alternative medicine can also be attempted; however, treatments with dong quai, ginseng, black cohosh, isoflavones (including soy protein), yoga, and acupuncture with placebo treatment.<sup>786,787,788,789,790,791,792,793,794,795,796</sup>

## Key points: Vasomotor Symptom Management

- HT remains the most effective of available therapeutic options for managing VMS.
- In patients in whom HT is contraindicated, non-hormonal pharmaceuticals can be effective against VMS.
- Patients and providers should be reassured regarding availability of effective standardized and approved bioidentical HT formulations.
- Utilization by patients of non-standardized, unapproved compounded formulations that are being advertised direct to consumers is to be discouraged due to concerns regarding safety as well as effectiveness of such products.
- Benefit of alternative therapies is at best minimal, if any.

# MANAGING BLEEDING DURING MENOPAUSAL HORMONE THERAPY

---

With sequential therapy, approximately 80–90% of women experience monthly withdrawal bleeding. With continuous, combined estrogen-progestin therapy, one can expect 40–60% of patients to experience breakthrough bleeding during the first 6 months of treatment; however, this percentage decreases to 10–20% after 1 year.<sup>568,569,952</sup> Although this percentage of amenorrhea with continuous, combined therapy is a gratifying accomplishment, the number of women who experience breakthrough bleeding is considerable, and it is a difficult management problem. Indeed, the single most aggravating and worrisome problem with daily, continuous therapy is this breakthrough bleeding.

Why call it breakthrough bleeding? The bleeding experienced by women on continuous, combined therapy is similar to that seen with oral contraceptives. It originates from an endometrium dominated by progestational influence; hence, the endometrium is usually atrophic and yields little, if anything, to the exploring biopsy instrument. Breakthrough bleeding is due to a progestational effect on vascular strength and integrity, producing a fragility that is prone to breakdown and bleeding. It is helpful to explain to patients that this bleeding represents tissue breakdown as the endometrium adjusts to its new hormonal stimulation. From our experience with oral contraceptives, we have learned to be comfortable with this type of bleeding. We have learned that for most patients, the incidence of breakthrough bleeding with oral contraceptives is greatest in the first few months of treatment and usually disappears in the majority of women. Indeed, this is the same pattern exhibited by postmenopausal women on continuous, combined therapy, and, therefore, the most effective management strategy is patient education and support.

It is common for women on a sequential regimen to begin bleeding while in the midst of progestin administration. The timing of withdrawal bleeding in women on a sequential estrogen-progestin program was suggested as a screening method for biopsy decision-making. In women taking a variety of progestins for 12 days each month, bleeding on or before day 10 after the addition of the progestin was associated with proliferative endometrium. Bleeding beginning on day 11 or later was associated with secretory endometrium, presumably indicating less need for biopsy.<sup>953</sup> But does this correlate with the risk of hyperplasia and cancer? According to a study of 413 postmenopausal women, the day of bleeding did not predict endometrial safety.<sup>954</sup> Late regular withdrawal bleeding on a sequential program does not give 100% assurance that there is no hyperplasia and perhaps endometrial cancer. This uncertainty with the sequential program is another reason to turn to the daily, combined method where

irregular bleeding and sonographic measurement of increased endometrial thickness provide good indications for endometrial biopsy.

Evaluation of abnormal uterine bleeding in the setting of hormone use is identical to the paradigm discussed earlier in this chapter. The thickness of the postmenopausal endometrium as measured by TVUS in postmenopausal women correlates with the presence or absence of pathology. However, the severity of pathologic change does not correlate with the measured thickness.<sup>955</sup> Endometrial thickness (the two layers of the anterior and posterior walls in the longitudinal axis) equal to or less than 4 mm is highly<sup>956</sup> reassuring (negative predictive value is >99%), supported by the American College of Obstetricians and Gynecologists, and allows conservative management.<sup>957,958,959,960,961</sup>

It is estimated that 50–75% of patients experiencing abnormal uterine bleeding on hormone therapy and evaluated by TVUS will eventually require a biopsy.<sup>955,962</sup> It seems logical that endometrial thickness by TVUS in patients on a sequential regimen can be affected by day in the treatment cycle, and for that reason, ultrasonography assessment should be obtained toward the end of the progestin phase or at the beginning of the cycle.<sup>963,964</sup> An Italian study concluded that endometrial thickness measured soon after withdrawal bleeding in women on a sequential regimen was comparable to thickness in women on a continuous, combined program of estrogen-progestin treatment.<sup>965</sup> When a thick endometrium is associated with atrophic endometrium on biopsy, polyps or submucous myomas should be suspected. A thorough curettage can miss such pathology, and either a SHG or hysteroscopy should be considered as the next step as discussed earlier.<sup>181</sup> Doppler velocimetry does not improve the accuracy of discriminating between normal and abnormal endometrium.<sup>966</sup> **A clinician should not be satisfied with “normal” findings on ultrasonography if a patient has persistent bleeding. The pursuit of abnormal bleeding despite “normal” findings should reduce missed cases of pathology to nearly zero.**<sup>967</sup> **In this circumstance, hysteroscopy is recommended.**

There is no effective method supported by clinical studies, or a large experience, of drug alteration or substitution to manage breakthrough bleeding. The breakthrough bleeding rate is only slightly better with a higher dose of progestin (5.0 mg medroxyprogesterone acetate) than with a lower dose (2.5 mg).<sup>568,952</sup> Therefore, there is not a strong reason to use the higher dose, thus minimizing side effects. The best approach is to gain time, because most patients will cease bleeding. This means good educational preparation of the patient beforehand and frequent contact to allay anxiety and encourage persistence. Estrogen-progestin combinations that contain a 19-nortestosterone progestin (e.g., norethindrone acetate) demonstrate the same pattern of

bleeding, but fewer patients bleed in the first 6 months and the amenorrhea rate by 1 year is higher than with other regimens.<sup>968,969,970</sup>

There is a subgroup of patients (10–20% at the end of 1 year) who continue to experience breakthrough bleeding. The closer a patient is to having been bleeding (either to her premenopausal state or to having been on a sequential method with withdrawal bleeding), the more likely that patient will experience breakthrough bleeding. Some clinicians, therefore, prefer to start patients near the menopause on the sequential method and convert to the continuous method some years later. Some patients may choose to undergo a progestin IUD as a menopausal hormone therapy strategy, discussed in detail in [Chapter 23](#). The local release of progestin is effective in suppressing endometrial response and preventing unscheduled bleeding in the long term. The LNG-IUD in menopausal women can be left in place for up to 10 years, a decided advantage.<sup>603,971</sup> **A combined estrogen-progestin program however, will not totally prevent endometrial cancer.<sup>972</sup> Vigilance on the part of the clinician, however, will detect endometrial cancer at an early stage, a stage that can be treated with excellent results.**

For the smaller subset of hormone-using menopausal women who are bothered by persistent unscheduled bleeding that remains unresponsive to above strategies, consideration for definitive surgery (such as vaginal hysterectomy) may not be unreasonable.

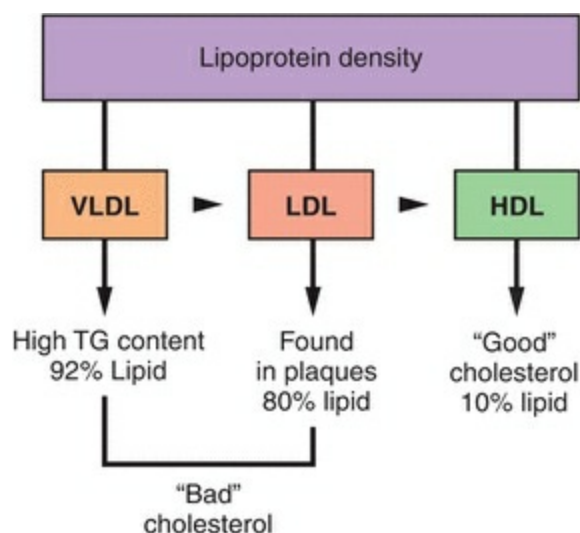

# HEALTH IMPLICATIONS OF MENOPAUSAL HORMONE THERAPY

---

# Cardiovascular Effects

## A Favorable Impact on Lipids and Lipoproteins

The most important lipid effects of postmenopausal estrogen treatment are the reduction in LDL cholesterol and the increase in HDL cholesterol. Estrogen increases triglyceride levels and LDL cholesterol catabolism as well as lipoprotein receptor numbers and activity, resulting in decreasing LDL cholesterol levels.<sup>973,974,975</sup> Estrogen induces a change in LDL cholesterol toward a smaller more dense particle, but it is in a form with a more rapid turnover in the circulation, allowing less time for oxidation and acquisition of cholesterol.<sup>976,977</sup> The increase in HDL cholesterol levels, particularly due to the HDL<sub>2</sub> subfraction, is to an important degree the consequence of the inhibition of hepatic lipase activity, which converts HDL<sub>2</sub> to HDL<sub>3</sub> (Figure 17.14). Postmenopausal estrogen therapy with or without added progestin also produces a reduction in the circulating levels of lipoprotein(a).<sup>424,978</sup>

**FIGURE 17.14**

The changes in circulating apoprotein levels mirror those of the lipoproteins: apolipoprotein B (the principal surface protein of LDL cholesterol) levels diminish in response to estrogen, and apolipoprotein A-I (the principal apolipoprotein of HDL cholesterol) increases. The positive effects of estrogens on cholesterol may be mitigated by the concomitant use of progestins.<sup>569,571,979,980,981,982,983,984</sup> The concomitant administration of estrogen and an HMG-CoA reductase inhibitor (such as pravastatin) produced a more favorable change in the lipid profile in hypercholesterolemic women

than either treatment alone.<sup>985</sup>

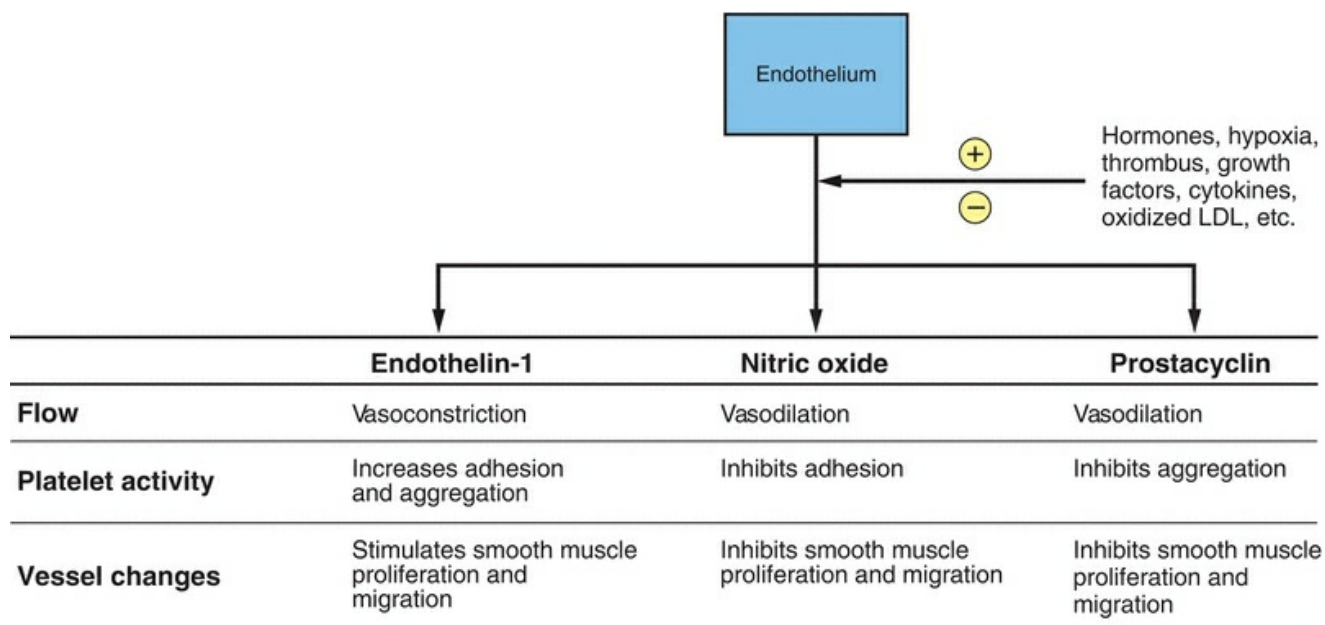

## Direct Antiatherosclerotic Effects

Studies in nonhuman primates (such as monkeys) have suggested that estrogen may have antiatherosclerotic effects that are independent of the cholesterol-lipoprotein profile. Oral administration of a combination of estrogen and a high dose of progestin to monkeys fed a high-cholesterol diet decreased the extent of coronary atherosclerosis despite a reduction in HDL cholesterol levels.<sup>986,987,988</sup> In somewhat similar experiments, estrogen treatment markedly prevented arterial lesion development in rabbits, and this effect was not reduced by adding progestin to the treatment regimen.<sup>989,990,991,992</sup>

The monkey studies were extended to a postmenopausal model (ovariectomized monkeys). Compared with no hormone treatment, treatment with either estrogen alone or estrogen with progesterone in a sequential manner significantly reduced atherosclerosis, once again independently of the circulating lipid and lipoprotein profile.<sup>993,994</sup> A direct inhibition of LDL cholesterol accumulation and an increase in LDL cholesterol metabolism in arterial vessels could be demonstrated in these monkeys being fed a highly atherogenic diet.<sup>995</sup> The daily administration of medroxyprogesterone acetate in this monkey model did not prevent the beneficial effect of CEE on coronary artery atherosclerosis.<sup>869</sup>

Estradiol fatty acid esters are present in low concentrations in the circulation, transported in lipoproteins. These esters are potent estrogens and protect against the oxidation of LDL cholesterol; the antioxidant efficacy of estradiol may require esterification and incorporation into LDL cholesterol.<sup>996</sup> Estradiol fatty acid ester concentrations are increased by oral estrogen but not by transdermal administration.<sup>997</sup>

## Endothelium-Dependent Vasodilation and Antiplatelet Aggregation (see [Figure 17.15](#))

**FIGURE 17.15**

Endothelium modulates the degree of contraction and function of the surrounding smooth muscle, primarily by the release of endothelium-derived relaxing and contracting factors. In hypertension and other cardiovascular diseases, the release of relaxing factors (such as nitric oxide) is blunted, and the release of contracting factors (the most important being endothelin-1) is augmented. The endothelins are a family of peptides that act in a paracrine fashion on smooth muscle cells. Endothelin-1 appears to be exclusively synthesized by endothelial cells. Endothelin-induced vasoconstriction is a consequence of a direct action on vascular smooth muscle cells, an action that is reversed by nitric oxide. Impaired release of nitric oxide, therefore, enhances endothelin action. Hypertension and atherosclerosis are believed to be influenced by the balance among these factors. Women have lower circulating levels of endothelin, which decrease in response to oral and transdermal estrogen treatment.<sup>998,999</sup>

Nitric oxide (and estrogen) also inhibits the adhesion and aggregation of platelets in a synergistic manner with prostacyclin (also a potent vasodilator derived from the endothelium).<sup>1000,1001</sup> Increased blood flow due to vasodilation and decreased peripheral resistance can be observed to occur rapidly following the administration of estrogen. This response can be produced by both transdermal and oral administration.<sup>1002,1003,1004</sup> The synthesis and secretion of nitric oxide (the potent endothelial vasodilating product) can be directly stimulated by estrogen in in vitro experimental preparations of coronary arteries.<sup>1005</sup> In both normotensive postmenopausal women and women with hypertension, hypercholesterolemia, diabetes mellitus, or coronary artery disease, the intra-arterial infusion of physiologic amounts of

estradiol into the forearm potentiates endothelium-dependent vasodilation, and there is a dose-response effect.<sup>1006,1007</sup> Similarly, brachial artery dilation has been reported with 0.3 and 0.625 mg conjugated estrogens.<sup>1008</sup> Comparing brachial artery responses in hormone therapy users versus nonusers (estrogens with/without progestin), improved endothelium-dependent vasodilation was observed with standard doses.<sup>1009</sup> Furthermore, the addition of norethindrone acetate or medroxyprogesterone acetate did not reduce the beneficial effect of estrogen on peripheral artery blood flow.<sup>1010,1011</sup> However, not all studies agree. A Danish assessment of brachial artery responses demonstrated no difference between postmenopausal women on long-term combined estrogen-progestin therapy compared with those receiving no treatment.<sup>1012</sup>

The synthesis of nitric oxide is involved in the regulation of vascular (and gastrointestinal) tone and in neuronal activity. A family of isozymes (nitric oxide synthases) catalyzes the oxidation of L-arginine to nitric oxide and citrulline. The action of nitric oxide synthase in the endothelium is calcium dependent.<sup>1013</sup> In animal experiments, the endothelial basal release of nitric oxide is greater in females, a gender difference that is mediated by estrogen.<sup>1005,1014</sup> In women treated with postmenopausal estrogen and either cyproterone acetate or medroxyprogesterone acetate, circulating nitric oxide (as reflected in nitrite-nitrate levels) is increased, a consequence of estrogen-induced nitric oxide production in the endothelium.<sup>1015,1016</sup> In contrast, long-term treatment with estradiol and norethindrone acetate was not associated with changes in nitric oxide, endothelin-1, prostacyclin, or thromboxane A<sub>2</sub>, suggesting that different progestins have differential effects.<sup>1017</sup>

Acetylcholine induces vasoconstriction in coronary arteries; however, the direct administration of estradiol in physiologic doses into the coronary arteries of postmenopausal women with and without CHD converts acetylcholine-induced vasoconstriction into vasodilation with increased flow.<sup>1018</sup> This favorable vasomotor response to acetylcholine can also be demonstrated in acute experiments with transdermal administration of estradiol (achieving blood levels of 67–89 pg/mL).<sup>1019</sup> This is an endothelium-dependent response, mediated to a significant degree by an increase in nitric oxide.<sup>1020</sup> In the monkey, the vasodilatory response to acetylcholine required a blood level of estradiol higher than 60 pg/mL.<sup>1021</sup>

## **Endothelium-Independent Vasodilation**

Estrogen causes relaxation in coronary arteries that are denuded of endothelium.<sup>1022</sup> This response is not prevented by the presence of inhibitors of nitric oxide synthase or prostaglandin synthase, thus suggesting that some degree of vasodilation in response to estrogen is achieved through a mechanism that is independent of the vascular

endothelium, perhaps acting via calcium-mediated events.<sup>1023</sup> The vasodilation produced by sodium nitroprusside is endothelium-independent. In otherwise healthy postmenopausal women and in those with risk factors for atherosclerosis (hypertension, hypercholesterolemia, diabetes mellitus, coronary artery disease), administration of physiologic doses of estradiol increased forearm vasodilation induced by sodium nitroprusside.<sup>1006</sup> However, others have reported no effect of estrogen administration on endothelium-independent vasodilation.<sup>1004</sup>

## **Actions on the Heart and Large Blood Vessels**

Estrogen treatment in some studies was associated with increased left ventricular diastolic filling and stroke volume,<sup>1004,1024,1025,1026</sup> an effect that probably reflects a direct inotropic action of estrogen.<sup>1027</sup> In a 3-month study, medroxyprogesterone acetate (5 mg daily for 10 days each month) did not attenuate the increase in left ventricular output (systolic flow velocity) observed with estrogen treatment.<sup>1028</sup> On the other hand, others have detected attenuation of estrogen's beneficial effects on compliance (stiffness) associated with combined estrogen-progestin treatment.<sup>1027,1029</sup> And others have not been able to demonstrate an effect of short-term oral estrogen or long-term transdermal estrogen treatment on cardiac structure and function.<sup>1030,1031</sup> The reasons for these observations as well as the differences remain unclear.

## **Actions on Glucose Metabolism**

An age-related decline in the basal metabolic rate is accentuated at menopause, associated with an increase in body fat, especially central (android) body fat.<sup>1032,1033</sup> Insulin resistance and circulating insulin levels increase in women after menopause, and impaired glucose tolerance predicts an increased risk of CHD.<sup>1034,1035</sup> Estrogen (with or without progestin) prevents the tendency to increase central body fat with aging.<sup>1036,1037,1038,1039</sup> The WHI randomized clinical trial documented improvements in fasting glucose and insulin levels in the estrogen-progestin-treated group.<sup>1040</sup> Hyperinsulinemia also has a direct atherogenic effect on blood vessels, perhaps secondary to insulin propeptides. In addition to its vasoconstrictive properties, endothelin-1 exerts a mitogenic effect and, therefore, contributes to the atherosclerotic process. Insulin directly stimulates the secretion of endothelin-1 in endothelial cells, and the circulating levels of endothelin-1 are correlated with insulin levels.<sup>1041</sup>

Postmenopausal women being treated with oral estrogen have lower fasting insulin levels and a lesser insulin response to glucose.<sup>981,1040,1042,1043,1044,1045</sup> In a 1-year randomized trial comparing unopposed conjugated estrogens to the usual sequential and

continuous regimens of conjugated estrogens and medroxyprogesterone acetate, no differences in the treatment groups were observed in the favorable decreases in fasting insulin levels.<sup>981</sup> Nonoral administration of estrogen has little effect on insulin metabolism, unless a dose is administered that is equivalent to 1.25 mg conjugated estrogens.<sup>1043,1046</sup> Because a lower oral dose produces a beneficial impact, this suggests that the hepatic first-pass effect is important in this response, at least in normal women; reports with transdermal hormone therapy have indicated improvements in insulin resistance and hyperinsulinemia, but no effect in women with normal insulin sensitivity.<sup>1047,1048</sup> In double-blind, crossover, placebo-controlled studies of postmenopausal women with type 2, non-insulin-dependent diabetes mellitus, estrogen treatment improved all glucose metabolic parameters (including insulin resistance), the lipoprotein profile, and measurements of androgenicity.<sup>1049,1050</sup>

**The evidence strongly indicates that postmenopausal estrogen therapy improves glucose metabolism. Epidemiologic studies impressively document that this beneficial metabolic effect associated with estrogen lowers the incidence of adult-onset, type 2 diabetes mellitus.** Three large cohort studies, the Nurses' Health Study, the Finnish Kuopio Osteoporosis Risk Factor and Prevention Study, and the French E3N study, reported decreases in new-onset diabetes associated with estrogen therapy.<sup>1051,1052,1053</sup> In the French cohort, no effect of progestins was observed, and the reduction in the incidence of diabetes (32%) was greater with oral administration of estrogen compared with the transdermal method.<sup>1053</sup> Clinical trial results are in agreement. In the HERS trial, the hormone-treated group developed diabetes at a rate that was 35% lower compared with the placebo group.<sup>1045</sup> Similar findings were observed in the Women's Health Initiative Hormone Trials wherein a 21% reduction in incident diabetes was observed in the combined E and P trial, whereas a 12% reduction with the estrogen-alone trial.<sup>534,1054</sup>

## **Inhibition of Lipoprotein Oxidation**

The oxidation of LDL cholesterol particles is a step (perhaps the initial step) in the formation of atherosclerosis, and smoking is associated with a high level of lipoprotein oxidation. In animal experiments, the administration of large amounts of antioxidants inhibits the formation of atherosclerosis and causes the regression of existing lesions. Estrogen is an antioxidant. Estradiol directly inhibits LDL cholesterol oxidation in response to copper and decreases the overall formation of lipid oxides.<sup>1055,1056</sup> Importantly, this antioxidant action of estradiol is associated with physiologic blood levels.<sup>1057</sup> In addition, estrogen may regenerate circulating antioxidants (tocopherols and beta-carotene) and preserve these antioxidants within LDL cholesterol particles.

This antioxidant action of estrogen preserves endothelial-dependent vasodilator function by preventing the deleterious effect that oxidized LDL cholesterol has on endothelial production of vasoactive agents.<sup>1058</sup> In an assessment of peroxide formation by platelets, women treated with both estrogen and medroxyprogesterone acetate in a sequential regimen had greater antioxidant activity compared with the days on estrogen alone.<sup>1059</sup> In a 1-year study, the presence of levonorgestrel did not attenuate the antioxidant activity of estradiol.<sup>1060</sup>

## A Favorable Impact on Fibrinolysis

Menopause is followed by increases in factor VII, fibrinogen, and plasminogen activator inhibitor-1 (PAI-1).<sup>1061,1062</sup> These changes produce a relatively hypercoagulable state and are associated with an increased risk of cardiovascular events. Postmenopausal women treated with estrogen have lower fibrinogen and plasminogen levels. Reduced levels of fibrinogen, factor VII, and PAI-1 have been observed in premenopausal women compared with postmenopausal women, and oral estrogen alone or combined with a progestin prevents the usual increase in these clotting factors associated with menopause.<sup>1063,1064,1065,1066,1067</sup> This would be consistent with increased fibrinolytic activity, a possible cardioprotective mechanism probably mediated, at least partially, by nitric oxide and prostacyclin. Platelet aggregation is also reduced by postmenopausal estrogen treatment, and this response is slightly attenuated by medroxyprogesterone acetate.<sup>1000</sup> In a randomized 1-year trial, the addition of medroxyprogesterone acetate, either sequentially or continuously, produced a more favorable change in coagulation factors compared with unopposed estrogen.<sup>1068</sup>

The transdermal and oral routes of administration of estrogen (combined with medroxyprogesterone acetate) have puzzling differences in the reported effects on most hemostatic risk factors, such as factor VII, fibrinogen, PAI-1, and antithrombin III. In at least one study, antithrombin III levels were reduced by oral estrogen but not transdermal administration; however, the values remained within the normal range.<sup>1069</sup> In regard to PAI-1, studies with transdermal estrogen have provided conflicting data, varying from favorable changes in PAI-1 levels to no effect.<sup>506,1070,1071</sup> However, in a crossover study designed to compare 100 µg transdermal estradiol with 0.625 mg oral conjugated estrogens (both combined with 2.5 mg medroxyprogesterone acetate daily), only the oral estrogen had a favorable reduction in PAI-1 levels.<sup>1071</sup> Appropriate doses of hormone therapy have been reported to not have an adverse impact on clotting factors<sup>1064,1072,1073</sup>; however, the clotting story is difficult to unravel. While no randomized control trials have analyzed the difference in VTE risk between oral and transdermal estrogen, observational studies have demonstrated a difference in risk based on routes of administration. A recent meta-analysis showed that oral estrogen

administration resulted in an increased risk of VTE, which was not seen with transdermal estrogen administration.<sup>1074,1075</sup> Additionally, oral estrogen use in conjunction with progesterone has been associated with a greater risk of VTE than oral estrogen use alone.<sup>1076</sup> Several factors, which are not controlled for in observational trials, also make it difficult to draw a conclusion from the aforementioned data. The frequency (cyclic vs. continuous) and derivative of progesterone used were not controlled for in observational trials. Inherent differences in estrogen's route of administration also likely affected the observed results—estrogens' effects on hepatic first-pass metabolism (namely, oral estrogen's ability to alter the synthesis and clearance of hemostatic proteins), oral estrogens' ability to activate the coagulation cascade, and estrogens' effects on thrombin generation. Thus, a randomized control study comparing the effects of oral versus transdermal estrogen, with or without the addition of progesterone derivative, is needed before a definitive statement regarding the superiority of one form of administration or another can be made.

How can there be favorable changes indicating an increase in fibrinolysis and at the same time an increased risk of venous thrombosis, and why in elderly women, especially those with clinically apparent CHD, does estrogen seem to have a prothrombotic effect? Decreases in antithrombin III and protein S associated with estrogen treatment, a hypercoagulable change, may have a greater impact on the venous system.<sup>1077</sup> There also may be subtle variations of inherited susceptibilities that tilt the balance toward thrombosis; for example, concentrations of factors that favor arterial thrombosis have been reported (tissue factor pathway coagulation inhibitor and thrombin-activatable fibrinolysis inhibitor) in women treated with estrogens.<sup>1078</sup> Another possibility is that the fibrinolysis is a response to coagulation activity and, therefore, not necessarily a beneficial response.

Estrogen has adverse effects on already established atherosclerosis. Matrix metalloproteinase enzymes are secreted by inflammatory cells and smooth muscle cells. These enzymes digest the proteins in the fibrous cap of an atherosclerotic plaque, making the plaque unstable and predisposed to rupture. Estrogen induces matrix metalloproteinase enzymes and decreases their specific inhibitors (TIMP); this is a mechanism involved in the prothrombotic effects of estrogen in the presence of established atherosclerosis. This effect of estrogen may be dose-related and might be avoided with transdermal administration.<sup>1079</sup>

## **Inhibition of Intimal Thickening**

Hypertension and atherosclerosis are associated with increased proliferation of vascular smooth muscle cells. This growth of smooth muscle cells is also characterized by migration into the intima. Arterial intimal thickening is an early indicator of

atherosclerosis. The proliferation and migration of human aortic smooth muscle cells in response to growth factors are inhibited by estradiol, and, importantly, this inhibition is not prevented by the presence of progestins.<sup>1080,1081</sup> Nitric oxide, which is regulated by estrogen, also inhibits smooth muscle proliferation and migration.<sup>1082</sup> Imaging studies have documented a reduction in intimal thickening in postmenopausal women who are estrogen users compared with nonusers, and this beneficial effect is not compromised by the addition of a progestational agent to the treatment regimen.<sup>1029,1083,1084,1085</sup> Thus, postmenopausal hormonal therapy can bring about a reduction in atherosclerosis, and this effect is comparable with that produced by a lipid-lowering drug.<sup>1083,1086</sup>

## **Protection of Endothelial Cells**

Endothelial cells can respond to injury by initiating the clotting process. Animal studies indicate that estrogen accelerates healing and recovery of the endothelium in response to injury.<sup>1087</sup> This is correlated with inhibition of intimal thickening and recovery of important functions such as nitric oxide production. In vitro studies of human endothelial cells demonstrate that estrogen can inhibit cytokine-induced apoptosis.<sup>1088</sup> In the rat, medroxyprogesterone acetate blocked the estrogen-induced healing response after carotid artery injuries.<sup>1089</sup>

## **Inhibition of Macrophage Foam Cell Formation**

A feature of atherosclerotic plaque formation is monocytic infiltration into the arterial wall and the formation of macrophage foam cells. In a non-antioxidant activity, estrogen inhibits macrophage foam cell accumulation in atherosclerotic lesions.<sup>1090</sup>

## **Reduction of ACE and Renin Levels**

Although oral estrogen, but not transdermal estrogen, increases angiotensinogen levels, ACE (angiotensin-converting enzyme) and renin levels are decreased (with or without progestin) by both routes of administration.<sup>1091,1092</sup> The angiotensin II receptor (the AT<sub>1</sub> receptor) is involved in vasoconstriction, aldosterone release, sodium and water retention, and growth and proliferation of myocardial and vascular cells. Estrogen induces down-regulation of the AT<sub>1</sub> receptor, and hypercholesterolemia is associated with AT<sub>1</sub> up-regulation and function.<sup>1093,1094</sup>

## **Reduction of Adhesion Molecules**

Adhesion molecules recruit leukocytes to the endothelium and play a role in attaching platelets to endothelium. Studies with multiple markers report that oral estrogen therapy

increases only CRP, the only marker synthesized in the liver. Although oral hormone therapy increases CRP, it reduces the circulating levels of other markers (E-selectin, P-selectin, intercellular adhesion molecule-1, vascular cell adhesion molecule-1, monocyte chemoattractant protein-1, and tumor necrosis factor- $\alpha$ ) with inconsistent effects on IL-6.<sup>418,421,422,1095</sup> An increase in CRP levels may be due to estrogen's well-known effect to stimulate the hepatic synthesis of proteins, especially because of the first-pass phenomenon with oral administration. For this reason, transdermal estrogen treatment reduces adhesion markers but does not change CRP levels.<sup>419,420,1096</sup>

## **Reduction of Homocysteine**

Increased circulating levels of homocysteine are correlated with increased risks of atherosclerosis and thrombosis. Homocysteine levels increase after menopause and are associated with hypertension and a degree of atherosclerosis.<sup>1097</sup> Homocysteine levels are significantly lowered by estrogen or estrogen-progestin treatment, administered either orally or transdermally.<sup>1098,1099</sup>

# Menopausal Hormone Use and Cardiovascular Disease: Evidence from Observational Studies

A review of case-control studies in the literature finds overwhelming support for about a 50% reduced risk of CHD in estrogen users.<sup>1100,1101,1102,1103,1104,1105,1106,1107,1108,1109,1110,1111,1112,1113,1114,1115,1116,1117</sup> In three studies of women undergoing angiography, a comparison of coronary artery occlusion in users and nonusers of estrogen indicated a significant protective effect of postmenopausal estrogen.<sup>1109,1110,1111</sup> Women using hormone therapy at the time of a myocardial infarction or with congestive heart failure have been reported to have an improved rate of survival.<sup>1118,1119</sup> Little attention has been given to peripheral artery disease, but one case-control study did report a decrease in risk in users of hormone therapy.<sup>1120</sup>

In a large number of cohort studies, most uniformly reported a reduction in CHD in estrogen users; only three produced conflicting data.<sup>1121,1122,1123,1124,1125,1126,1127,1128,1129,1130,1131,1132,1133,1134,1135,1136</sup> In the Nurses' Health Study with 20 years of follow-up, the age-adjusted relative risk of coronary disease in current users of hormone therapy was 39% reduced (RR = 0.61; CI = 0.52–0.71).<sup>1137</sup> The benefit was observed with both the 0.625-mg and the 0.3-mg doses of conjugated estrogens. The beneficial impact was observed to diminish beginning 3 years after discontinuation. It was suggested that higher doses might be harmful because there was an apparent increase in the risk of coronary disease among women taking more than 0.625 mg conjugated estrogens per day. Current postmenopausal hormone users in the Nurses' Health Study have had a 37% reduced risk of mortality due largely to protection against CHD, an effect that was still present after adjusting for dietary factors, alcohol intake, vitamin or aspirin use, and exercise.<sup>1132</sup>

Electron beam tomography (also called ultrafast computed tomography) can assess for the presence of coronary artery disease by quantifying the amount of calcium in the coronary arteries, a measure that is known to correlate with the degree of disease and the risk of coronary events. Studies using this technique have demonstrated a lower prevalence of coronary artery calcium (CAC) in women younger than age 60, a prevalence comparable to men (of any age) in women older than 60, and less calcium (and, therefore, less coronary artery disease) in women using postmenopausal hormone therapy compared with nonusers.<sup>1138,1139</sup> In women with an average age of 59 who had used hormone therapy for an average of 9 years, coronary artery calcification was significantly reduced, with a greater effect observed with increasing duration of use.<sup>1140</sup> This salutary effect of estrogen was confirmed in a substudy of the WHI estrogen-only

arm.<sup>1141</sup>

These observational studies have been criticized by arguing that estrogen treatment is a marker for variables (e.g., better diet and better health care) that place postmenopausal estrogen users in a low-risk group for cardiovascular disease (the “healthy user” effect). And indeed, women who choose to use hormone therapy have been reported to have a better cardiovascular risk profile than nonusers.<sup>1142</sup> This question was addressed by the Lipid Research Clinics Study, the Leisure World Study, and the Nurses’ Health Study.<sup>1125,1143,1144</sup> These epidemiologists concluded that their evidence strongly indicated that in women receiving estrogen treatment who have the same risk factors for cardiovascular disease as those not receiving treatment, the same beneficial effect of estrogen was present. This is especially the case in the Nurses’ Health Study, in which the participants are of a relatively homogeneous socioeconomic group. A cohort follow-up study in Southeastern New England documented similar levels of total cholesterol, HDL cholesterol, BMI, and blood pressure in estrogen users and nonusers, indicating that selection of significantly more healthy women for estrogen use could not fully explain the beneficial effect of estrogen on the risk of cardiovascular disease.<sup>1145</sup> In a comparison of health variables among users and nonusers in South Australia, there was no evidence to support the presence of a “healthy user” effect.<sup>1146</sup> In Chile, users and nonusers of hormone therapy had identical risk factors for cardiovascular disease.<sup>1147</sup>

In contrast to the uniform results from observational studies of the association between postmenopausal hormone therapy and CHD, epidemiologic data over the last 30 years regarding estrogen use and stroke have not been consistent. The many studies have indicated either a small increase or no effect of postmenopausal hormone therapy on the risk of stroke or a reduction in risk associated with estrogen or estrogen-progestin use.<sup>1123,1125,1131,1137,1148,1149,1150,1151,1152,1153,1154,1155,1156,1157</sup> A prospective cohort study in Denmark recorded an increase in ischemic strokes, but only among hypertensive women, and a large cohort study from Sweden found no link between stroke and hormone therapy.<sup>1158,1159</sup>

Within this confusing mixture of results on stroke, there was one consistent observation. The cohort studies (with a sufficient number of cases) that have assessed the impact of hormone use on the risk of death from stroke have all indicated a beneficial impact. For example, the NHANES recruited a very large cohort of women in 1971–1975 for epidemiologic analysis. The follow-up longitudinal study of this cohort yielded a U.S. national sample of 1,910 white postmenopausal women. Postmenopausal hormone use in this cohort provided a 31% reduction in stroke incidence and a strongly significant 63% reduction in stroke mortality.<sup>1152</sup> These relative risks were present even after adjusting for age, hypertension, diabetes, body weight, smoking, socioeconomic

status, and previous cardiovascular disease. This study specifically addressed the criticism that one should expect less disease in estrogen users because they are healthier. After adjusting for physical activity as a marker of general health status, the risk estimates remained identical.

Hypertension is both a risk factor for cardiovascular mortality and a common problem in older people. Studies have either shown no effect or a small, but statistically significant, decrease in blood pressure due to estrogen treatment.<sup>1160,1161,1162,1163,1164,1165</sup> This has been the case in both normotensive and hypertensive women.<sup>1166,1167,1168,1169,1170,1171</sup> The addition of a progestin did not affect this response.<sup>569,1172</sup> Discontinuing hormone therapy in women with hypertension does not result in a decrease in blood pressure (an expected response if the treatment were raising blood pressure), and in some patients, discontinuation is followed by an increase in blood pressure.<sup>1173</sup> The acute administration of estrogen to women with hypertension is followed by decreases in blood pressure, pulse rate, and circulating levels of norepinephrine.<sup>1174</sup> **The very rare cases of increased blood pressure due to oral estrogen therapy truly represent idiosyncratic reactions. Blood pressure should be assessed every 6 months in hypertensive women being treated with postmenopausal hormones, and if the blood pressure is labile, blood pressure should be measured every 3 months.**

Observational studies have also reported that hormone users have a decreased risk of developing venous leg ulcers or pressure ulcers.<sup>1175,1176</sup>

# Menopausal Hormone Use and Cardiovascular Disease: Evidence from Clinical Trials

## The Women's Health Initiative

The WHI was organized by the U.S. National Institutes of Health in 1992 to study the health of postmenopausal women and was scheduled to be completed in 2007.<sup>1177</sup> From 1993 to 1998, the WHI enrolled 161,809 women aged 50–79 in 40 clinical centers. The major components of the WHI were (1) two randomized trials of postmenopausal hormone therapy scheduled to conclude in 2005, (2) a dietary modification trial that randomized 48,000 women to either a sustained low-fat or a self-determined diet, (3) a calcium/vitamin D supplementation trial, and (4) an observational study. One of the randomized trials of postmenopausal hormone therapy, the combined estrogen-progestin arm (daily 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate), randomized 16,608 women to either treatment or placebo. The other hormone trial, an estrogen-only arm (daily 0.625 mg conjugated estrogens), randomized 10,739 hysterectomized women to treatment or placebo.

On May 31, 2002, the Data and Safety Monitoring Board (DSMB) made its periodic review of the data accumulated by the WHI. The DSMB made two recommendations that were announced on July 9, 2002: (1) to discontinue the trial arm administering daily estrogen-progestin and (2) to continue the trial arm with daily unopposed estrogen in hysterectomized women. The combined estrogen-progestin arm was discontinued after about 5 years of follow-up because of a statistically significant increase in invasive breast cancer and an increase in cardiovascular events.<sup>1178</sup> The statistical parameters for benefit or harm were established in 1997 early in the study. When the increase in breast cancer exceeded the predetermined boundary, the DSMB was obligated to recommend discontinuation of this arm of the trial.

On March 2, 2004, the National Heart, Lung, and Blood Institute of the U.S. National Institutes of Health canceled the estrogen-only arm of the WHI. This arm of the WHI included 10,739 hysterectomized, postmenopausal women who had completed an average of 6.8 years of follow-up. The WHI Data and Safety Monitoring Board made their last periodic review of the study data in December 2003. The DSMB was not unanimous in its decision; some members wanted to stop the study, and others wanted the study to continue after sending a letter to the participants describing the findings. Even though none of the findings had crossed the predefined boundaries, the NIH made the decision to stop the study on February 2, 2004. The decision was based on the following results<sup>1179</sup>:

- An increased risk of stroke similar to that reported in the canceled estrogen-progestin arm of the WHI
- No increase or decrease in CHD
- A trend toward an increased risk of probable dementia and/or mild cognitive impairment
- A reduction in hip fractures
- No increase in breast cancer

**With the exception of breast cancer and CHD, the results in the estrogen-only arm were essentially identical to those in the estrogen-progestin arm of the study.** But keep in mind that the populations in the two clinical, randomized trial arms of the WHI were not identical.<sup>1180</sup> Considering risk factors for cardiovascular disease, the women in the estrogen-only arm were more obese, were less active, and had more pre-existing cardiovascular disease. The estrogen-only arm also differed in regard to risk factors for breast cancer: more early births and bilateral oophorectomy and more and longer duration of previous hormone therapy. **Therefore, these were two different trials with two different populations and treatments, making direct comparisons inappropriate.**

**The published results of the WHI trial agree with more than 30 years of case-control and cohort data with the exception (as first presented by the WHI) of the cardiovascular results.** The updated results on the risk of CHD from the canceled estrogen-progestin arm of the WHI reflected central adjudication of the cardiac diagnoses in contrast to the initial report that relied on local diagnoses.<sup>1181</sup> The final report covered an average of 5.6 years of follow-up, compared with 5.2 years in the initial report. Based on these data, there would be an increase of six cases of CHD per 10,000 women per year in the treated group.

Central adjudication disagreed with 10% of the diagnoses for myocardial infarction and 3% for death due to CHD. This small degree of disagreement changed the strength of the conclusions comparing the initial report<sup>1178</sup> with the updated report. Indeed, the overall results by definition did not achieve statistical significance in the follow-up report, and only the first year results were statistically significant in the year-by-year analysis, a conclusion based on a difference of only 19 cases. In all of the WHI reports, the intent-to-treat analyses were adjusted for multiple outcomes, the Bonferroni adjustment. All adjusted results were not statistically significant. It is difficult to understand the clinical meaning of this manipulation, but most believe that this indicates a slightly lower mathematical conclusion than presented in the nonadjusted data. This, of course, would further weaken the power of the reported results.

Consider also the possibility of diagnostic bias. 40.5% of the estrogen-progestin

group in the WHI (nearly 5,000 of the 8,500 in the treated group), in contrast to 6.8% of the placebo group, were unblinded because of vaginal bleeding. What was the impact on the clinicians' final management and diagnosis when told that the patient is in the WHI study and experiencing vaginal bleeding? This problem affects the data not only in regard to cardiovascular disease but also for breast cancer. Unblinding was not a problem in the estrogen-only arm of the WHI and no increase in CHD was recorded—was this because of an absence of diagnostic bias in the estrogen-only arm?

The characteristics of the participants in the two WHI hormone trials are noted in [Table 17.12](#).

## **TABLE 17.12 WHI Hormone Trials**

	Estrogen-Progestin Arm	Estrogen-Only Arm
Average age	63.3 y	63.6 y
Drop-out rate	42%	53.8%
Drop-in rate (began hormone use)	6.2%	5.7%

The women in the estrogen-progestin arm were an average of slightly more than 12 years distant from menopause.<sup>1179</sup> Most had been without hormone therapy for more than a decade. In the estrogen-only arm, the published results do not specify the number of years distant from menopause, but this duration may have been even greater, influenced by the age of subjects at the time of bilateral salpingo-oophorectomy. Women with significant menopausal symptoms were excluded from the study to avoid an exceedingly high drop-out rate in the placebo group. Women who had been on hormone therapy (about 25% of the participants in the estrogen-progestin arm and 35% in the estrogen-only arm) and then underwent a 3-month “washout” period and experienced menopausal symptoms were discouraged from participation (about 12.5% of the participants in the estrogen-progestin arm reported vasomotor symptoms on entry but were willing to be assigned to placebo, and, therefore, their symptoms were unlikely to have had a major disturbing effect). This exclusion means that only a small number of women in the WHI were close to their age of menopause (about 16.5% of the participants in the estrogen-progestin arm were <5 years since their menopause). For example, there was only a total of 574 women who were age 50–54 in the estrogen-progestin arm.<sup>301</sup>

Over the time of the studies, the participants discontinued their medication at a consistently increasing rate, so that at termination, about half were no longer adhering to treatment. The WHI investigators argued that the high drop-out rate could lead to an underestimation of adverse effects; however, this would not be the case if longer duration of treatment exerts a beneficial effect. For example, a case-control study in the United Kingdom found a significant reduction in the risk of myocardial infarction only

with the use of hormone therapy for more than 5 years.<sup>1182</sup> Indeed, a trend for an emerging protection against CHD was observed in both arms of the WHI with increasing duration of treatment. Analysis of subsamples in the WHI revealed that the treated group had greater reductions in total cholesterol, LDL cholesterol, glucose, and insulin levels and greater increases in HDL cholesterol and triglyceride levels. It is tempting to link these findings with the test for trend that revealed a favorable, decreasing relative risk of CHD over time, which was statistically significant. However, this analysis was hampered by decreasing numbers over time, and the conclusion was not a strong one.

**In subgroup analyses, only the women in the estrogen-progestin arm who were 20 or more years distant from menopause had a statistically significant increased risk of CHD. Subtracting this group from the rest of the participants, CHD now was observed in an identical prevalence comparing the treated and placebo groups. It is not appropriate to conclude, based on the WHI, that hormone therapy increases the risk of coronary clinical events in all postmenopausal women; this conclusion can only be applied to a specific older group of women. Indeed, as early as 2004, the data from the estrogen-only arm suggested that younger women experienced a reduced risk of CHD with estrogen treatment.<sup>1179</sup>**

A reanalysis of the CHD data in the canceled estrogen-progestin arm of the WHI, published 7 years after the initial report, contributed nothing new, confirming that a statistically significant increase in coronary heart events occurred only in the women 10 or more years distant from their menopause.<sup>1183</sup>

One response to the publications from the WHI has been a scientific and clinical effort to assess and use lower doses of estrogen. Half of the standard dose of CEEs has been demonstrated to effectively treat menopausal symptoms and to prevent bone loss. It is reasonable to ask whether symptoms and bone are especially sensitive to the effects of estrogen and whether lower doses of estrogen will beneficially impact other target tissues. The cardiovascular system is of obvious concern because it was already apparent that lower doses of estrogen do have a lesser effect on circulating lipids and lipoproteins.

Clarkson and his colleagues studied the effects of a lower-dose estrogen trial in a monkey model of coronary atherosclerosis.<sup>1184</sup> The animals were fed an atherogenic diet for 10 months, calculated to induce atherosclerosis comparable to that observed in early postmenopausal women. After oophorectomy, the animals were randomized to treatment for 2 years with a placebo or a dose of CEEs equivalent to 0.3 mg/day in women. This dose had no effect on circulating lipid levels; nevertheless, the treated animals had an average of 52% reduction in coronary atherosclerosis. This degree of protection was similar to studies in this model using a dose of conjugated estrogens

equivalent to 0.625 mg/day.

The reliability and value of results obtained in Clarkson's monkey model have stood the test of time. Repeatedly, results from this model proved to be predictive of hormonal effects in women. Therefore, this experiment using a lower dose of estrogen is important, providing information regarding the effect of a lower dose on coronary atherosclerosis. Consistent with some reports in women, the lower dose of estrogen had no effect on levels of LDL cholesterol, HDL cholesterol, or triglycerides. But the treatment markedly reduced the extent of coronary artery atherosclerosis, a further indication that estrogen-induced inhibition of atherosclerosis occurs to a large extent independently of changes in lipids and lipoproteins. In the dose-response clinical trial that led to FDA approval of lower doses of CEEs, the 0.3-mg dose still produced statistically significant beneficial changes in lipids and lipoproteins, and this dose prevented bone loss.<sup>577,583</sup>

## The WHI and Stroke

The WHI reported an overall increase in the estrogen-progestin arm of ischemic stroke, but no increase in fatal strokes.<sup>1178,1185</sup> The increase in nonfatal ischemic stroke in the estrogen-only arm of the WHI was of similar magnitude.<sup>1159,1186</sup> A randomized, double-blind, placebo-controlled secondary prevention trial (the WEST trial) of daily 1 mg estradiol therapy was conducted in postmenopausal women after a recent (within 90 days) ischemic stroke or transient ischemic attack (25% of the women).<sup>1187</sup> After an average of 2.8 years of follow-up (range 16–50 months), there were no significant overall differences comparing the treatment and placebo groups in any of the assessed outcomes, including nonfatal stroke, fatal stroke, coronary death, nonfatal myocardial infarction, or transient ischemic attack. The WEST trial retrospectively analyzed the time course of cerebrovascular events and found a significantly increased risk of stroke only at 6 months based on 21 strokes in the estradiol group and 9 strokes in the placebo group.

A major limitation of the WEST study was the reduced compliance with treatment because of the problems associated with unopposed estrogen treatment. Over a 3-year period, 116 women in the estradiol group discontinued treatment (34%) compared with 79 in the placebo group (24%). **Nevertheless, the clinical meaning is straightforward: patients should not be given estrogen treatment after a vascular event in the expectation that recurrent vascular events would be prevented by the initiation of estrogen treatment. However, this recommendation is specifically targeted to women with existing vascular disease.**

The Nurses' Health Study reported an update of its data on the use of hormone therapy and stroke, focusing on the timing of initiation of treatment and the effect of

estrogen doses.<sup>1188</sup> In the analyses adjusted for age, BMI, cholesterol levels, diabetes, hypertension, smoking, and family history of early CHD, the following relative risks were observed for ischemic stroke (there was no significant increase in hemorrhagic stroke):

**Current use of estrogen alone:** RR = 1.43 (CI = 1.17–1.74)

**Current use of estrogen-progestin:** RR = 1.53 (CI = 1.21–1.95)

Comparing initiation of hormone therapy near menopause with initiation 10 or more years after menopause, there was no major difference.

The Nurses' Health Study also reported an increasing risk of stroke with an increasing dose of estrogen (Table 17.13).

**TABLE 17.13 Estrogen Dose and Stroke Risk**

TABLE 17.13 Estrogen Dose and Stroke Risk		
0.3 mg estrogen	25 cases	RR = 0.93 (CI = 0.62–1.40)
0.625 mg	268 cases	RR = 1.54 (CI = 1.31–1.81)
1.25 mg	60 cases	RR = 1.62 (CI = 1.23–2.14)

It is not easy to derive a take-home message from the Nurses' Health Study report. The authors stated that their findings are “virtually identical to those of the WHI trials.” However, in the last report from the WHI, when women with prior cardiovascular disease or those older than 60 years were excluded, the risk of stroke with hormone use in women less than 10 years since their menopause was not significantly increased.<sup>1189</sup> Therefore, there is disagreement.

In women with risk factors for stroke, it is prudent to use low doses of estrogen and to vigorously address the risk factors, such as effective treatment of hypertension. Would the transdermal route of hormone administration be safer? This is an important question that cannot be categorically answered because of lack of high quality prospective data. However, as has been discussed earlier in this chapter, it is quite plausible that transdermal HT confers a lower risk of thrombosis

**compared to oral formulations. Therefore, it seems wise to preferentially recommend transdermal route of HT for older postmenopausal hormone users.**

# Secondary Prevention Randomized Clinical Trials

## The Heart and Estrogen-Progestin Replacement Study

HERS was a randomized, double-blind, placebo-controlled clinical trial designed to determine whether daily treatment with 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate would reduce CHD events in women with pre-existing coronary disease.<sup>1190,1191,1192</sup> 2,763 women (average age 66.7 years) were enrolled in 20 U.S. clinical centers and randomized to treatment and placebo beginning in February 1993 and ending in July 1998. Overall, there were 172 myocardial infarctions and coronary deaths in the hormone group and 176 in the placebo group—no difference.

At baseline, the use of statins and aspirin was essentially equally prevalent in the treated and placebo groups (about 40% of the subjects used statins and 80% used aspirin). However, more women in the placebo group began treatment with statins, so that by the end of the follow-up period, the 69% versus 65% difference comparing placebo with treatment was statistically significant. The authors addressed this potential confounder by adjusting for the difference in statin use (as well as other confounders) and concluded that the adjusted analyses were essentially identical to the original analyses. However, no mention is made of the fact that the percentage use of statin use is impressively high. What if any beneficial effect of estrogen is lost because of the impact of statin therapy? Indeed, in a primary prevention trial, inhibition of atherosclerosis with estrogen treatment was observed only in women not receiving statins.<sup>1193</sup> The HERS investigators compared CHD events in the hormone group with the placebo group in women not using statins or aspirin and found no difference, but this very important possible explanation for the lack of a beneficial effect of estrogen in HERS cannot be answered by the analysis of the HERS data because statin and aspirin treatments were not randomized and the number of events in women not on statins or aspirin was very small.

Of the 2,763 postmenopausal women in the HERS trial, 2,321 (93%) agreed to be involved in additional follow-up evaluation, HERS II. The original study<sup>1190</sup> lasted 4.1 years, and the average extended follow-up equaled 2.7 years, for a mean total of 6.8 years. At the beginning of the follow-up period, the average age of the participants was 71 (67 at baseline and 74 at closure). The investigators could detect no significant differences in the rates of coronary events or secondary cardiovascular events comparing the treated group with the placebo group. There was no statistical trend for a beneficial effect of hormone therapy with longer duration of treatment. Because of the absence of a difference, the follow-up period, scheduled to last 4 years, was terminated

early.

The additional follow-up period was unblinded; patients and physicians could choose to continue, discontinue, or initiate hormonal or other therapy. Hormone use in the original treated group in HERS declined from 81% after 1 year to 45% during the sixth year (and 11% were using preparations other than the original 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate). During the sixth year, 8% of the placebo group were now receiving hormone therapy. Raloxifene or tamoxifen had even been initiated, 3% in the hormone group and 4% in the placebo group. The investigators recognized this problem conceding that their power to detect an increasing benefit was eroded by the changing treatments; however, their analysis indicated an ability to detect at least an 18% reduction in cardiac risk.

The original HERS report indicated a two- to threefold increase in deep vein thrombosis and pulmonary embolism in the hormone-treated group. In the follow-up period, there was no longer a statistically significant increase in deep vein thrombosis. There was no reduction in pulmonary embolism, but the number of events was too small to provide accurate assessment. The event rates for venous thrombosis were 5.9 per 1,000 women per year of treatment and 2.8 in the placebo group. Overall, there was a 48% increase in risk for biliary tract surgery in the treated group, 6 more cases per 1,000 women per year compared with placebo.

Intention-to-treat analysis compares all individuals in the treated group to all in the placebo group, regardless of individual compliance or completion of the study. Proponents argue that this is the best method of analysis for clinical trials because it reflects the full impact of randomization. Opponents contend that this method is intuitively wrong; how can the long-term benefit of a treatment be assessed if subjects receiving treatment for only a short period of time are included? HERS II performed an “as-treated” analysis, focusing on women with 80% or more compliance, and found relative hazards (like relative risk) similar to those in the intent-to-treat analysis. However, the relative hazard in the as-treated analysis for primary CHD events in HERS II was reduced, although not statistically significant (RH = 0.81; CI = 0.52–1.32). Events were fewer in the as-treated analyses because only 37% of the events qualified. Adjustment for statin use was performed only in the intent-to-treat analysis (“only a trivial effect on the findings”). The HERS clinical trial results that reflect intent-to-treat analyses are compromised by a difficulty in detecting a long-term effect, and the results that reflect the as-treated analysis are compromised by few events because of compliance and drop-out problems. Therefore, unanswered questions remain: whether reported increases in cardiovascular events early after the initiation of hormone therapy reflect a true risk of hormone therapy or the effect of reduced events in the placebo groups because of new-onset treatment with statins and aspirin, or an effect limited to women with significant preexisting coronary artery disease.

## Other Secondary Prevention Trials

The results of a multicenter trial (the Estrogen Replacement and Atherosclerosis [ERA] trial) examined the effect of postmenopausal hormone therapy on the progression of coronary atherosclerosis as assessed by angiography.<sup>1194</sup> A total of 309 women were randomly assigned to receive either unopposed estrogen, 0.625 mg conjugated estrogens per day; a daily combination of estrogen and progestin, 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate; or placebo. Over 3.5 years of treatment, angiography did not detect any differences in disease progression between any of the groups. The women in this study had documented heart disease on entry and were a relatively older group of women (mean age 65.8 years). Half had a previous myocardial infarction. There were no reported increases in cardiac events in any of the three treatment groups.

The ERA trial joins the HERS trial in demonstrating no secondary preventive effect of postmenopausal hormone therapy on older women with significant CHD. However, **in comparing the two trials, there is an important observation. The ERA trial contained an estrogen-only arm, and the absence of a difference between the estrogen-only arm and the estrogen-progestin arm argues against a negative effect due to the daily administration of medroxyprogesterone acetate.**

Another secondary prevention, 3-year trial (Women's Estrogen-progestin Lipid-Lowering Hormone Atherosclerosis Regression Trial, WELL-HART) assessed whether unopposed estradiol or a sequential regimen of estradiol and medroxyprogesterone acetate could slow the progression of atherosclerosis.<sup>1195</sup> The double-blind, placebo-controlled trial involved 226 postmenopausal women with an average age of 63.5 years (range 48–75), who already had at least one demonstrated coronary artery lesion. The results were based on follow-up angiograms in 59 women in the placebo group, 54 in the estradiol group, and 53 in the estradiol-medroxyprogesterone acetate group. A reduction of LDL cholesterol to less than 130 mg/dL was achieved by dietary intervention, but coronary angiography to measure the change from baseline in the percent stenosis failed to demonstrate a difference among the groups receiving placebo; unopposed, daily 1 mg estradiol; or daily 1 mg estradiol and 12 days each month of 5 mg medroxyprogesterone acetate. **There were also no differences in cardiovascular events during treatment. The results indicated that medroxyprogesterone acetate administered in a sequential regimen is not associated with an adverse cardiovascular effect.**

At least three other secondary prevention trials in women with CHD failed to demonstrate a beneficial impact of hormone therapy.<sup>1196,1197,1198</sup> These various trials tested oral conjugated estrogens, oral estradiol valerate, and transdermal estradiol

combined with either medroxyprogesterone acetate or norethindrone. **The results of the secondary prevention trials in older women with established heart disease are uniformly consistent in finding no beneficial effects of hormone therapy, and the data indicate that different estrogens and different progestins behave similarly.**

# The Timing Hypothesis

The timing hypothesis argues that estrogen can reduce the risk of CHD when administered to relatively young postmenopausal women before atherosclerosis has developed to the stage of unstable plaques (plaques with necrosis and inflammation).

The WHI investigators conducted a secondary analysis of the two canceled clinical hormone trial arms.<sup>1189</sup> The results in the estrogen-only arm, in the combined estrogen-progestin arm, and with the participants combined were separated into age groups at randomization (50–59, 60–69, and 70–79) and according to years since menopause (<10, 10–19, and 20 or more). **An increased risk for CHD was present only in the oldest women in the trials. There were no increases for CHD, stroke, or total mortality in women aged 50–59. In fact, only the increase in CHD events in women 20+ years since menopause reached statistical significance. There was no apparent increase in cardiovascular disease risk in treated women close to their menopause. Indeed, a statistically significant reduced risk was present for total mortality in women aged 50–59.**

The data in this 2007 WHI report were not new. A careful reading of the initial adjudicated reports reveals that the risk of CHD was present only in the oldest women in the trials.<sup>1181,1199</sup> In subgroup analyses, the only significant increase in stroke occurred in the estrogen-only arm in women aged 60–69. But as noted previously, when women with prior cardiovascular disease or those older than 60 years were excluded, the risk of stroke in women less than 10 years since their menopause was not significantly increased. In a meta-analysis of RCTs examining CHD outcomes when HT was used in younger versus older women, lower CHD was noted in the younger group.<sup>1200</sup> To further assess the effects of ET on coronary health, CAC was measured in women aged 50–59 years by computed tomography (CT). Calcium atheromas are indicative of the chronic inflammatory process associated with atherosclerosis and are the best known predictors of clinical heart disease. As such, calcium atheroma scores were used to assess cardiovascular disease. Women in the ET group had a statistically significant lower calcium atheroma score than those in the placebo group ( $p = 0.02$ ). Moreover, in participants with greater than 80% adherence (to ET or placebo), there was a 61% lower risk of severe coronary calcium in the ET group ( $p = 0.002$ ).<sup>1200</sup>

Will postmenopausal hormone therapy begun at or near the time of the menopause, and maintained for a relatively long duration of time, provide protection against coronary artery disease (primary prevention)? The design of the canceled arms of the WHI did not allow an answer to this question. As previously noted, women with significant menopausal symptoms were excluded from the study to avoid an exceedingly high drop-out rate in the placebo group. The WHI addressed this problem by pointing

out that the ratios of cardiovascular events in the treated and placebo arms were the same when assessed by decades of age, 50s, 60s, and 70s. However, this was not the critical analysis. By excluding women with menopausal symptoms, it is very likely that a small number of the participants were close to their age of menopause. Only 574 in both the treated and placebo groups were age 50–54 in the estrogen-progestin arm, and it is likely that even some of these women were relatively distant from their menopause. Even with the appropriate analysis according to years from menopause, the results are limited by very small numbers of women in their early postmenopausal years. Furthermore, the high drop-out rates in these clinical trials erode the statistical power for assessing year-by-year new statin or aspirin treatment.

There is a small primary prevention trial of 199 healthy postmenopausal women randomized to a daily dose of 1 mg estradiol or placebo and followed for 2 years measuring with ultrasonography the change in carotid artery intimal-medial thickness.<sup>1193</sup> The women receiving estradiol had a small decrease in intimal-medial thickness in contrast to a marked increase in the placebo group. Interestingly, in those participants taking lipid-lowering medications, there was no difference comparing estrogen treatment with placebo (both groups had a small decrease in thickness), indicating that lipid-lowering drugs and estrogen had similar beneficial effects on atherosclerosis that were not additive. There have been two other similar ultrasonography studies. A 2-year Dutch study did not achieve a significant difference comparing treatment with placebo, but the results were handicapped by a very high drop-out rate and problems with follow-up.<sup>1201</sup> A German study that found no effect of hormone therapy enrolled women who already had increased intimal-medial thickness, and the duration of the study was only 1 year.<sup>1202</sup>

A meta-analysis of 23 randomized hormone therapy trials concluded that treatment reduced the risk of CHD events by 32% in younger women compared with older women (10 or more years since menopause or >60 years of age).<sup>469</sup> This is a conclusion that is less firm than at first apparent, because most of these trials were not designed to measure an endpoint of cardiovascular disease. However, another meta-analysis by the same authors concluded that hormone therapy reduced overall mortality in women with an average age of less than 60.<sup>470</sup> There is a growing story that adequate estrogen exposure prior to the onset of clinical events provides protection against cardiovascular disease.

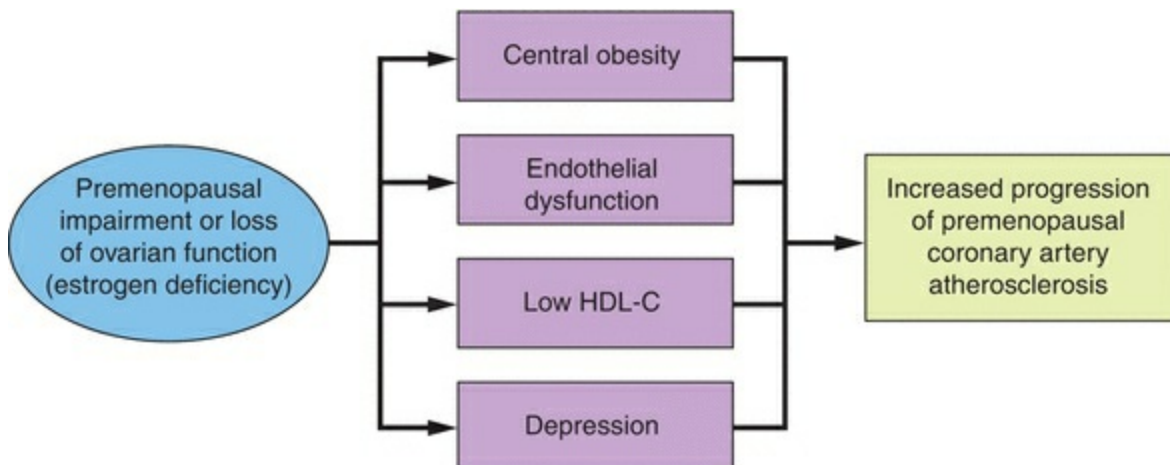

The timing hypothesis originated in the hormone trials conducted in monkeys by the Wake-Forest group headed by Tom Clarkson and provides some of the initial support of the timing hypothesis.<sup>468</sup>

## Key Points: Timing Hypothesis

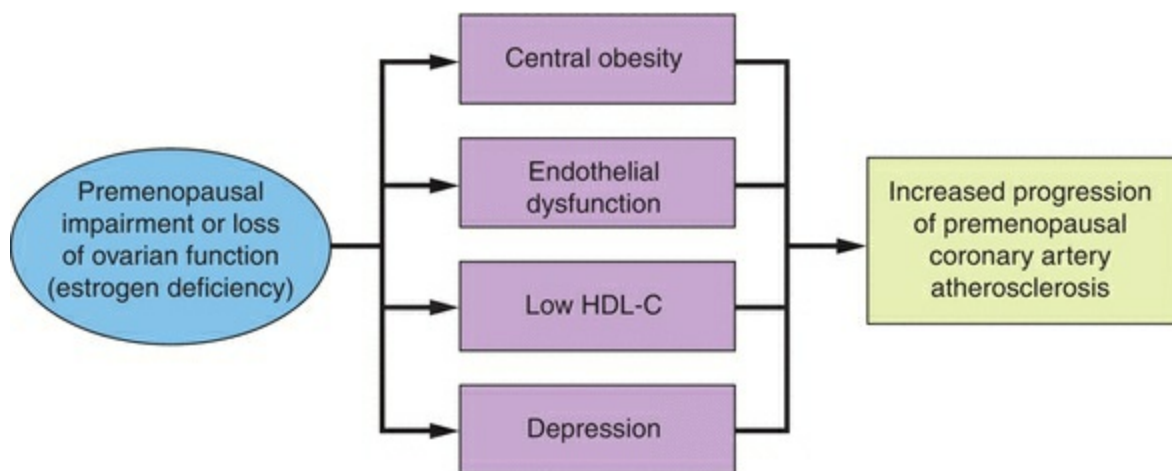

- Estrogen treatment initiated immediately after menopause in monkeys inhibited progression of coronary artery atherosclerosis by about 70%. When treatment was delayed by 2 years (equivalent to about 6 years in women), there was no effect.<sup>468</sup>
- Next in line, according to strength of evidence in our view, would be the WHI reports of reduced coronary artery calcium in estrogen-treated women and an increase in cardiac events only in the oldest women in the trials.<sup>1141,1189</sup> The problem of low event rates in younger women in the WHI was addressed by lumping together, in one hazard ratio, myocardial infarction, coronary death, coronary revascularization, and confirmed angina—the risk in women aged 50–59 years for all of these events was significantly reduced (HR = 0.66; CI = 0.45–0.96).<sup>1199</sup> In addition, the WHI measured coronary artery calcium in a substudy of the estrogen-only arm and found that women with bilateral oophorectomies who were not treated with estrogen had an increase in subclinical coronary heart disease.<sup>1203</sup>
- Every woman has a trajectory of atherosclerosis development, the slope of which determines the age of onset for clinical events. Premenopausal women with lower estrogen levels have higher cardiovascular risk factors and develop more and earlier coronary heart disease.<sup>1204</sup>
- The importance of premenopausal estrogen is also supported by Clarkson's monkey studies. Premenopausal monkeys with normal ovarian function have less progression of coronary artery atherosclerosis as compared with monkeys with impaired ovarian function.<sup>468</sup>
- The Mayo Clinic Cohort Study of Oophorectomy and Aging included 1,274 premenopausal women with unilateral oophorectomy (followed for a median of 29.5 years) and 1,091 premenopausal women with bilateral oophorectomy (followed for a median of 25 years) who had surgery from 1950 to 1987, compared with 2,383 matched women from the same population of women who had not undergone oophorectomy.<sup>1205</sup> Women with bilateral oophorectomy before age 45 had about a fivefold increase in risk of mortality for neurologic or mental diseases and experienced almost a twofold increase in mortality from cardiovascular disease, increased risks of parkinsonism, cognitive impairment and dementia, and an increase in depressive and anxiety symptoms later in life (**Figures 17.16**).<sup>1206,1207,1208,1209</sup>
- The Nurses' Health Study compared, after 24 years of follow-up, ovarian conservation (13,035 women) and bilateral oophorectomy (16,345 women) at the

time of premenopausal hysterectomy.<sup>1210</sup> An all-cause increase in mortality, coronary heart disease, and stroke was observed in those women who never used estrogen after surgery; this amounted to one additional death for every nine surgeries.

- The results in observational studies strongly indicate that hormone treatment of young postmenopausal women reduces the risk of coronary heart disease. In the Nurses' Health Study, the reduction was approximately 50%.<sup>1137</sup> The women in the Nurses' Health Study who were under age 60 when hormone treatment was initiated had a significant reduction in coronary heart disease risk compared with no effect in women over age 60.<sup>1211</sup> A similar reduction was present in the observational arm of the WHI.<sup>1212</sup> In fact, after adjustment for confounding influences in the WHI observational arm such as behavioral, dietary, physical activity, and cardiovascular risk factors, the relative risks for cardiovascular events were 30–38% lower than in the clinical trials. These data were derived from populations of women usually treated with postmenopausal hormone therapy, women close to their natural age of menopause.
- In a primary prevention trial using ultrasound measurement of carotid artery intima-media thickness, estradiol-treated women had slower progression of atherosclerosis.<sup>1193</sup> These same investigators demonstrated no effect of estrogen treatment in older women who had angiographic evidence of coronary atherosclerosis.<sup>1195</sup>

**FIGURE 17.16**

## **Primary Prevention Randomized Clinical Trials Addressing the Timing Hypothesis**

**Kronos Early Estrogen Prevention Study (KEEPS)** was a randomized, double-blind placebo-controlled trial aimed at assessing the effects of early initiation of oral or transdermal HT on progression rates of subclinical atherosclerosis.<sup>1213</sup> Women were eligible for enrollment if they were healthy, aged 42–58 years, between 6 and 36 months from their last menstrual period with no prior CVD events, a CAC score less than 50 Agatston units, and without exogenous estrogen exposure or lipid-lowering therapy for the past 90 days. Women were randomized to receive oral (o) CEE 0.45 mg/day, or transdermal (t) E2 50 µg/day, each with 200 mg oral progesterone for 12 days per month, or placebo for 48 months. The primary endpoint was annual change in carotid artery intima-media thickness (CIMT) by ultrasonography, with secondary endpoints of changes in markers of CVD risk, including CAC scores (determined by computed tomography scan of the chest).<sup>1213</sup> Of the 727 randomized women, 89.3% had at least one follow-up CIMT, while 79.8% had a CIMT annually. The KEEPS trial found that the mean CIMT increase of 0.007 mm/year was similar among all three groups. Similarly, the percentage of subjects in whom CAC scores increased was not different. LDL and HDL levels improved, levels of CRP and SHBG increased with o-CEE, but IL-6 did not. Insulin resistance decreased with t-E2; there were no changes in blood pressure with either o-CEE or t-E2 use.<sup>1213</sup> Thus, the KEEPS trial did not demonstrate a significant difference in CIMT (a measure of preclinical progression of atherosclerosis) among oral, transdermal, or placebo groups. In a follow-up of a subgroup of subjects (representative of the placebo, o-CEE, and t-E2 groups) 3 years after stopping HT from the KEEPS trial, the effects of cessation of HT on CIMT were analyzed.<sup>1214</sup> There did not appear to be a “rebound” effect on CIMT progression upon discontinuation of o-

CEE or t-E2.<sup>1214</sup> Regardless of HT regimen, there was an overall increase in CIMT over time, which may be inherent to the aging process.<sup>1214</sup>

**Early versus Late Intervention Trial with Estradiol (ELITE)** also assessed the effect of early administration of HT on the development/progression of atherosclerosis.<sup>1215</sup> Six hundred and forty-three healthy postmenopausal women are stratified by years since menopause (early equal to <6 years or late [>10 years]) and randomly assigned to oral E2 1 mg/day plus vaginal progesterone 45 mg for 10 days/month for women with a uterus or placebo (including sequential vaginal gel for subjects with a uterus). The primary outcome was the rate of change in CIMT (measured every 6 months). Secondary outcomes included assessment of coronary artery atherosclerosis by cardiac CT scan (performed at completion of study medication). Following 5 years, it was found that oral E2 with/without vaginal progesterone resulted in a significantly slower increase in CIMT in the early postmenopause group, compared to placebo.<sup>1215</sup> In women who were greater than 10 years past menopause, CIMT progression rates were not different from placebo. Measures of CAC by CT, total stenosis, and plaque burden did not differ between placebo groups and the estradiol groups for early or late menopause status.<sup>1215</sup> Thus, unlike KEEPS, results of the ELITE trial support the timing hypothesis in that early initiation (i.e., closer to the timing of menopause) of HT was associated with more favorable cardiovascular outcomes. The differences between ELITE and KEEPS may, among many possibilities, relate to inherent differences in the studied populations or reflect differences in the choice and dose of estrogen formulations utilized.<sup>1216,1217</sup>

## Key Points: Hormones and CHD

- **The message from multiple secondary prevention trials is clear: exogenous estrogen should be avoided in postmenopausal women with existing CHD, and there are no grounds for an expectation that such treatment will reduce subsequent cardiac events.**
- **Evidence from primary prevention clinical trials, while less clear, suggests that early initiation of estrogen may confer cardioprotective effects (as evident in the ELITE trial); however, additional studies are needed to establish consistency of such a benefit across populations and to clarify if such benefit may depend on the type and dose of estrogen formulation given the discrepant findings between ELITE and KEEPS trials. Until clarity is attained, cardioprotection alone should not be used as an indication for prescribing hormone therapy.**

- **A reasonable goal is to maintain a healthy level of estrogen during the premenopausal years and in the early postmenopausal period.**
- **Experimental evidence in the monkey indicates that the beneficial effects of hormonal treatment are progressively diminished with increasing atherosclerosis.**<sup>1216</sup>
- **In postmenopausal women, the vasodilatory effects of estrogen dissipate with increasing age.**<sup>1217</sup>

# VENOUS THROMBOSIS

---

Results from multiple studies indicate that postmenopausal hormone therapy increases the risk of VTE about twofold, mostly in the first year or two of treatment, a conclusion supported by the results from the canceled estrogen-progestin arm of the WHI.<sup>1178,1218</sup> The absolute risk in the WHI estrogen-progestin arm was 18 additional cases per 10,000 women per year. In the estrogen-only arm of the WHI, a smaller increase in deep vein thrombosis was observed, and an increase in pulmonary embolism was not statistically significant.<sup>1179,1219</sup> There are some notable observations in the WHI data on venous thrombosis. Most of the cases occurred in the first 2 years of exposure, and the risk was greatest in the women over age 70 and in overweight women. The risk was higher in women who were susceptible to venous thrombosis, specifically those with the Leiden mutation. This raises a very important question: is it possible that the risk of venous thrombosis is very low in younger, normal postmenopausal women?

**It should be emphasized that the risk of VTE appears to apply only to new hormone starters; women who have been on hormone therapy can be reassured that the evidence indicates that the increased risk of venous thrombosis is concentrated in the first 1–2 years of treatment.<sup>1076</sup> The actual risk is very low because of the low frequency of this event. If the relative risk is increased twofold, this would increase the incidence of VTE by about 2 cases per 10,000 women per year of hormone use. Furthermore, venous thrombosis carries with it a very low risk of mortality, around 1%, and most of the fatal cases have followed venous thrombosis associated with trauma, surgery, or a major illness.<sup>1220</sup>**

VTE is a risk that is reduced with the use of statins and low-dose aspirin,<sup>1221,1222</sup> although it is not known whether statin and aspirin use would completely protect against the increased risk associated with postmenopausal use of hormone therapy.

Accruing data are reassuring in regarding lesser VTE risk with transdermal route of estrogen compared to oral use, a benefit that is attributed to avoidance of the first-pass hepatic effect with nonoral route. For example, oral administration of estrogen compared with transdermal administration in male-to-female transsexuals is associated with a greater prothrombotic state and risk of venous thrombosis; however, this effect could be at least partly attributed to major differences in the estrogen doses.<sup>1223</sup> It would be better to have evidence uninfluenced by dosage, and for this purpose, we can consider responses of APC resistance, recognized as a marker for venous thrombosis risk. In one randomized trial, oral estrogen treatment increased APC resistance, but transdermal estrogen was no different than placebo.<sup>511</sup> Another randomized trial found that both routes of administration increased APC resistance; however, the increase with

oral estrogen was about 4 times greater compared with transdermal estrogen.<sup>510</sup> A French case-control study concluded that there was a fourfold increase in VTE with current use of oral estrogen but no increase in risk with transdermal estrogen.<sup>512</sup> In addition, this study reported that oral estrogen treatment adds to the risk of VTE associated with obesity, but transdermal estrogen does not.<sup>1224</sup> The French study also reported (although limited by small numbers) that transdermal treatment, in contrast to oral estrogen, does not further increase the risk of VTE associated with known prothrombotic conditions such as factor Leiden or prothrombin mutations.<sup>513</sup>

However, there are some problems with the French case-control study. There are wide confidence intervals for the significant odds ratio associated with oral estrogen treatment. Usually, this reflects small numbers, but the number of cases and controls in this study should allow greater precision. It is possible that this imprecise conclusion is influenced by the fact that the cases and controls differed significantly in several characteristics that influence the risk of VTE, specifically greater body weight and a positive family history of VTE. We know that a twofold increased risk of VTE is uniformly reported, including the data from the WHI.<sup>1218,1219</sup> It is very likely that the French estimate is higher compared with the usual twofold increased risk because of confounding differences between their cases and controls. **It is worth noting again that in the WHI, the cases of venous thrombosis were concentrated in the first years of exposure, in the oldest and in the heaviest women in the study.**

The French case-control study found no increase in VTE risk associated with estrogen combined with progesterone or pregnane derivatives and an increase with norpregnane derivatives. The pregnane group includes synthetic progestins familiar to use such as medroxyprogesterone acetate, chlormadinone, and cyproterone. The norpregnanes (progesterone without the 19-carbon) included two progestins, nomegestrol acetate and promegestone, that are not used in the United States (nomegestrol acetate is the progestin in Uniplant, a single-rod implant contraceptive, and combined with estradiol in an oral contraceptive). But can we make the conclusion that the norpregnanes are thrombogenic? The confidence interval in the norpregnane group was very wide, again apparently not due to small numbers, but this makes this conclusion shaky and suspect. Similar results were reported from the E3N French prospective cohort study, with an increased risk of VTE of 1.7 (CI = 1.1–2.8) associated with current users of oral therapy (a hazard ratio more in keeping with the usual twofold increase reported in the literature) and no increase with transdermal estrogen.<sup>515</sup> Again, an increase was observed with norpregnane progestins, this time with tighter confidence intervals. In contrast, several other studies have demonstrated an increased VTE risk in women using medroxyprogesterone.<sup>1225</sup>

In the French studies, oral hormone users used almost exclusively estradiol in doses

that averaged 1.5 mg/day. Transdermal users most commonly used an estradiol dose of 50 µg or less daily. To legitimately compare oral and transdermal methods, one would have to be sure the two groups had similar blood levels, to account for the wide variation in metabolism and clearance among individuals. It is possible that the difference between the oral and transdermal groups represents differences in estrogen doses. Nevertheless, the French conclusions are supported by a very large case-control study (23,505 cases of VTE) using the U.K. General Practice Research Database.<sup>742</sup> The use of transdermal estrogen alone or combined with a progestin was not associated with an increase in VTE, compared with about a 1.5-fold increase with oral estrogen alone and oral estrogen-progestin.

A greater safety with transdermal administration of estrogen with regard to VTE makes some sense because of the known lesser impact on clotting proteins when the first-pass liver effect is avoided. This is supported by transdermal estrogen's almost negligible effect on APC resistance when compared with oral therapy.<sup>510,1226</sup> A randomized trial assessing the risk of recurrent VTE in women with a prior history of thrombosis being treated with an oral hormone regimen was canceled after 1 year when eight women in the treated group developed recurrent venous thrombosis compared with only one in the placebo group.<sup>1227</sup> The eight women were studied retrospectively, and six of the eight had an inherited susceptibility to venous thrombosis. The numbers were not large, but the results are a strong argument for the recommendations detailed in [Chapter 22](#). There is no argument that inherited abnormalities in the clotting scheme increase the risk for VTE. The evidence is mixed for arterial thrombosis, but most of the evidence fails to find an association between specific inherited defects (thrombophilia) and arterial thrombosis, although this is still unsettled.<sup>1228,1229,1230,1231</sup>

If a patient has a close family history (parent or sibling) or a previous episode of idiopathic thromboembolism, an evaluation to search for an underlying abnormality in the coagulation system is warranted before exposing the patient to exogenous hormone therapy. The following measurements are recommended, and abnormal results require consultation with a hematologist regarding prognosis and consideration for prophylactic treatment with an anticoagulant. The list of laboratory tests is long, and, because this is a dynamic and changing field, the best advice is to consult with a hematologist ([Table 17.14](#)). When a diagnosis of a hereditary thrombotic tendency is made, screening should be offered to other family members.

## **TABLE 17.14**

## Hypercoagulable Conditions

Anticardiolipin antibodies

Lupus anticoagulant

Beta2 glycoprotein antibodies

Hyperhomocysteinemia

Homocysteine level

Malignancy

Complete blood count (leukemias, lymphoma)

Fibrinogen

Other risk factors for thromboembolism that should be considered by clinicians include an acquired predisposition, such as the presence of lupus anticoagulant or malignancy, and obesity, immobility, or trauma. Varicose veins are not a risk factor unless they are very extensive, and, unlike arterial thrombosis, smoking either has no effect or at best is

a weak risk factor for VTE. Raloxifene (and tamoxifen) shares with estrogen an increased risk for VTE.<sup>655</sup> The size of the risk is comparable for all three drugs, about a twofold increase.

## Key Points: Hormone Therapy and VTE

- **Observational studies support the clinical choice of a transdermal method for women who are at higher risk for VTE and for whom menopausal HT is being considered due to failure of symptom benefit from nonhormonal strategies.**
- **Although existing data are overall reassuring regarding safety of progestin regimens commonly used in menopause hormone regimens, an absence of good data does not allow making any statements with confidence regarding an absence of thrombogenic risk for the various progestins. However, it may be prudent to consider transdermal E2 with micronized progesterone (in women with a uterus) in those deemed at risk for VTE until RCTs confirm/refute the safety of alternative progestogens.<sup>1225</sup> The clinician and patient can together consider a combination of hormone therapy (preferably transdermal administration) and chronic anticoagulation, in consultation with a hematologist.**
- **We recommend appropriate prophylactic anticoagulant treatment in hormone users anticipating immobility with hospitalization, especially if other risk factors (most notably, obesity) are present. Some patients may elect to discontinue hormone treatment 4 weeks prior to major surgery if extended immobility is to be expected, but this is an empiric, individual decision. Hormone therapy can be resumed when the patient is ambulatory.**

# BREAST CANCER AND POSTMENOPAUSAL HORMONE THERAPY

---

Women and clinicians are regularly reminded about the threat of breast cancer, in the media, by advertisements, and by the experience of a friend or family member fighting this disease. Breast cancer is a major focus in the health concerns and care for postmenopausal women because it has an increasing frequency with age. About 95% of all breast cancers and 97% of breast cancer deaths in the United States occur in women over age 40.<sup>1232</sup> Thus, there are good reasons why this medical condition is a prominent factor in clinical decision-making regarding postmenopausal hormone therapy.

The long-term use of postmenopausal hormone therapy has been challenged by data that have been interpreted to indicate that the risk of breast cancer is increased in hormone users. The debate and publicity over this issue have made decision-making very difficult for both patients and clinicians. **The most important unanswered question is whether postmenopausal hormone therapy initiates the growth of new breast cancers or whether the epidemiologic results reflect an impact on pre-existing tumors.**

## Biologic Plausibility

The most compelling reason to believe that long-term use of postmenopausal estrogen increases the risk of breast cancer is the inherent biologic plausibility. Factors known to increase a woman's exposure to estrogen are known to increase the risk of breast cancer; for example, there is a small decrease in risk with late menarche and a moderate increase in risk with late natural menopause.<sup>1233</sup> In premenopausal women who are overweight, the risk of breast cancer is lower compared with normal-weight individuals, and in postmenopausal women, excess weight is associated with either an unchanged or slightly increased risk.<sup>1234,1235,1236</sup> This is attributed to an increase in total and free estrogen levels in overweight postmenopausal women, in contrast to lower levels with increasing weight in premenopausal women. Postmenopausal obese women have later menopause, higher estrone production rates and higher free estradiol levels (lower SHBG), and a slightly greater risk for breast cancer.<sup>1237</sup> Greater bone density, believed to be a marker for estrogen exposure, is also associated with an increased risk of breast cancer.<sup>1238,1239,1240</sup>

Studies seeking a correlation between circulating levels of sex hormones and breast cancer have yielded conflicting results. In the Rancho Bernardo cohort, no relationship between estrogen, androgen, and SHBG levels and the incidence of breast cancer could be demonstrated.<sup>1241</sup> Using serum collected earlier in life, no differences in endogenous hormones could be detected in 51 women who subsequently developed breast cancer, including the various estrogens, progesterone, androstenedione, and even SHBG.<sup>1242</sup> On the other hand, in a very large prospective study in Italy, estradiol, testosterone, and SHBG levels were higher in postmenopausal women who subsequently developed breast cancer.<sup>1243</sup> In a British report, women who subsequently developed breast cancer had higher levels of estradiol.<sup>1244</sup> Two North American prospective studies also found higher levels of estrogen in women who subsequently developed breast cancer, and most impressively, an increasing risk of breast cancer correlated with increasing levels of free estradiol.<sup>1245,1246</sup> In another study, women who developed breast cancer displayed higher levels of nonbound, free estradiol and lower levels of SHBG.<sup>1247</sup> In the Nurses' Health Study, an association was reported between an increased risk of breast cancer and higher levels of estradiol, estrone, and DHEA-S, whereas no association could be demonstrated with the percent free or bioavailable levels of estradiol, androstenedione, testosterone, or DHEA.<sup>1248</sup> **The discrepancies among the various studies seeking a correlation between hormone blood levels and the risk of breast cancer reflect the fact that the differences are very small, and it is a struggle to achieve statistical significance.**

Overall, the biologic plausibility for an estrogen link with breast cancer is an

impressive argument. This argument is further strengthened by the proven benefit of reducing the incidence of breast cancer with the antiestrogen, tamoxifen. However, as we shall see, establishing a clinically real cause-and-effect relationship with epidemiologic data requires more than the rationale of biologic plausibility.

## Key Points: Postmenopausal Breast Cancer Risk

- **The risk of breast cancer is increased with increasing duration of lifelong exposure to estrogen.**
- **Postmenopausal women who are overweight have a slightly increased risk of breast cancer.**

# Results from Observational Studies

In the past decade, a large number of case-control and cohort studies indicated a slightly increased risk of breast cancer with postmenopausal hormone therapy. Overall, most of these studies indicated a greater risk associated with estrogen-progestin compared with unopposed estrogen treatment.<sup>1249,1250,1251,1252,1253,1254,1255,1256,1257,1258,1259,1260,1261,1262,1263,1264,1265</sup>

## A Reanalysis of the World's Literature

Prior to the publications from the WHI, the 1997 report of a reanalysis of the world's literature was the most referenced article on this subject. A team of epidemiologists invited all investigators who had previously studied the association of postmenopausal hormone use and the risk of breast cancer (51 studies) to submit their original data for a collaborative combined reanalysis, an undertaking more rigorous than a standard meta-analysis. This analysis reached the following conclusions<sup>1266</sup>:

- Ever users of postmenopausal hormones had an overall increased relative risk of breast cancer of 1.14.
- Current users for 5 or more years had a relative risk of 1.35 (CI = 1.21–1.49), and the risk increased with increasing duration of use.
- Current and recent users had evidence of having only localized disease (no metastatic disease) and ever users had less metastatic disease.
- There was no effect of a family history of breast cancer.

This was the first important indication that women with a positive family history of breast cancer do not have a further increase in risk with hormone therapy, a finding also reported in the WHI.<sup>1267</sup> There were two other notable conclusions: all of the increase in risk was localized disease, and women who used hormone therapy and developed breast cancer had better survival rates than nonusers; these observations have been repeatedly confirmed.

## The Million Women Study

The Million Women Study recruited 1,084,110 women between 1996 and 2001 from those invited by the U.K. National Health Service Breast Screening Programme to have screening mammography every 3 years (about half had ever used postmenopausal hormone therapy).<sup>1260</sup> The study data were recorded from questionnaires returned prior to the initial mammography, and the women were followed to determine cancer incidence and death. The study is noteworthy for its large numbers and adjustments for

the well-recognized factors associated with risk of breast cancer. No increase in risk of breast cancer was measured in past users of any hormone preparation, regardless of length of time since discontinuation, from less than 5 years to 10 or more years (with the exception of discontinuation in the year previous to diagnosis), and regardless of duration of use. Based on an average follow-up of 2.6 years (a very short exposure; indeed, the breast cancers were diagnosed on an average of 1.2 years after the study began), the relative risk for invasive breast cancer in current users of estrogen only was 1.30 (CI = 1.22–1.38) and, for current users of estrogen-progestin, 2.00 (CI = 1.91–2.09).

There are many criticisms of the Million Women Study. For example, the study reported a lower risk of breast cancer for perimenopausal and postmenopausal women compared with premenopausal women despite the well-established fact that breast cancer risk increases with aging. There were many differences comparing users and nonusers, requiring multiple adjustments. Hormone use or nonuse was established at entry and not changed during follow-up despite multiple crossovers in treatment among the women. Validation of the questionnaire data was claimed based on information obtained from only 570 women. Breast cancer mortality was assessed after an average of 4.1 years of follow-up, based on a total of 517 deaths; however, breast cancer was diagnosed very rapidly (an average of 1.2 years) and deaths occurred swiftly (within an average of 1.7 years). Current users and past users were compared with the never-users, and, although the risk of mortality was increased, it did not reach statistical significance (1.22; CI = 1.00–1.48). This finding was highlighted because it differed with a consistent story reported in the literature over a decade that hormone users had better survival rates. The Million Women Study calculated their risk of mortality by dividing deaths from breast cancer by the total number of users or nonusers. When the data are recalculated appropriately by dividing deaths from breast cancer by the total number of cases of breast cancer in the user and nonuser groups, the results agree with the literature—the risk of mortality was reduced about 27% in the hormone users.

## **The Danish Nurse Cohort**

The Danish Nurse Cohort of 10,874 women was established in 1993.<sup>1268</sup> The results reflected a variety of hormone products and regimens, and an increased hazard ratio for breast cancer was associated with hormone therapy (HR = 2.42; CI = 1.81–3.26), with a twofold increase in breast cancer mortality. Stated simply, hormone users had a greater mortality rate from breast cancer because they had more breast cancers. Even though the case fatality rate was better (more favorable prognosis), the increased incidence produced a net effect of an increase in mortality.

Danish case-control and cohort studies are noted for their ability to accurately

obtain information from the national registries. Nevertheless, there were important limitations to this study. The most glaring problem was that not all causes of death could be verified and a death in a woman with a diagnosis of breast cancer was assumed to be a breast cancer death. The authors state that this problem would be balanced by similar numbers in the user and nonuser groups, but this is an assumption. In this population of older women, one would expect deaths from other causes to outnumber deaths from breast cancer. This single assumption by the epidemiologists could have skewed the results.

In addition, the case fatality and breast cancer mortality calculations were adjusted only for age. The authors stated that a relatively small number of deaths precluded multiple adjusting. But there are so many factors that influence the risk of breast cancer, including age of menarche, age at menopause, age at first full-term pregnancy, parity and age at diagnosis, use of mammography, presence of benign breast disease (specifically with atypical hyperplasia), body size, and alcohol intake. How can we know that the results did not reflect an imbalance in some of these factors?

## **Hormone Therapy and Lobular Breast Cancer**

A population-based, case-control study adds to the previous reports from this Seattle group of epidemiologists focusing on the relationship between postmenopausal hormone therapy and the histologic subtype of breast cancer.<sup>1269</sup> The main conclusions are an increased risk of tumors of the lobular type or with a lobular component and an increase in the odds ratio that appeared with 3 or more years of use with combined estrogen-progestin therapy. Similar results were reported in Swedish and German case-control studies.<sup>1263,1270</sup>

It is a logical conclusion that the results reflect increasing proportions of hormonally sensitive tissue. Lobular tumors are characteristically estrogen receptor positive and more hormone sensitive. If hormone therapy is affecting pre-existing tumors, one would expect the hormonally sensitive lobular cancers to be detected earlier.

### **Key Points: Hormone Use and Breast Cancer**

- **Case-control and cohort studies have identified an increased risk of breast cancer associated with hormone therapy, greater with combined estrogen-progestin regimens.**
- **The incident cases of breast cancer associated with hormone therapy use are predominantly estrogen receptor–positive tumors, perhaps mostly tumors**

**with lobular tissue.**

- **An increased risk of breast cancer is predominantly observed only in current users and is detected relatively rapidly.**

# The Women's Health Initiative

The impression gained from the observational data concluding that exposure to estrogen-progestin was more harmful was reinforced when clinicians were confronted by the results in the prematurely stopped estrogen and progestin arm of the WHI.<sup>1271</sup> Invasive breast cancer was increased, 199 cases in the treated group and 150 in the placebo group (HR = 1.24; CI = 1.01–1.54). The absolute risk was four to six additional cancers per 10,000 women per year. The WHI performed subgroup analyses focusing on how prior hormone therapy use influenced the risk of breast cancer found in the estrogen-progestin trial arm.<sup>1272</sup> Prior hormone users totaled 4,311 participants (26%), with 42% reporting less than 2 years of use (17% used hormones 5–10 years previously and 26% more than 10 years before enrolling in the WHI study). Prior users had an increased hazard ratio compared to placebo (1.96; CI = 1.17–3.27) in contrast to no increase among never-users (1.02; CI = 0.77–1.36). The WHI concluded that this difference could reflect an increasing risk with cumulative exposure to hormone therapy.

Many of the factors associated with the risk of breast cancer were slightly but significantly more prevalent in the group of prior hormone users in the WHI, such as younger age, more education, lower body mass, more physical activity, smoking, alcohol use, vasomotor symptoms, and lower bone density. The overall risk of breast cancer in the treated estrogen-progestin group was the same as previously reported by the WHI (1.24; CI = 1.02–1.50).<sup>1271</sup> However, after adjusting for the multiple factors recognized to influence the risk of breast cancer, the hazard ratio was 1.20 and no longer statistically significant (CI = 0.94–1.53). The placebo group failed to demonstrate an age-related increase over the duration of the trial, and the treatment group and the placebo group differed in regard to breast cancer risk factors, forcing the investigators to perform multiple adjustments. Why did not the randomization of large numbers avoid this confounding problem? The strength of the WHI conclusion is limited by the fact that the participants in the treatment and placebo groups differed considerably.

The updated results in the second estrogen-only arm of the WHI, which too was prematurely stopped, failed to detect an increase in breast cancer risk associated with estrogen-alone use (RR = 0.80; 95% CI = 0.62–1.04).<sup>1273</sup> Indeed, the decreased risk of breast cancer in the CEE group reached statistical significance in the postintervention phase (HR = 0.77; 95% CI = 0.62–0.95).<sup>1274,1275</sup> In addition, there was a significantly lower mortality risk from breast cancer in the estrogen-treated group compared to placebo (HR = 0.37; 95% CI = 0.13–0.91).<sup>1275</sup> This striking difference between the two canceled arms led many to conclude that the results indicated an adverse effect of progestin exposure or, more bluntly, that there is no increase in risk with up to 5 years of

estrogen-only use in contrast to an increased risk with estrogen-progestin.

It cannot be emphasized too strongly that it is not appropriate to compare the two hormone treatment WHI trials and conclude that differences reflect the effects of progestin exposure. Even the WHI investigators cautioned clinicians to avoid comparing the two trial arms because the participants in the two arms differed considerably.<sup>1180</sup> In regard to breast cancer risk, women in the estrogen-only arm had a higher rate of previous exposure to hormones and longer durations of prior use. It is possible that earlier and greater use of hormone therapy before participation in the study identified those individuals with pre-existing tumors who were then excluded from participation, accounting for the lower incidence of breast cancer in the treated group. **The breast cancer results in the WHI do not allow us to answer the important question whether exposure to estrogen-progestin has a greater risk of breast cancer or whether preexisting tumors respond differently to the various hormone regimens, accounting for differences in epidemiologic reports. This will be addressed in detail later in the chapter.**

# BREAST CANCER RISK AND DURATION OF HORMONE USE

---

A cohort study assessed the risk of breast cancer in postmenopausal Finnish women using oral, transdermal, and vaginal estrogen-only or estrogen-progestin products containing either estradiol or estriol.<sup>1276,1277</sup> The use of estradiol for 5 or more years and the use of estrogen-progestin for 3 or more years were associated with a statistically significant increased risk. The risk was similar comparing oral and transdermal therapy. An increase was observed in both localized and metastatic diseases. A statistically significant increase was noted with carcinoma in situ.

Only 7% of Finnish postmenopausal women use hormone therapy for more than 5 years. This study reported an increase in breast cancer risk in this long-term user group of women. No increase in breast cancer risk was detected either in association with estriol given orally or with vaginal estrogen products; however, it is inappropriate to conclude that these formulations can be used without risk. To make this conclusion, users and nonusers of these formulations would have to be identical in terms of breast cancer risk factors and to be comparable in terms of bioequivalent blood levels of estrogen. Only then could a valid comparison be made. This study could not adjust for these factors.

The use of postmenopausal hormone therapy in Finland can be accurately recorded because all treatments must be prescribed and then paid for by the National Social Insurance Institution. However, the study is affected by an overwhelming problem: the results are questionable because of an inability to control for confounders. The risk was expressed as incidence ratios, calculated by dividing the observed number of cases by the numbers expected (based on the general statistics in Finland). Therefore, the study could not be controlled for confounders. Risk ratios less than 2.0 can easily be inaccurate because they can reflect confounding factors. It is well-demonstrated that hormone users differ when compared to nonusers in terms of recognized risk factors for breast cancer. The differences also include a greater prevalence of mammography among hormone users. A good example can be found in the report from the Nurses' Health Study that, like the cohort from Finland, indicated an increased risk of breast cancer with long-term users of estrogen only.<sup>1278</sup> The long-term users in the Nurses' Health Study had more bilateral salpingo-oophorectomies, more nulliparity, more benign breast disease, and greater alcohol consumption, and they were thinner—all factors that make a comparison of users to nonusers very difficult.

In order to minimize the problem of confounders, the Finnish report argued that “there are no socioeconomic differences between postmenopausal hormone therapy users and the general population in Finland,” citing a previous report. This statement is

not totally accurate. The previous report in 1999 was based on population surveys and measured only two things: length of education and rural versus urban living.<sup>1279</sup> A lack of educational differences was present in Finnish women under the age of 55, but older postmenopausal women had more years of education. In addition, there were regional differences at all ages, with the current use of hormone therapy being most common in the Helsinki area (especially among older women). Therefore, the 1999 study does not imply a lack of differences in hormone users in Finland, in fact, just the opposite. Age information is not provided in the reports on breast cancer, but the longer-term hormone users were probably an older group of women, and according to the 1999 Finnish report, they do differ when compared to the general population of Finland. Remember, this cohort study is not comparing users with nonusers. It compares users to general population statistics. Therefore, we cannot know whether the results of this study reflect long-term use of estrogen or whether the results reflect a greater prevalence of risk factors and mammography in the hormone-using group (see [Table 17.13](#)).

# Hormone Therapy and Breast Cancer Outcome

Long-term use of HT increases the risk of breast cancer, yet cause-and-effect mechanisms are unclear. In the WHI trials, estrogen plus progestin use showed increased risk, while use of estrogen alone did not result in added risk for breast cancer. This disparity in results of the two WHI hormone trials raised concerns that progestin may be the culprit in causing breast cancer in hormone-using menopausal women. Most of the studies that have examined breast cancer mortality rates of women who had used postmenopausal hormone therapy at the time of diagnosis have documented improved survival rates.<sup>1132,1143,1151,1280,1281,1282,1283,1284,1285,1286,1287,1288,1289</sup> Even a study that indicated a reduction in mammographic sensitivity also reported smaller, more differentiated tumors among the users compared with the nonusers.<sup>773</sup> Evidence indicates that hormone users develop smaller, better-differentiated (lower grade), and lower-stage tumors, evidence that is consistent with effects on preexisting tumors and that surveillance/detection bias is not the only explanation for better survival.<sup>1259,1288,1289,1290,1291,1292,1293,1294,1295,1296,1297,1298,1299,1300,1301,1302,1303,1304,1305,1306</sup>

Lower-grade tumors are present even when there is no difference in the prevalence of mammography comparing hormone users and nonusers or when the data are adjusted for the method of detection.<sup>1284,1286,1297,1307</sup> This is not a totally uniform story, in that at least one prospective study concluded that estrogen-progestin users had both lower and higher stage and grade tumors.<sup>1259</sup> However, nearly all reports indicate that more tumors in hormone users are detected by screening mammography, and when assessing outcomes in all cancers detected by mammography, hormone users have more ductal in situ tumors, more node-negative cancers, smaller tumors, and less invasive disease and, thus, better survival rates.<sup>1289,1302</sup>

In contrast, the WHI results in the estrogen-progestin arm indicated an earlier appearance of invasive, lymph node-positive tumors than previously reported in case-control and cohort studies. The WHI argued that the results (both the invasive breast cancers and the mammography findings) are consistent with stimulation of growth of established breast cancers (supported by no statistical difference in in situ tumors in the WHI trial) but at the same time a delay in diagnosis. This certainly challenges the idea that hormone users have better outcomes because of earlier detection. The WHI suggested that this disagreement could be because of a difference of mammography use in the observational studies. However, as pointed out, even studies that examine tumor characteristics and outcome in users and nonusers who have equally used mammography, lower-grade and lower-stage disease with a better outcome is identified in the users.<sup>1284,1286,1302</sup> In addition, a prospective cohort study found little impact of hormone use on mammography specificity.<sup>1308</sup>

Differing with many reports in the literature, the WHI concluded that their results suggested that invasive breast cancers diagnosed in women who use hormone therapy may have a worse prognosis, basing this conclusion on the differences observed in tumor size and spread of disease. As previously discussed, it is well-recognized that the participants in the WHI represent an older postmenopausal population (average age 63 and an average of about 12 years since menopause in the estrogen-progestin arm). This older population is more likely to have preexisting occult tumors that would become detectable quickly after hormonal stimulation. In addition, breast tissue in older postmenopausal women may respond differently to hormone stimulation than breast tissue in women close to their menopause. It is possible that the WHI results reflect this older population that might have occult tumors that are in fact larger and more prone to respond to hormonal stimulation than tumors in younger women.

There is another problem with the WHI data on tumor size and stage of disease. The WHI reported that estrogen-progestin users had slightly larger tumors (an average of 2 mm) and less localized disease. However, there are reasons, both apparent and not apparent, why the WHI data disagree with the great bulk of the literature. First, no nodes were examined in nearly 10% of the subjects who developed breast cancer; information was missing on node involvement in 4.0% of the treated group and 4.7% of the placebo group and on tumor size in 6.5% of the treated group and 6.0% of the placebo group. Because case numbers were not large, a change in a few cases could change the conclusions. Next, the WHI investigators assumed that tumors less than 1 cm in size with no node information should be classified as localized disease, and those greater than 1 cm in size were not staged. According to the U.S. SEER data, breast tumors 1 cm in diameter have a 20% incidence of positive nodes.<sup>1309</sup> Finally, there is a major problem that is hard to explain. The WHI conclusion of less localized disease in hormone users is based on, once again, a difference in the placebo group, a surprisingly low incidence of positive nodes. There is a linear relationship between tumor diameter and the percent of cases with positive nodes.<sup>1309</sup> The average tumor size in the placebo group was 1.5 cm, and according to U.S. data, this should give about a 25% incidence of positive nodes, not the 15.8% that was reported.<sup>1309,1310,1311,1312</sup> Why is the placebo group different? Whatever the reason, it influences the conclusion.

The WHI investigators reported health outcomes at 3 years after the estrogen-progestin arm of the clinical trial was terminated.<sup>1313</sup> This follow-up report included 15,730 participants who were followed from July 2002 to April 2005 (95% of randomized women). No increase in cardiovascular events, including venous thrombosis, in the women treated with estrogen-progestin was observed in the follow-up period. There were 79 cases of invasive breast cancer in the treated group in the follow-up period compared with 60 in the placebo group, a difference that gave a hazard ratio of 1.27, but it was not statistically significant. There was no difference in

cases of colorectal cancer or fractures and a nonsignificant decrease in endometrial cancer in the treated group. There was a greater rate of mortality in the treatment group in the follow-up period, but this difference was small and not statistically significant.

A strong case can be made that the epidemiologic data on breast cancer reflect an impact of hormone therapy on pre-existing tumors. This WHI follow-up report concluded that the trend of increasing breast cancer during the trial period did not extend into the follow-up period. This is the pattern one would expect if hormone therapy is causing earlier detection of pre-existing tumors only in current users. An adverse interpretation of the WHI follow-up report was based on a small and nonsignificant increase in mortality in the treated group, because of deaths from various cancers, but most prominently lung cancers (discussed later under the heading “Lung Cancer”).

## Key Points: Breast Cancer in Hormone Users

- **Lower grade and stage of disease account for the better survival rates in hormone users who develop breast cancer compared with nonusers.**
- **Hormone users who develop breast cancer usually have earlier detection of their tumors.**
- **The survival and detection results are consistent with an impact of hormone therapy on preexisting tumors.**

# The Impact of Hormone Therapy on Breast Density

An increase in mammographic breast density occurs at a greater rate in postmenopausal hormone users who develop mastalgia.<sup>1314</sup> According to the PEPI and WHI clinical trials, about 25–30% of women receiving combinations of estrogen and progestin develop breast tenderness.<sup>1314,1315</sup>

The subject of greatest clinical relevance, in our view, is the connection between breast tenderness and breast density and ultimately the impact on the risk of breast cancer. Although the increase in new-onset breast tenderness is associated with a greater increase in mammographic breast density compared with women who do not develop mastalgia, it is worth noting that one study asking whether hormone-induced changes in breast density increase the risk of breast cancer could find no evidence that this was so.<sup>1316</sup>

A report from the WHI concluded that new-onset breast tenderness in the canceled estrogen-progestin arm of the WHI was associated with an increased risk of breast cancer (HR = 1.48; CI = 1.08–2.03) when compared to women who did not develop mastalgia.<sup>1315</sup> The WHI report gave the impression that this linkage was of sufficient magnitude that it should be a major clinical concern, but there are reasons to place it in a different perspective.

The WHI compared the numbers for sensitivity, specificity, and positive predictive value with the Gail model, implying clinical worthiness by their similarity. However, the positive predictive value of new-onset mastalgia in the WHI was 2.7%, meaning that 97.3% of the women would be expected not to develop breast cancer. Furthermore, in the references cited by the WHI to buttress their use of the Gail model, one actually concluded that the Gail model is not particularly sensitive in identifying individuals at risk, and the other was a study of false-positive mammogram screening.<sup>1317,1318</sup> A positive predictive value of 2.7% is not clinically strong.

The WHI report appropriately acknowledges the increase in breast tenderness noted in some postmenopausal women treated with hormone therapy and the link between mastalgia and an increase in mammographic density; however, the WHI report discusses these subjects as if it has accepted that the hormone-induced increase in density is associated with an increased risk of breast cancer. Let's consider these issues.

Increased density impairs the detection of breast masses.<sup>1319</sup> A failure to detect masses because of high tissue density causes an increase in interval cancers (cancers that present between mammographic screenings; in other words, cancers diagnosed after a negative mammogram).<sup>1320</sup> Difficulties in reading high-density mammograms also

produce false-positive recalls (patients who are recalled for assessment and found not to have cancer). Being recalled for reassessment after an initial mammogram is a cause of significant psychological stress.<sup>1321</sup> In addition, at least 25% of the overall cost of mammographic screening in one U.S. program was attributed to investigations of false-positive readings.<sup>1318</sup>

These two problems, an increase in interval cancers (a decrease in mammographic sensitivity) and an increase in false-positive recalls (a decrease in mammographic specificity), are consistent with a possible decrease in the detection of cancer. Thus, the concern with dense breasts in postmenopausal women is a reduced quality of mammograms that would decrease the ability to detect early breast cancers.

Factors that are associated with greater breast density are nulliparity, older age at first birth, and current use of postmenopausal hormone therapy.<sup>1322</sup> Mammographically, dense breasts reflect a high proportion of stromal, ductal, and glandular tissue, associated with epithelial and stromal cell proliferation.<sup>1323</sup> The likelihood of dense breasts in hormone nonusers decreases with advancing age and increasing body weight as glandular tissue is replaced by fat.<sup>1322</sup> The link with nulliparity supports the contention that a full-term pregnancy early in life produces a change in structure in the breast that persists throughout life and is associated with resistance to proliferation.

Assessing the impact of breast density on the risk of breast cancer is complicated by two factors that produce heterogeneous data: (1) results from programs with biennial screening are less favorable when compared with annual screening and the available data are derived from both, and (2) results from recent years are better, reflecting improvements in technology. Nevertheless, high breast density (75% dense) on mammography in hormone nonusers is reported to be associated with a four- to sixfold increased risk of breast cancer.<sup>1324,1325,1326,1327</sup> **Although hormone therapy increases breast density in some women, it is not certain that the short-term increase in density with hormone therapy changes an individual's risk of breast cancer.**

More current users of hormone therapy have dense breasts than nonusers.<sup>1322,1328,1329,1330,1331</sup> In women younger than age 55, it is difficult to find any differences between hormone users and nonusers.<sup>629</sup> The impact is essentially limited to women older than age 55. The effect of hormone therapy on breast density occurs rapidly; thus, duration of use has no effect.<sup>629</sup> In the PEPI 3-year randomized trial, almost all increases occurred within the first year, with an increase in breast density observed in 8% of estrogen users and 19–24% of estrogen-progestin users and only 2% in the placebo group.<sup>1332</sup> The users of estrogen-progestin combined regimens had a greater risk of developing denser breasts compared with estrogen-alone treatment (7–13-fold greater in the PEPI trial with no differences observed comparing

medroxyprogesterone acetate to micronized progesterone).<sup>1332</sup> In the WHI, estrogen-progestin use increased density in an average of 6.0% of users in the first year, with attenuation in the second year to 4.9%.<sup>1333</sup> In careful studies, the daily, continuous, combined estrogen-progestin regimens have been reported to have a greater effect than sequential regimens, with an increase in density occurring within the first months of treatment and then maintained with no change.<sup>772,773,1334,1335,1336</sup>

**Therefore, hormone therapy increases breast density mainly in older postmenopausal women, more women respond to combined estrogen-progestin regimens (especially the daily, continuous programs), and the effect occurs within the first months of use and remains stable with no changes or some attenuation with increasing duration of use. However, this effect is only seen in at most about 25% of estrogen-progestin users, but usually around 10% of hormone users; indeed, it should be emphasized that most women do not respond in this fashion.**

Overall, studies have suggested that hormone users experience a decrease in mammographic sensitivity with a lesser impact on specificity (false-recall rates). However, the studies are based on small numbers of interval cancers, and it is uncertain how real or how large this effect is because of the difficulty in controlling for confounding factors (e.g., age, age at menopause, and time since menopause). If the effectiveness of breast cancer screening is reduced by postmenopausal hormone therapy, one would expect an adverse impact on breast cancer mortality. Instead, a study that indicated a reduction in mammographic sensitivity also reported smaller, more differentiated (grade I) tumors among the users compared with the nonusers,<sup>773</sup> and most of the studies that have examined the breast cancer mortality rates of women who had used postmenopausal hormone therapy, as reviewed above, have documented improved survival rates.

If breast density and breast cancer were a reflection only of hormone exposure, a strong preponderance of estrogen receptor–positive tumors would be expected in women with increased density. However, women with increased density demonstrated equal increases in risk for both estrogen receptor–positive and estrogen receptor–negative breast cancers, and one study found a preponderance of estrogen receptor–negative tumors in hormone users with dense breasts.<sup>1337,1338</sup> This suggests that other factors besides hormone exposure are involved in the relationship between density and breast cancer. For example, there is an association between breast density and family history of breast cancer, indicating an underlying genetic basis for both density and breast cancer.<sup>1339</sup> In a case-control study that assessed the relationship between hormone therapy and breast density, leaner women were more likely to increase their breast densities with hormone therapy, but there was no association between the response to hormones and family history, late age at first birth, or history of benign

breast disease; the study concluded that recognized risk factors influenced the response to hormone therapy only to a minor degree, suggesting again that unknown genetic factors are involved.<sup>1340</sup> In a study designed to correlate histologic findings in dense breast tissue, an increase in fibrous stroma and type 1 lobules was observed to be more prevalent in hormone users, but these changes were also present in nonhormone users, and overall, there was no statistically significant difference between histologic features and breast density in women undergoing mastectomy for breast cancer.<sup>1341</sup> If breast density in postmenopausal women were strictly related to the hormonal environment, a drastic reduction in the estrogen milieu of the breast should have a salutary impact on density. The MAP1 randomized trial evaluated the effect of letrozole treatment on breast density; no effect of aromatase inhibitor administration on breast density was observed despite 1 year of treatment.<sup>1342</sup>

The increase in breast density associated with postmenopausal hormone therapy appears in some studies to be a transient, reversible change, a change not consistent with a persistent effect on cellular proliferation. After discontinuing hormone therapy, it was reported that breast density rapidly decreases so that former users do not display an increase compared to never-users.<sup>1322,1331,1343,1344</sup> In a retrospective analysis, regression of hormone-induced abnormalities was found to occur within 2 weeks of cessation of treatment.<sup>1344</sup> Similar results were observed in a prospective study observing a reduction in density 3 weeks after stopping treatment.<sup>1345</sup> However, in a large randomized trial of 1,704 women aged 45–80, although suspension of hormone therapy for 1 or 2 months produced small but significant decreases in density, mammography recall rates of 10–12% were not affected.<sup>1346</sup> Furthermore, a nonrandomized before and after study (but of only 47 women) detected no significant changes in mammographic density after a 4-week cessation of hormone therapy.<sup>1347</sup> Besides discontinuing hormone therapy, another approach is to consider lower doses of hormone therapy; there is some evidence that low-dose treatment has little effect on breast density.<sup>1348</sup> The combination of the levonorgestrel intrauterine contraceptive device and estrogen therapy in postmenopausal women does not seem to increase breast density.<sup>1349,1350</sup>

## Key Points: Breast Density and Hormone Use

- **Some women develop an increase in breast density with the current use of postmenopausal hormone therapy, more often associated with continuous, combined use of estrogen-progestin regimens.**
- **The older a postmenopausal patient is, the greater the risk of developing an increase in breast density with hormone therapy.**

- **There is no strong evidence to indicate that new-onset tenderness or the increase in density with hormone therapy changes an individual's risk of breast cancer.**
- **The evidence to support a recommendation that hormone therapy should be discontinued for several weeks prior to mammography in women who have dense breasts is mixed, and the only randomized study found no impact of suspension of treatment on a mammography recall rate of about 10%. Nevertheless, this is a reasonable recommendation.**
- **In women who develop breast tenderness and/or an increase in density with postmenopausal hormone therapy, consider a dosage reduction of the administered hormones.**

# The Effect of Hormone Therapy on Mammographic Screening

The impact of screening mammography has been established by multiple randomized trials: about a 28% reduction in breast cancer mortality in women 50 years and older.<sup>1351</sup> At the same time, it is recognized that it is difficult for mammography to detect noncalcified masses, especially in dense breasts. This sensitivity problem has been improved by digital mammography, but not eliminated.

Does the hormonal effect on breast density impair mammographic screening? In other words, is there an increase in interval cancers and false-positive recalls in postmenopausal hormone users? In a review of seven studies, there were relatively few interval cancers in the user groups; nevertheless, six of the seven studies reported decreased mammographic sensitivity in hormone users with a small increase in interval cancers in users compared with nonusers.<sup>1352</sup> Excluding women under age 50, the relative risk for an interval cancer was summarized as 1.7 (CI = 1.2–2.4). American, Scottish, and Australian studies have indicated a 5–20% decrease in mammographic sensitivity in hormone users who have dense breasts.<sup>1353,1354,1355,1356</sup> A Finnish study concluded that women with the densest breasts, and using hormones, had the highest relative risk of breast cancer, but this conclusion was based on only four cases of cancer in women with dense breasts.<sup>1357</sup>

The risk of false-positive recall (mammographic specificity) was investigated in five studies.<sup>1353,1357,1358,1359,1360</sup> The rate of false-positive recall in nonusers ranged from 2.1% in the United Kingdom to as high as 14.7% in an American program; four of the five studies found a slight increase in the risk of false-positive recalls in hormone users. In a French study, mammographic sensitivity was reduced from 92% to 71% in users because of an incidence of interval cancers that was 3.5 times that of nonusers within the first year of the initial exam and 1.7 times greater during the following 2 years.<sup>1358</sup> Most of the hormone users were on combined estrogen-progestin regimens. The false-positive recall rate was only slightly higher, 3.3% in users and 2.8% in nonusers. A prospective study of screening mammograms from Massachusetts General Hospital concluded that recall rates were essentially the same comparing hormone users and nonusers and that hormone therapy rarely causes a diagnostic dilemma.<sup>1359</sup> However, in New Hampshire, increased breast density and use of hormone therapy independently increased the need for supplemental imaging.<sup>1360</sup>

Treatment with either estrogen alone or estrogen-progestin in the WHI was associated with more abnormal mammograms compared with placebo.<sup>1274,1361</sup> The difference was about 12% with estrogen-progestin and 8% with estrogen alone, but

remember the characteristics of the participants differed in the two arms of the clinical trial. Nevertheless, the higher prevalence with estrogen-progestin is consistent with the other studies in the literature. Overall, the studies have suggested a decrease in mammographic sensitivity with a small impact on specificity (false-recall rates).

## **Adding Ultrasound to Mammography**

The American College of Radiology conducted a prospective, multicenter, randomized trial in 21 centers in the United States, with 2,725 women, designed to validate the performance of screening ultrasound in conjunction with mammography in women with dense breasts and at high risk for breast cancer.<sup>1362</sup> Each patient underwent mammography and ultrasound in a randomized sequence. Forty cases of cancer were diagnosed, 12 on ultrasound alone, 12 on mammography alone, 8 suspicious with both techniques, and 8 with negative exams. Adding ultrasound yielded an additional 4.2 cancers per 1,000 high-risk women. The false-positive rate for mammography alone was 4.4%, for ultrasound alone 8.1%, and for combined mammography plus ultrasound 10.4%. **Thus, adding ultrasound to mammography screening in high-risk women with dense breasts improved the sensitivity of screening, but increased the rate of false-positive examinations. Breast cancer mortality was not an endpoint in this trial, but the fact that the cancers detected by ultrasound are usually asymptomatic, node-negative, and not detected by mammography should yield a reduction in mortality.**

Ultrasound screening can detect cancers not seen on mammography and its performance is not affected by dense breast tissue. Adding ultrasound to a screening program seems straightforward, but its impact on mortality reduction has not been measured in a large trial. In the single center studies of screening ultrasound that have been published, cancers have been found only by ultrasound, and most are small, early-stage tumors. An Italian multicenter study reported that 29 cancers were found by ultrasound in 6,449 women with dense breasts and negative mammograms.<sup>1363</sup>

The problem with all screening methods is a substantial rate of false positives. In the American study, 91.4% of suspicious ultrasound findings were benign.<sup>1362</sup> The positive predictive value for ultrasound was only 8.6%, but the value for mammography was 14.7%. The crucial question is how many false positives are worth the gain in additional cancer diagnoses. In the American study, the gain was an additional 29% (the number of cancers detected only by ultrasound). In women with elevated risks, this seems worthwhile.

**Combining MRI with mammography yields a very high sensitivity, and this is now recommended for women at very high risk for breast cancer.** Breast MRI is the most sensitive technique, but it is very expensive, requires the intravenous injection of

contrast, and isn't always tolerated by patients. Ultrasound has the advantage of being less expensive, easily tolerated, and widely available. Thus, the combination of ultrasound and mammography seems best for women of intermediate risk. Ultrasound has a disadvantage of not detecting ductal carcinoma in situ, which is detected by mammography and MRI.

In general, supplemental screening for dense breasts (either ultrasound or MRI) will identify more breast cancers (invasive cancers), but it may come at the cost of increased false-positive rates and biopsies.<sup>1364</sup> What is not known however is if cancers identified from ultrasound and MRI have improved outcomes and reduced mortality.<sup>1364</sup> **Further research studies are clearly needed.**

## Key Points: Mammography Screening

- **There is sufficient evidence to support utilizing more than one screening technique (mammography, ultrasound and MRI) for high risk patients defined as a combination of factors that produces a threefold increase in risk), especially in women with radiographically dense breast tissue. Thus far, over 90% of cancers detected only on ultrasound have been in women with dense breasts. Therefore, it seems advisable to add ultrasonography to mammography for hormone users who develop dense breasts, and the density persists despite a short period without hormone therapy. In addition, digital screening mammography is superior to conventional film screening for women with dense breasts.**<sup>1365</sup>
- **Hormone users who develop an increase in breast density have a small decrease in mammography sensitivity and an increase in false recalls. An adverse impact of this increase in breast density is not apparent in breast cancer mortality statistics in hormone users. Digital mammography is preferred for women with dense breasts.**
- **Ultrasonography should be added to mammography screening in hormone users who develop dense breasts with no regression after a short period without hormone treatment.**

# The Effect of Progestins in Combined Regimens

Recent studies support the conclusion that the relative risk of breast cancer is higher in users of combinations of estrogen and progestin. The effect is confined to estrogen receptor–positive, progesterone receptor-positive (ER+/PR+) tumors, mainly lobular cancers. **What if this conclusion reflects early detection of better-differentiated tumors, a consequence of a favorable response of pre-existing tumors to estrogen-progestin exposure?**

Almost every study that has reported an increase in breast cancer risk with postmenopausal hormone therapy has found the increase within a few years. Remember that although the doubling time of breast cancer is variable, in general, a tumor doubles in size every 100 days. Thus, it takes a single malignant cell approximately 7 years to become detectable by mammography and 10 years to grow to a clinically detectable 1-cm mass.<sup>1366</sup> The rapid finding of an increased risk within a few years of exposure to hormone therapy suggests that the epidemiologic studies are detecting preexisting tumors.

Older studies on the hormone receptor content in breast cancers diagnosed in hormone users were limited by small numbers. Furthermore, recent studies examining receptor status are likely to be more accurate in that receptor status assays have improved. In the Nurses' Health Study, the use of postmenopausal hormone therapy has been associated with a significant increase in ER+/PR+ breast cancer, but not receptor-negative disease.<sup>1367</sup> This relationship, greatest in lean women, was stronger and observed sooner with the use of estrogen-progestin, a significant increase with 5 or fewer years of combined use and no increase with 5 or fewer years of the use of estrogen alone. In a cohort of women from the area of Lund, Sweden, an increased risk of breast cancer was reported only in users of continuous combined estrogen-progestin, and this increase was observed within 2 years of use.<sup>1368</sup> Other epidemiologic studies have reported a similar greater risk in current users of continuous, combined estrogen-progestin, concentrated in estrogen receptor–positive disease.<sup>1255,1258,1261,1369,1370</sup> Indeed, use of hormone therapy is the greatest predictor of estrogen receptor–positive disease.<sup>1371</sup> In a retrospective study in the Northern California Kaiser program, only the current use of combined estrogen and progestin increased the odds of estrogen receptor–positive tumors.<sup>1372</sup>

E3N is a French prospective cohort study initiated in 1990, which concluded that it would be preferable to use progesterone or dydrogesterone because estrogen use with these two progestins was not associated with an increase in the relative risk of invasive breast cancer.<sup>1373,1374</sup> For any given progestin, the route of administration of estrogen (oral or transdermal) had no effect on relative risk. A statistically significant increase in

relative risk was associated with estrogen alone (RR = 1.29; CI = 1.02–1.65) and with progestins other than progesterone or dydrogesterone (RR = 1.69; CI = 1.50–1.91). The increased relative risks seemed to rapidly dissipate after discontinuation of treatment; although this analysis was initially limited by small numbers, it was confirmed in a later follow-up.<sup>1375</sup>

The French study argued that their results indicate that the “natural” progestins are safer than “synthetic” progestins. But to accurately differentiate among various agents, one would have to be certain that the doses administered represented bioequivalent doses in terms of target tissue impact, something that would be difficult to do. Let’s focus on the rapidity at which cases of breast cancer were identified. The use of estrogen combined with “other progestins” had an increased relative risk even with less than 2 years of exposure (RR = 1.37; CI = 1.07–1.72). In their earlier report, an increased relative risk was even apparent with less than 1 year of exposure of estrogen combined with synthetic progestins.<sup>1373</sup> **The results in the French study could be due to earlier detection of pre-existing tumors, an effect accelerated by specific progestins with greater potency.**

A follow-up report from the French study indicated that the increased risk of breast cancer was evident only in women with recent use of hormone therapy and not in past users.<sup>1375</sup> Furthermore, the risk with short-term use was confined to hormone use with synthetic progestins for 2 or fewer years in the 3-year period immediately following menopause. With longer duration of hormone use, the risk was apparent even in those who initiated treatment years after the menopause. The logical conclusion is that this striking finding with short-term use early in the postmenopausal years reflects an impact of hormone therapy on pre-existing tumors.

Molecular biology studies provide support for a favorable effect of estrogen-progestin exposure. In vitro studies using microarray analysis have profiled the gene network both up- and down-regulated by estrogen.<sup>1376</sup> Genes that are up-regulated by estrogen are down-regulated by estrogen-progestin treatment.<sup>1377</sup> Comparing hormone users and nonusers, 276 genes were activated by hormone exposure (11 of the 13 women used estrogen-progestin and 2 used estrogen alone). All patients in this cluster were free of recurrence 5 years after diagnosis. In a cohort of 131 women, those patients exhibiting the gene profile associated with estrogen-progestin exposure preferentially benefited from tamoxifen treatment.<sup>1377</sup> This Swedish study found that estrogen-progestin use altered the gene expression profile only in estrogen receptor-positive cancers. Among the genes regulated, many were involved in either DNA repair or cell cycle regulation. For example, the p63 gene, involved in tumor differentiation, was overexpressed in estrogen-progestin users. Previous reports have found this gene to be expressed in normal tissue, partially expressed in ductal hyperplasia, and not

expressed in invasive cancers.<sup>1378</sup>

It is well recognized that early pregnancy produces a mammary gland that is resistant to carcinogenesis. In rodents, this is accomplished by treatment with estrogen plus a progestin. The refractory phenotype that is produced is associated with progestin-induced changes in gene expression involved in cell proliferation.<sup>1379</sup>

The progesterone receptor is induced by estrogens at the transcriptional level and decreased by progestins at both the transcriptional and translational levels (probably through receptor phosphorylation).<sup>1380</sup> The progesterone receptor has two major isoforms, designated the A and B receptors.<sup>1381</sup> The two forms are expressed by a single gene, a consequence of transcription from distinctly different promoters, in a complex system of transcription regulation.<sup>1382</sup> Progestational agents can elicit a variety of responses determined by target tissue production and activity of the two receptor forms with dimerization as AA and BB (homodimers) or AB (heterodimer).

PR-A and PR-B are expressed in varying amounts in breast cancer and endometrial cancer cell lines. Studies indicate that the two receptors can be regulated independently; for example, the relative levels differ in endometrium during the menstrual cycle.<sup>1383</sup> Tissue specificity with the progesterone receptor is influenced by which receptor and which dimer is active, and in addition, the transcriptional activities of PR-A and PR-B depend on target cell differences, especially in promoter context. In most cells, PR-B is the positive regulator of progesterone-responsive genes, and PR-A inhibits PR-B activity. Thus, repression of human estrogen receptor transcriptional activity (as well as glucocorticoid, mineralocorticoid, and androgen transcription) is dependent on the expression of PR-A.<sup>1384,1385</sup> The PR-A and PR-B progesterone receptors have different molecular functions, affecting different genes, and, therefore, target tissue response to progesterone will be influenced by the differential expression of each receptor and the ratio of their concentrations, as well as the target tissue context of adaptor proteins.<sup>1386,1387</sup>

**PR-A–positive breast cells exhibit more aggressive growth, and PR-A isoforms are dominant in the absence of progesterone.** Even without its ligand, PR-A can exert gene regulation in estrogen receptor–positive breast cell lines.<sup>1388</sup> In the absence of progesterone, PR-A up-regulates genes known to be associated with invasion and poor prognosis, including those genes that provide resistance to apoptosis. In the presence of progesterone, PR-B is a stronger regulator of gene transcription. The breasts of normal women express equal amounts of PR-A and PR-B.

PR-A excess and breast cancer are linked. Estrogen receptor–positive tumors with a higher rate of recurrence are rich in the PR-A isoform.<sup>1388</sup> As breast cancers become less differentiated, metastatic tumors become dominated either by PR-A or PR-B. PR-

A-rich tumors with a low PR-A:PR-B ratio do poorly and respond less well to tamoxifen.<sup>1389</sup> PR-A excess is also present in breast tissue from women with the BRCA mutations.<sup>1390</sup>

Thus, progesterone receptors are not just passive markers of estrogen activity. ER+/PR+ tumors are well differentiated and have better outcomes. In the absence of progesterone, the unliganded PR-A can adversely influence the cell biology of estrogen receptor-positive tumors. Cells rich in PR-A are more likely to be invasive, poorly differentiated, and aggressive. In monkeys, the breast levels of PR-A were unchanged after 3 years of treatment with conjugated estrogens alone.<sup>1391</sup> Treatment with conjugated estrogens and medroxyprogesterone acetate produced a decline in PR-A levels, producing a 10-fold beneficial change in the PR-A:PR-B ratio. It is possible that the exposure of an estrogen receptor-positive tumor to estrogen-progestin treatment can prevent an unfavorable PR-A:PR-B ratio, promoting the beneficial actions of PR-B. In addition, progestins may activate androgen receptors, a factor that has been demonstrated to inhibit growth and cause apoptosis in breast cancer cells.<sup>1392,1393</sup>

In a series of in vitro experiments, estradiol and its catechol metabolites induced neoplastic transformation in human breast epithelial cells.<sup>1394</sup> This, of course, would be consistent with a genomic impact of estrogen that initiates breast cancer, an effect earlier than a promoting influence on already-established cancers. However, it is difficult to transfer in vitro effects on cell lines to the in vivo situation, and this is especially true with breast tissue that is bathed in a complicated and large collection of stimulating and inhibiting substances. Furthermore, the cells in the in vitro experiments were negative for both estrogen and progesterone receptors. These receptor-negative malignant cells may well be something different than the receptor-positive tumors associated with postmenopausal hormone therapy.

Favorable effects of progestin exposure are reflected in the studies of the association between endogenous hormone levels and the risk of breast cancer. A pooled analysis of nine prospective studies of postmenopausal women concluded that the risk of breast cancer increases with increasing concentrations of all endogenous estrogens and androgens, including estradiol, estrone, estrone sulfate, androstenedione, DHEA, DHEA-S, and testosterone.<sup>1395</sup> The overall increase in breast cancer risk was about twofold comparing the lowest endogenous levels in postmenopausal women with the highest levels. Women who ultimately develop breast cancer do not have different blood levels of progesterone.<sup>1242</sup> Postmenopausal women who are overweight have an increased risk of breast cancer, and an analysis that adjusted for the increase in circulating estrogens associated with obesity concluded that the increasing risk with increasing body weight is the result of the increase in estrogens.<sup>1396</sup>

In contrast to the endometrium, epithelial cell proliferation in the normal breast and

in estrogen receptor–positive tumors reaches its peak during the progesterone-dominant luteal phase of the menstrual cycle.<sup>1368,1397,1398,1399</sup> This observation has been the driving force behind the argument that progesterone (progestins) is the major hormonal mitogen in the breast. However, studies do not support a major role for an adverse progestational influence. In animal models, it is estrogen that is the major inducer of proliferation and not progesterone. Indeed, evidence indicates that with increasing duration of exposure, progesterone can limit breast epithelial growth as it does with endometrial epithelium.<sup>1400,1401,1402</sup> In vitro studies of normal breast epithelial cells reveal that progestins inhibit proliferation.<sup>1403</sup> The story with human breast tissue specimens removed after the patients were treated with estradiol and progestin is more confusing, indicating on one hand that progestins inhibit in vivo estradiol-induced proliferation<sup>1400,1402,1404</sup> and, on the other hand, markers of epithelial and stromal cell proliferation were higher in women being treated with estrogen-progestin.<sup>627,1405</sup> Nevertheless, progestins have been demonstrated to decrease antiapoptotic protein expression,<sup>1406</sup> and apoptosis in breast tissue is higher in the luteal phase than in the follicular phase.<sup>1407</sup> Conversely, research comparing human breast cancer cell lines to noncancerous cells has demonstrated that progestogens differentially affect breast cell proliferative activity.<sup>1408</sup> A study by Courtin et al. analyzed the effects of estradiol (E2) alone, E2 + progesterone (P4), and E2 + medroxyprogesterone acetate (MPA) on cellular proliferation and apoptosis in breast cancer cells, as well as normal human breast cells.<sup>1409</sup> Treatment with E2 alone in all cell types resulted in increased cell proliferation. In normal human breast cells, the addition of P4 blocked estradiol's proliferative effect and also resulted in an increased number of apoptotic cells. When normal cells were treated with E2 + MPA, however, there was little effect on cellular proliferation, and the number of apoptotic cells was decreased. In MCF-7 and T47-D breast cancer cell lines, MPA did not induce cellular proliferation and neither MPA nor P4 affected apoptosis in these cells. Microarray studies revealed induction of different sets of genes in hormonally treated cells, compared to control cells. E2 + MPA modified genes in a distinctly different pattern from E2 + P4. In a study by Sweeney et al., it was found that MPA combined with E2 stimulated proliferation in long-term estrogen-deprived MCF-7 (MCF-7:5C) cells, while E2 alone resulted in cell death.<sup>1410</sup> Additional support for progestogens' role in breast cancer comes from studies analyzing MPA's effects on estrogen-metabolizing enzymes in breast cancer cells. Using T47-D and MCF-7 cells, it was demonstrated that E2 + MPA increased the expression of estrogen-activating enzymes but did not increase expression of estrogen-inactivating enzymes.<sup>1411</sup> The increase was greater than cells treated with E2 alone. Although there was an increase in estrogen-activating enzymes, there was no associated increase in cell proliferation. It is important to note, however, that locally increased estrogen levels can be seen in the breast cancer cell milieu, and this high-estrogen environment facilitates

cancer cell growth.<sup>1411</sup> Thus, MPA may exert its carcinogenic effect via induction of a local state of estrogen excess. However, as mentioned earlier, these in vitro models must be interpreted with caution, as what happens in vivo is influenced by many other factors.

In the postmenopausal monkey model, greater breast cell proliferation was observed after 30 months of treatment with estrogen-progestin compared with estrogen alone.<sup>1412</sup> In this same model, the administration of progesterone produced no differences in proliferation markers, but adding medroxyprogesterone acetate to estrogen increased breast proliferation by about 30% compared with placebo.<sup>1413,1414</sup> However, in this 2-month study, the administration of progesterone inexplicably lowered the blood levels of estradiol and estrone by 30–50%, in contrast to no effect with medroxyprogesterone acetate. Thus, the tissue results may reflect estrogen differences, not progestin differences. Nevertheless, the monkey experiments do not detect a beneficial effect of medroxyprogesterone acetate; a 2-year monkey study recorded lower levels of p53, a tumor suppressor gene, and lower levels of caspase-3, an enzyme involved in apoptosis.<sup>1415</sup> Given the marked similarities in macaques to human gene coding sequences, this primate serves as a more reliable model for studying the effects of menopausal hormone therapy on breast cancer acquisition.

A prospective study of premenopausal women in Italy found that higher progesterone levels in the luteal phase were associated with a reduction in breast cancer risk.<sup>1416</sup> However, a nested case-control analysis based on the Nurses' Health Study could find no influence of progesterone levels on breast cancer risk.<sup>1417</sup> In this study, women with the highest levels of total and free estradiol in the early follicular phase had about a twofold increase in breast cancer risk, predominantly ER+/PR+ tumors, and a similar increase in risk was associated with higher levels of total and free testosterone and androstenedione. There was no association with luteal estradiol levels, and the authors speculated that this is because early follicular phase levels reflect nonovarian target tissue levels and also that progesterone down-regulation of estrogen receptors may occur in the breast during the luteal phase.

Although it is not a uniform story, it is possible that favorable breast tissue effects of progestins translate into better differentiation and earlier detection of pre-existing tumors. Supporting data can be found in two important American studies. A retrospective cohort study in the Southern California Kaiser program found a reduction in breast cancer case mortality that was significant only among women with breast cancer who were users of estrogen-progestin, not with estrogen alone.<sup>1418</sup> An increase in lower-grade, lower-stage, estrogen receptor-positive cancers was found only in current users of estrogen-progestin in a study remarkable for its size, 374,465 women screened in six U.S. mammography centers.<sup>1259</sup> These data are consistent with a

beneficial effect of estrogen-progestin treatment.

Breast cancer mortality was recorded in the Collaborative Breast Cancer Study Cohort, a prospective cohort of 12,269 postmenopausal women from Wisconsin, Massachusetts, and New Hampshire.<sup>1419</sup> Women were followed for an average of 10.3 years after breast cancer diagnosis. After adjusting for BMI, smoking, and history of mammography screening, compared with nonusers, mortality from breast cancer was lower among current users of estrogen-progestin and an even greater effect, a 40% reduction, with 5 or more years of use. These are striking data. The strength of the study is the large size of the cohort. Indeed, this is the strongest evidence thus far published that the use of estrogen-progestin is associated with the development of less aggressive breast cancers. Even in studies that adjusted for the prevalence of mammography screening, breast cancers in hormone users were smaller, had fewer positive axillary lymph nodes, and were of lower-grade disease.

**The following evidence supports a beneficial impact of progestins on preexisting tumors:**

- **An increase in estrogen receptor–positive tumors is seen sooner with estrogen-progestin treatment, and greater risk is observed with continuous, daily estrogen-progestin use.**
- **Genes up-regulated by estrogen are down-regulated by estrogen-progestin therapy.**
- **Genes that are activated by estrogen-progestin are involved in DNA repair and cell cycle regulation.**
- **Progestins decrease breast tissue levels of PR-A, causing a beneficial change in the PR-A:PR-B ratio that is associated with better differentiation and outcome.**
- **A reduction in breast cancer case mortality has been reported with estrogen-progestin use, and not with estrogen alone.**

# Prevalence of Breast Cancer and Hormone Therapy

Multiple reports have documented a U.S. decline in breast cancer incidence that paralleled the decrease in use of postmenopausal hormone therapy that followed the publications from the WHI.<sup>1420,1421,1422,1423</sup> A similar decline was documented in France, Scotland, Switzerland, and Australia.<sup>1424,1425,1426,1427</sup> The decline was partially influenced by a decrease in screening mammography in the United States, but the correlation with hormone use exists even when the examined population includes only women screened with mammography. A similar pattern was evident in the WHI in the years following the cancellation of the estrogen-progestin arm as well as among the women in the observational arm, despite no change in the frequency of mammography in the WHI population.<sup>1428</sup>

This decrease in prevalence is consistent with the uniform findings in case-control and cohort studies of an increase in breast cancer risk only in current users, with a rapid reduction after cessation of treatment. An impact on existing tumors is supported by the other side of the coin, apparent in breast cancer statistics derived from the area around Geneva, Switzerland. Beginning in 1997, the peak breast cancer incidence in the Geneva area moved to a younger group of women (ages 60–64), with an increase occurring only in stage I and stage II disease with estrogen receptor–positive tumors in hormone users.<sup>1429</sup>

A median 8-year follow-up from the WHI was an anticipated postintervention follow-up report from the canceled arms of the WHI.<sup>1313,1430</sup> The trend of increasing breast cancer during the trial period did not extend into the follow-up period. Thus, it is very likely that the WHI results agree with the national data, and furthermore, the absence of a trend for increasing cases of breast cancer is the pattern one would expect if hormone therapy is causing earlier detection of preexisting tumors in current users. This agreement with national data was confirmed when the prevalence of breast cancer in the estrogen-progestin arm and the observational arm was reported by the WHI, indicating a marked decline after cancellation of the randomized trial.<sup>1428</sup>

The national decline in prevalence and the WHI results are both consistent with an impact of hormone therapy on preexisting tumors. If hormone therapy is affecting preexisting tumors, one would expect small, undetectable tumors to stop changing (at least temporarily) when women discontinue hormone therapy. This response would be consistent with the effects being reported, a decrease in estrogen receptor–positive tumors in younger postmenopausal women. The data most likely primarily reflect existing cancers just below the detection limit in 2002 that slowed or stopped their

growing.

The choice of estrogen used in the estrogen-alone arm of the WHI (CE) has been suggested to explain the favorable effects seen on the breast. The CE formulation contains a mixture of multiple estrogens, and each estrogen type not only preferentially binds the two estrogen receptors (ER-alpha and ER-beta), but may also exert differential actions depending on the target tissue.<sup>1431,1432</sup> In studying the effects of 11 equine estrogens (in CE preparations) on the transcriptional activity of ER-alpha and ER-beta, it was found that many of the equine estrogens preferentially bind ER-beta; ER-beta activation can inhibit ER-alpha activity on cell proliferation.<sup>1433,1434,1435</sup> The potential SERM-like properties of CE have also been demonstrated in breast cancer cells treated with CE and estradiol, where CE and estradiol were noted to have distinct effects on gene expression.<sup>1436</sup> Furthermore, it has been demonstrated that several estrogenic compounds in CE act as partial estrogen agonists; thus, like SERMs, the differences in binding and downstream cell signaling may afford CE with specific tissue manifestations that are unlike estradiol's purely stimulatory effects (i.e., manifestation of ER antagonistic effects).<sup>1436,1437</sup> This inhibition induced by equine estrogens may in part explain the decreased risk of breast cancer in the WHI estrogen-alone study; however, additional research is needed before definitive conclusions can be made. Lastly, the SERM BZA paired with a CE may further allow for favorable effects on breast tissue; BZA/CE also has the added benefit of avoiding a progestin.<sup>1438</sup>

## Key Points: Breast cancer prevalence and hormone use

- **A decrease in breast cancer prevalence paralleled the decrease in hormone use following the publicity generated by the WHI publications.**
- **The decrease in prevalence is consistent with the removal of hormonal effects on small undetectable tumors.**

# Hormone Therapy and the BRCA Mutations

Women with either BRCA1 or BRCA2 germline mutations are advised to undergo bilateral prophylactic oophorectomy after completion of childbearing because of a high lifetime risk (approximately 90%) for developing breast or ovarian cancer. This surgery reduces the risk of ovarian cancer by about 90% and the risk of breast cancer by about 50%. These relatively young women must consider the postoperative consequences of surgical menopause in their decision-making. In a cohort of 462 women with BRCA1/2 mutations from 13 medical centers in North America and Europe, the incidence of breast cancer was compared in 155 of the women who had undergone bilateral prophylactic oophorectomy with 307 women who did not have the operation.<sup>1439</sup> The women who had oophorectomy had a 60% reduction in the risk of developing breast cancer. Hormone therapy of any type did not alter the reduction in breast cancer experienced by the women undergoing oophorectomy. Thus, short-term use (several years) of hormone therapy did not have an adverse effect on the beneficial reduction in breast cancer risk following prophylactic oophorectomy. In a later follow-up of this group of women, 93 (60%) of the women who underwent oophorectomy used hormone therapy.<sup>1440</sup> The average length of follow-up was 2.6 years (more than 5 years in 16%) in the surgically treated group and 4.1 years (more than 5 years in 33%) in the nonoophorectomized group. There was no hint of a difference in breast cancer reduction comparing hormone users and nonusers. The findings were similar in 34 women who used a combination of estrogen and progestin, but the power of this finding was limited by the small number in this category.

A case-control study of 472 postmenopausal women with a BRCA1 mutation found that women who used hormone therapy after prophylactic oophorectomy, either estrogen only or combined estrogen-progestin, not only did not have an increased risk of breast cancer, but hormone use was actually associated with a decreased risk.<sup>1441</sup> The findings were the same regardless of duration of use or current or past use. The conclusion is encouraging, but limited by the fact that 68% of the tumors in the study were estrogen receptor–negative, making the estrogen receptor–positive tumors (that are more likely to be influenced by hormone use) relatively small in number.

Women who are BRCA carriers face difficult decisions. **The experience thus far indicates that hormone therapy can be used safely for several years.** Continuing follow-up of these patients may extend this period of safety even longer. A TSEC (CE paired with a SERM BZA) may be particularly suitable HT option in this population given its efficacy for symptom control and skeletal benefit while having neutral effects on the breast and potential of BZA for blockade of breast cancer cell proliferation as has been demonstrated in vitro.<sup>673,1436,1438</sup> However, future studies are needed to establish both safety and efficacy of this newer class of menopausal hormonal regimen

in breast cancer survivors as well as those who are at risk for breast cancer, such as BRCA1/2 carriers.

Prophylactic oophorectomy in women with BRCA mutations reduces the risk of breast cancer by about 50%. Thus far, hormone use after prophylactic oophorectomy has not diminished the beneficial reduction in breast cancer risk.

# Summary: Postmenopausal Hormone Therapy and Breast Cancer

## Key Points

- The WHI agrees with case-control and cohort studies indicating that current use of hormone therapy has a slightly increased risk of breast cancer.
- The increased risk is observed sooner with the use of combined estrogen-progestin regimens.
- The increased risk with hormone therapy is confined to estrogen receptor-positive tumors, mainly lobular cancers.
- Epidemiologic data indicate that a positive family history of breast cancer or other risk factors should not be contraindications to the use of postmenopausal hormone therapy.
- Women who develop breast cancer while using postmenopausal hormone therapy have a reduced risk of dying from breast cancer compared with never-users. This is probably because of two factors: (1) increased surveillance and early detection and (2) an effect on preexisting tumors so that tumors appear at a less virulent and less aggressive stage.
- The most important unanswered question in regard to breast cancer is whether postmenopausal hormone therapy initiates the growth of new breast cancers or whether the epidemiologic findings reflect an impact on preexisting tumors. A summary of the wide range of evidence supports a favorable effect of hormone therapy on preexisting tumors.
- Epidemiologic studies find an increased risk within a few years of hormonal exposure.
- Breast cancer associated with estrogen-progestin therapy is estrogen receptor-positive, lower-grade, lower-stage disease with better survival rates.
- Epidemiologic studies find an increased risk only in current users; 5 years after discontinuation, the risk returns to baseline.
- A recent rapid decrease in breast cancer prevalence coincides with a decrease in the use of postmenopausal hormone therapy.

**Postmenopausal hormone therapy may be associated with a small increase in the risk of breast cancer. Of course, even a small increase in risk for breast cancer is frightening for patients to contemplate. It is helpful to remind patients of the risk**

**of lung cancer associated with smoking (a relative risk of 10–20), a risk magnitude that provides perspective on the possible risk associated with hormone therapy. It is also worth pointing out that the reported risk with hormone therapy is even smaller than that associated with recognized risk factors such as a positive family history, being overweight after menopause, and alcohol intake. In our view, because the literature is sufficiently strong, it is appropriate to share with patients an alternative explanation for the epidemiologic reports regarding breast cancer and postmenopausal hormone therapy. It is helpful to emphasize the possibility that the studies reflect an effect of hormone therapy on pre-existing tumors and that hormone users who develop breast cancer have a reduced risk of dying of breast cancer because their tumors are better differentiated, more localized, and smaller. Contrary to the prevailing belief, estrogen-progestin exposure may cause greater differentiation and earlier detection of preexisting tumors, resulting in better outcomes.**

# ENDOMETRIAL NEOPLASIA

---

There are two different types of endometrial cancer. The more common form, endometrioid carcinoma, develops slowly from a precursor lesion in response to estrogen stimulation. This type is less aggressive, is better differentiated, and responds to progestational treatment. In contrast, the uncommon form (perhaps 10–20%) develops rapidly, usually in older women, with a histologic pattern that is more characteristic of serous or clear cell carcinomas, in a background of atrophic endometrium.

Estrogen normally promotes mitotic growth of the endometrium. Abnormal progression of growth through simple hyperplasia, complex hyperplasia, atypia, and early carcinoma has been associated with unopposed estrogen activity, administered either continuously or in cyclic fashion. **Only 1 year of treatment with unopposed estrogen (0.625 mg conjugated estrogens or the equivalent) will produce a 20% incidence of endometrial hyperplasia, largely simple hyperplasia.** In the 3-year PEPI trial, 30% of the women on unopposed estrogen developed adenomatous or atypical hyperplasia.<sup>566,569,570</sup> Some 10% of women with complex hyperplasia progress to frank cancer, and complex hyperplasia is observed to antedate adenocarcinoma in 25–30% of cases. **If histologic evidence of atypia is present, 20–25% of these cases will progress to carcinoma within a year.**<sup>1442</sup>

Approximately 40 case-control and cohort studies estimated that the risk of endometrial cancer in women on estrogen therapy (unopposed by a progestational agent) is increased by a factor of somewhere from 2 to 10 times the background incidence of 1 per 1,000 postmenopausal women per year.<sup>1443,1444</sup> **The risk increases with the dose of estrogen and with the duration of exposure** (reaching a 10-fold increase with 10–15 years of use, perhaps an incidence of 1 in 10 with very long-term use) **and lingers for up to 10 years after estrogen is discontinued.**<sup>1445,1446,1447</sup> The risk of cancer that has already spread beyond the uterus is increased threefold in women who have used estrogen a year or longer.<sup>1445,1448</sup> Although most endometrial cancer associated with estrogen use is of low grade and stage, and associated with better survival (probably because of early detection), the overall risk of invasive cancer and death is increased. The risk of endometrial hyperplasia and cancer is not reduced by the administration of unopposed estrogen in a cyclic fashion (a period of time each month without treatment).<sup>1443,1449</sup>

A short-term study (2 years) indicated that estrogen-only treatment in one-half the usual standard dose of estrogen (in this case, 0.3 mg esterified estrogens) was not associated with an increased incidence of endometrial hyperplasia compared with a placebo group.<sup>1450</sup> In a similar 2-year study, endometrial stimulation with the

transdermal delivery of a very low dose of estradiol, 14 µg/day, also did not differ compared with placebo.<sup>1451</sup> However, **we have learned that long-term exposure to low levels of estrogen can induce abnormal endometrial growth (it just takes longer), and, in our view, lower-dose estrogen therapy requires either endometrial assessment annually or the addition of a progestin to the treatment regimen.** This is supported by a case-control study from Washington that contained 18 cases and 9 controls who had exclusively used only 0.3 mg/day of unopposed conjugated estrogens.<sup>1452</sup> The use of this half-dose estrogen was associated with an overall fivefold increased risk of endometrial cancer, reaching a relative risk of 9.2 in current users for more than 8 years' duration. Although limited by small numbers, the conclusion is logical and consistent with our understanding of the importance of duration of exposure to any increased level of endometrial estrogen stimulation. In a randomized trial, endometrial hyperplasia was increased after 2 years of treatment with 0.3 mg conjugated estrogens without a progestin.<sup>572</sup>

**The risk of endometrial excessive proliferation is reduced by the addition of a progestational agent to the treatment regimen.**<sup>566,570</sup> Although estrogen promotes the growth of endometrium, progestins inhibit that growth. This counter effect is accomplished by progestin-induced reduction in cellular receptors for estrogen and by induction of target cell enzymes that convert estradiol to the excreted metabolite estrone sulfate. As a result, the number of estrogen receptor complexes that are retained in the endometrial nuclei is decreased, as is the overall intracellular availability of the powerful estradiol. In addition, progestational agents suppress estrogen-mediated transcription of oncogenes.

Reports of the clinical impact of adding progestin in sequence with estrogen include both the reversal of hyperplasia and a diminished incidence of endometrial cancer.<sup>1453,1454,1455,1456,1457,1458</sup> The protective action of progestational agents operates via a mechanism that requires time in order to reach its maximal effect. For that reason, the duration of exposure to the progestin each month is critical. Studies indicate that in estrogen users, the minimal requirement for progestin exposure is for a period of 10 days each month.<sup>188,1459,1460</sup> More recently, this recommendation has been extended to 12–14 days of progestin exposure each month. **About 2–3% of estrogen-using women per year develop endometrial hyperplasia when the progestin is administered for less than 10 days monthly.**

Important unanswered questions are the following: what is the actual incidence of endometrial cancer in very long-term users of postmenopausal hormone therapy, and are there differences among the various regimens and routes of administration? A case-control study from Seattle reported that the use of combined estrogen-progestin (essentially all sequential and oral) for 5 or more years was associated with an

increased relative risk of endometrial cancer, even with 10–21 days of added progestin per month.<sup>1461</sup> However, the increased risk was confined to those women who had been previously exposed to unopposed estrogen treatment; remember, **after discontinuing unopposed estrogen treatment, the risk of endometrial cancer lingers for up to 10 years, even if a subsequent regimen includes a progestin.** In the Swedish prospective cohort in Uppsala, a reduced risk of mortality due to endometrial cancer was observed in women receiving an estrogen-progestin combination; however, there were only two deaths, precluding statistical significance.<sup>1135</sup> A case-control study from Los Angeles found no increased risk of endometrial cancer with the continuous, combined estrogen-progestin regimen or when at least 10 days of progestin were provided in a sequential regimen.<sup>1460</sup> **Epidemiologic studies have suggested that continuous, combined estrogen-progestin regimens provide superior protection against endometrial cancer. Long-term sequential regimens still carry a small increase in the risk of endometrial cancer.**<sup>600,1462,1463</sup> **In our view, periodic endometrial surveillance (annual sonohysterogram and/or endometrial biopsy) is recommended in estrogen users exposed only intermittently to progestin treatment.**

It is not an uncommon perception that protection against endometrial cancer requires periodic “shedding” of the endometrium. However, we know that at least one-third and up to one-half of the functioning endometrium are not lost during withdrawal bleeding, and it has not been established that endometrial shedding is essential to protect against cancer.<sup>1464</sup> It is just as logical to believe that prevention of growth with the development of atrophic endometrium is protective. Case-control studies have indicated that not only is the excess risk associated with unopposed estrogen prevented by continuous, combined estrogen-progestin regimens, but with increasing duration of use, the risk of endometrial cancer is lower than that in never-users.<sup>1462,1465</sup> In a small number of women who developed hyperplasia on a sequential regimen, conversion to continuous, combined treatment produced a return to normal endometrium, and in 345 women who completed 5 years of treatment with a continuous, combined regimen, not a single case of hyperplasia was detected.<sup>587</sup>

The WHI reported a 21% decrease in endometrial cancers in the canceled estrogen-progestin arm after 5 years of this clinical trial, although this difference was not statistically significant.<sup>1466</sup>

The lowest daily dose of progestin that protects the endometrium has not been established. Currently, the sequential program with conjugated estrogens uses 5 or 10 mg medroxyprogesterone acetate, and the combined daily method uses 1.5 or 2.5 mg. A 2-year study has indicated that 1.5 mg medroxyprogesterone acetate combined with 0.3 or 0.45 mg conjugated estrogens effectively prevents endometrial hyperplasia.<sup>572</sup> The

dose of norethindrone that is comparable with 2.5 mg medroxyprogesterone acetate is 0.25 mg.<sup>573</sup> The French E3N cohort study has demonstrated that endometrial safety effects vary by type of progestin; the risk of endometrial cancer in estrogen users was higher when micronized progesterone and dydrogesterone were used compared to other progestin formulations.<sup>1467</sup>

**Although the protective effect of progestin is considerable and predictable, it is unwise to expect all patients on estrogen-progestin therapy to never develop endometrial cancer. Appropriate monitoring of patients cannot be disregarded. Although routine assessments are not cost-effective, interventions directed by clinical responses are prudent and necessary. Greater surveillance is warranted in women on sequential estrogen-progestin regimens.**

# OVARIAN CANCER

---

Prospective cohort studies concluded that the risk of fatal ovarian cancer is increased with long-term estrogen use.<sup>1468,1469,1470,1471,1472,1473,1474</sup> And some case-control studies reported a small increase in risk in ever users that was higher with long duration of use.<sup>1475</sup> However, by no means is it certain if this association between menopausal hormone use and ovarian cancer is real. A pooled analysis of 12 case-control studies could find no consistent evidence for an association between ovarian cancer and estrogen therapy.<sup>1476</sup> A meta-analysis concluded that there is a 14% increased risk of ovarian carcinoma among ever users of hormone therapy and that this risk increased to 27% with more than 10 years of hormone use.<sup>1477</sup> However, existing data included in this meta-analysis are subject to multiple potential biases. Among the six studies included in the analysis of duration of use, only one reported a statistically significant increase in risk with 10 or more years of hormone use. Another meta-analysis concluded that there was no clear evidence of an increased risk of ovarian cancer with estrogen therapy and no effect of increasing duration of hormone use.<sup>1478</sup>

Individual studies have been hampered by relatively small numbers, but the lack of a uniform and consistent association argues against a major impact of postmenopausal estrogen treatment on the risk of ovarian cancer. In a relatively large case-control study, no indication could be found for an association between postmenopausal hormone therapy and the risk of epithelial ovarian cancer, even with long-term treatment.<sup>1479</sup> Another case-control study reported a slightly increased risk, but it was not statistically significant.<sup>1480</sup> And another case-control study could find no increase in risk with ever use, past use, or long duration of use (and no differences comparing various estrogens and regimens).<sup>1481</sup> In a comparison of users and nonusers of hormone therapy in the state of Washington, the risk of epithelial ovarian cancer was increased among current and recent users of estrogen only, but not in past users or in users of estrogen-progestin.<sup>1482</sup>

The canceled estrogen-progestin arm of the WHI reported an increase in ovarian cancer that was not statistically significant (HR = 1.58; CI = 0.77–3.24), prompting this statement: “The possibility of an increased risk of ovarian cancer incidence and mortality remains worrisome and needs confirmation.”<sup>1466</sup> The Kaplan-Meier curves suggested an increasing effect over time, but this, too, was not statistically significant. There were no differences reported in histologic type, stage, or grade (but the small numbers made it essentially impossible to assess subcategories).

All of the studies found it difficult to control for most of the factors that influence the risk of ovarian cancer. This is because there are multiple factors, and information regarding each factor is not readily available.

## Factors that decrease the risk of ovarian cancer

- Use of steroid hormone contraceptives
- Pregnancy and parity; a greater effect with a recent pregnancy and pregnancy at older age<sup>1483,1484</sup>
- Breastfeeding<sup>1485</sup>
- Hysterectomy and tubal ligation<sup>1486</sup>
- NSAIDs<sup>1487</sup>

## Factors that increase the risk of ovarian cancer

- Increasing BMI<sup>1488,1489</sup>
- Infertility<sup>1490</sup>

Family history of ovarian and breast cancer<sup>1473</sup>

### Mixed reports on risk

- Alcohol intake<sup>1491,1492</sup>
- Cigarette smoking<sup>1493,1494,1495</sup>

Because of the many factors that influence the risk of ovarian cancer, case-control and cohort studies have found it difficult (in fact, impossible) to match cases and controls. Hormone users usually have used more oral contraceptives, have had fewer children, and are more educated and thinner. Adjustments have been made only for major factors, such as oral contraceptive use. The technique of meta-analysis is especially hampered by these confounding issues.

A major problem has been the impact of endometrioid cancers, an ovarian cancer that logically can be expected to be influenced by estrogen therapy. In many of the studies, the overall results are swayed by the increase in endometrioid cancers, a cancer that could originate in hormonally stimulated endometriosis.<sup>1496</sup> An accurate analysis requires a separate consideration of endometrioid cancers, but this is difficult because the small numbers do not allow effective subcategorization.

An Australian case-control study reported a statistically significant increase only in the 18 cases with endometrioid cancer.<sup>1497</sup> A Swedish case-control study reported a small but significant increase in risk with unopposed estrogen and with sequential estrogen-progestin, but 49% of the cases were endometrioid cancers.<sup>1475</sup> In a cohort report from the Breast Cancer Detection Demonstration Project, only endometrioid cancer was significantly increased.<sup>1469</sup> In the WHI, there were two endometrioid

cancers in the treated group and none in the placebo group.

It should also be noted that in one randomized trial, a case-control study, and two retrospective cohort analyses, no detrimental effect on prognosis after surgery for ovarian cancer could be detected in patients subsequently treated with hormones.<sup>1498,1499,1500,1501</sup>

**Overall, there is an indication that ever users of hormone therapy, no matter what formulation, progestin, or treatment regimen, have a small increase in the risk of epithelial ovarian cancers. The data are consistent with a promotional effect on existing malignancies because the risk diminishes after discontinuation of treatment. It is not difficult to review the epidemiologic data and conclude that there is no uniform story, that there are studies with both positive and negative results, and that most of the studies struggled with limited power because of small numbers and all of the studies are affected with confounding because of the difficulties in assessing and controlling for risk factors. The case-control and cohort studies inconsistently controlled for level of education, parity, oral contraceptive use, BMI, tubal ligation, and family history of ovarian and breast cancer (not a single study controlled for all the known risk factors!). It is a real possibility that there exists an increased risk for the hormonally sensitive ovarian cancer of the endometrioid type, and studies should carefully segregate this cancer for separate analysis. It is appropriate to emphasize the weak associations and the mixed story, but at the same time, the seriousness of the specific relationship dictates that the association between postmenopausal hormone therapy and the risk of ovarian cancer remains an unresolved issue.**

# COLORECTAL CANCER

---

A number of observational studies show a reduced risk of colorectal cancer in those taking hormone therapy.<sup>1502,1503,1504,1505,1506,1507,1508,1509,1510,1511</sup> The effect is greatest in current users and most studies have not indicated an increased effect with increasing duration of use; for example, the Nurses' Health Study (which found a 34% reduced risk in current users) could not demonstrate an added benefit with longer duration of hormone use.<sup>1512</sup> A reduction in fatal colon cancer has also been documented in current users.<sup>1505,1513</sup> In addition, there appears to be a reduced risk of polyps, especially large polyps, among current and recent hormone users. A reduced risk of colorectal cancer has also been reported with a high intake of phytoestrogens.<sup>911,1514</sup>

The canceled estrogen-progestin arm of the WHI reported a statistically significant 44% reduction in incidence of colorectal cancer, and this was achieved within only a few years of estrogen-progestin therapy.<sup>1040</sup> This result in the estrogen-progestin arm was not without concern however, in that the hormone-treated group had more advanced disease. Indeed, the conclusion was largely because of a difference in localized disease, 10 cases in the treated group and 36 in the placebo group. The results suggest that already-present cancers were influenced by hormone therapy to reach a more advanced stage, but that estrogen-progestin treatment reduced the risk of new colonic cancers. Unlike the combination regimen arm of WHI, there was no significant difference in the occurrence of colorectal cancer among hormone users or placebo group in the estrogen-alone WHI trial.<sup>1515</sup> However, it must be appreciated that the E-alone WHI trial had two important problems when contrasted with the EP trial: a very high drop-out rate and about 6,000 fewer participants. Furthermore, interpretability of WHI results must be confined to older postmenopausal women, an age group where carcinogenetic events are likely already underway. Analysis of the California Teacher study for risk of invasive colon cancer also revealed a decreased risk in postmenopausal women taking hormone therapy.<sup>1516</sup> In another case-control study, both oral and transdermal hormone therapies reduced the risk for developing colorectal cancer.<sup>1517</sup>

While the mechanisms underlying decreased colorectal cancer risk in HT users remain unclear, a few hypotheses have been put forth. The estrogen-induced change in the bile (a decrease in bile acids with an increase in cholesterol saturation) favors gallstone formation but may reduce the promotion (by bile acids) of colonic cancer. Other possible mechanisms include a direct suppressive effect of hormones on mucosal cell growth and an effect on beneficial mucosal secretions. The colon contains only estrogen receptor- $\beta$ , and the reduction in the risk of colonic cancer associated with postmenopausal estrogen therapy may reflect an antiproliferative activity of the beta

estrogen receptor. **This potential benefit deserves greater attention; colorectal cancer ranks third in women, both in incidence and mortality, and is more prevalent than cancers of the uterus or ovary.**<sup>1232</sup> **However, it should be noted that data supporting benefits of HT against colon cancer are not uniform, and until clarity is attained, there is no place for use of HT for prevention of colon cancer.**

# LUNG CANCER

---

The leading cause of cancer mortality in American men and women is lung cancer; 87% of the deaths occur in smokers and there are twice as many deaths from lung cancer in women as with breast cancer, annually.<sup>1232</sup> In a post hoc analysis that combined data from 0 to 4 years of follow-up with the treatment period in the canceled estrogen-progestin arm of the WHI, the incidence of non-small cell lung cancer, the type that accounts for about 80% of cases of lung cancer, was nonsignificantly increased, but the number of deaths and the number of poorly differentiated and metastatic tumors were increased in the treatment group.<sup>1518</sup> The cases were essentially limited to past and current smokers and to women over age 60. Although the WHI was not designed to assess lung cancer and chest imaging was not part of the study protocol, the results are provocative and concerning.

There is reason to believe lung cancer might be a target tissue for estrogen; at the same time, there is evidence to indicate that the impact is not uniformly detrimental and may even be protective. Estrogen receptors are present in normal and non-small cell lung cells.<sup>1519</sup> Case-control studies have indicated a decrease in risk for lung cancer and specifically for non-small cell tumors.<sup>1520,1521,1523,1524</sup> Two studies even reported a protective effect in hormone users against lung cancer especially in smokers.<sup>1525,1526</sup> One study reported decreased survival in women with lung cancer who used hormone therapy,<sup>1527</sup> but others did not detect a decreased survival in lung cancer patients with a history of hormone therapy.<sup>1528,1529</sup> The Nurses' Health Study found an increase in lung cancer mortality in women who underwent early bilateral oophorectomy and did not use estrogen.<sup>1210</sup> Gene expression is stimulated in non-small cell lung cancer cells by estrogen, and proliferation of these cells is reduced by an estrogen antagonist.<sup>1530,1531</sup> In the Rancho Bernardo cohort study, there was no significant association between hormone use and lung cancer; however, there was a suggestion that women over age 55 had a small nonsignificant increase in lung cancer; no such increase was noted in younger women using hormones (although not statistically significant, the results with stratification by age are similar to the WHI findings).<sup>1532</sup> **The overall data, including the WHI analysis, suggest that hormone therapy initiated in older women with a history of smoking may promote the growth of existing lung cancers. The WHI evidence in women under the age of 60 is reassuring, and case-control and cohort data that reflect hormone use in a younger population than in the WHI indicate that estrogen is associated with some protection against lung cancer.**

# CERVICAL CANCER

---

Any association between postmenopausal hormone therapy and cancer of the uterine cervix has not been extensively studied. Evidence from one cohort study and one case-control study is reassuring and indicates that the postmenopausal use of estrogen does not increase the risk of cervical cancer.<sup>1533,1534</sup> Indeed, these studies observed protection against cervical cancer in the estrogen users, but this may reflect detection bias (more examinations and Pap smears in estrogen users). Another case-control study suggested an increased risk in cervical adenocarcinomas, but there were only 13 cases.<sup>1535</sup> In a follow-up report of 120 women treated for stage I and II cervical cancers, no associations with hormone therapy as regards survival or recurrence were observed.<sup>1536</sup>

# MALIGNANT MELANOMA

---

The possibility of a relationship between exogenous hormones and cutaneous malignant melanoma has been the subject of many observational studies. Accurate evaluation utilizing the Royal College of General Practitioners and Oxford Family Planning Association prospective cohorts and accounting for exposure to sunlight did not indicate a significant difference in the risk of melanoma comparing users of oral contraceptives to nonusers.<sup>1537,1538</sup> Results with the use of postmenopausal estrogen therapy have not indicated a major impact. A slightly increased risk with long-term use of estrogen was noted in one case-control study (a conclusion based on 10–20 cases and not achieving statistical significance), whereas other case-control studies could find no association with postmenopausal estrogen treatment.<sup>1539,1540,1541,1542,1543</sup> Others have reported slight increases in the risk of malignant melanoma associated with the use of exogenous estrogen, but all failed to reach statistical significance.<sup>1533,1539,1544</sup> In an analysis of cancer incidence in a Swedish cohort of women prescribed postmenopausal hormone therapy, no increase in malignant melanoma was observed.<sup>1281</sup> On the adverse side, a Dutch case-control study reported a significant 42% increase in melanoma risk in postmenopausal hormone users, but it was based on only 33 cases and there was no consideration of sun exposure.<sup>1545</sup> In post hoc analyses of the two WHI trials, HT did not affect the incidence of melanoma.<sup>961</sup> **No solid evidence exists to suggest an increase in risk for cutaneous malignant melanoma with the use of hormone therapy.**

# METABOLIC EFFECTS

---

Severe hypertriglyceridemia and pancreatitis can be precipitated by the administration of oral estrogen to women with elevated triglyceride levels.<sup>1546,1547</sup> In women with triglyceride levels between 250 and 500 mg/dL, estrogen should be provided with great caution, and a nonoral route of administration is strongly advised in those being considered for hormone therapy. **The triglyceride response to estrogen is rapid, and a repeat level should be obtained in 2–4 weeks. If levels are substantially increased, hormone therapy must be discontinued. A level greater than 500 mg/dL represents an absolute contraindication to estrogen treatment.** Triglyceride levels in the normal range were not affected by progestins in the PEPI trial.<sup>569</sup> An exaggerated triglyceride response to estrogen might be attenuated by a progestin, especially a progestin of the 19-nortestosterone family, and, therefore, the daily, combination method of treatment could be considered for women with slightly elevated triglycerides. **However, the treatment of choice is transdermal estrogen, a route of administration that does not affect triglyceride levels; indeed, triglyceride levels markedly elevated in response to oral therapy return to normal when route of administration is changed to transdermal administration.**<sup>518,521</sup>

Although physiologic and epidemiologic evidence indicates that estrogen use increases the risk of gallbladder disease, the overall impact is not great. The Nurses' Health Study indicated that oral estrogen therapy may carry a 1.5- to 2.0-fold increased risk of gallbladder disease.<sup>1548</sup> The risk of cholecystectomy appeared to increase with dose and duration of use and to persist for 5 or more years after stopping treatment. Other observational studies also reported increased risks of cholecystectomy in past and current users of estrogen.<sup>1192,1549,1550</sup> At least two case-control studies concluded that estrogen use is not a risk factor for gallstone disease in postmenopausal women, although the statistical power was limited by small numbers.<sup>1551,1552</sup> A cross-sectional study of gallstone disease could detect no association with postmenopausal hormone treatment.<sup>1553</sup> In the HERS clinical trial, the relative risk of gallbladder disease was 1.38; however, this did not achieve statistical significance.<sup>1190,1554</sup> The risk of gallbladder disease and gallbladder surgery was significantly increased in both the estrogen-progestin and estrogen-only WHI hormone trials.<sup>1555</sup> This amounted to an increase of 20–30 cases per 10,000 per year in this older population of postmenopausal women. The routine, periodic use of blood chemistries is not cost-effective, and careful monitoring for the appearance of the symptoms and signs of biliary tract disease suffices. It is not certain that this potential problem is limited to oral therapy. Nonoral routes of estrogen administration have been reported to inconsistently increase biliary cholesterol saturation (a lithogenic response).<sup>1556,1557</sup> In the Million Women Study in the

United Kingdom, the risk of gallbladder disease was actually lower with transdermal estrogen compared with oral estrogen, but the many problems with this observational cohort make it difficult to allow a confident statement.<sup>1558</sup>

# Weight Gain

Weight gain in midlife is common, and lifestyle remains the dominant contributor to this occurrence; specifically, the balance of dietary intake and exercise is tilted toward excessive caloric intake because of a decline in physical fitness and the age-related decrease in basal metabolic rate. Despite common perception, the weight gain in women around menopause is not due to the hormonal changes associated with menopause.<sup>398,1557,1558,1559,1560</sup> Likewise, postmenopausal hormone therapy cannot be blamed for weight gain. The large Rancho Bernardo prospective cohort study and the randomized PEPI clinical trial documented that hormone therapy with or without progestin does not cause an increase in body weight.<sup>1561,1562</sup> In fact, in the PEPI trial, the hormone-treated groups actually gained less weight than the placebo group. In the 2-year clinical HOPE trial assessing the efficacy of lower estrogen-progestin doses, hormonal treatment was associated with lesser increases in body weight and body fat compared with placebo.<sup>1563</sup>

After menopause, there is an increase in abdominal fat and total body fat that is associated with an increase in insulin resistance, a consequence of the decrease in estrogen levels.<sup>1564</sup> Postmenopausal estrogen therapy maintains the premenopausal body habitus, preventing the increases in abdominal fat, insulin resistance, blood pressure, and diabetes mellitus associated with estrogen deficiency.<sup>1565</sup> Estrogen (with or without progestin) prevents the tendency to increase central body fat with aging.<sup>1036,1037,1038,1039,1566</sup> This would inhibit the interaction among abdominal adiposity, hormones, insulin resistance, hyperinsulinemia, blood pressure, and an atherogenic lipid profile that results in the metabolic syndrome. An excellent randomized trial in Denmark documented less weight gain with hormone therapy because of a smaller increase in fat mass.<sup>1567</sup> In a substudy of the WHI, assessments of body composition by dual-energy x-ray absorptiometry (DEXA) indicated that estrogen-progestin users had less fat and greater lean mass.<sup>1568</sup> This same salutary effect on central body fat has also been observed with tibolone treatment.<sup>1569</sup> **Rather than causing body weight gain, therefore, postmenopausal hormone therapy reduces the increase in insulin resistance and abdominal fat usually seen with aging, with a beneficial impact on the risks of hypertension, diabetes mellitus, and dyslipidemia.**

# **PRESENTATIONS REQUIRING CLINICAL JUDGMENT**

---

# Patients with Endometrial Cancer, Endometrioid Tumors, and Endometriosis

Gynecologic oncologists have reported that hormone therapy can be safely considered in patients who have had stage I and stage II adenocarcinoma of the endometrium without fear of an increased risk of recurrence or a decrease in disease-free interval.<sup>1570,1571,1572,1573</sup> In a matched cohort of 249 women with stage I, stage II, and stage III endometrial cancer with a long follow-up, there was no indication of an increase in recurrent disease with hormone therapy.<sup>1574</sup> Similar negative results were reported in a Turkish case-control study.<sup>1575</sup> The only randomized trial, organized by the Gynecologic Oncology Group, closed prematurely because of recruitment difficulties following the publicity associated with the WHI.<sup>1576</sup> Nevertheless, a total of 1,236 patients with stage I or stage II endometrial cancer were randomized to either estrogen-only or placebo, and although the participants constituted a low-risk group, the recurrence rate was low, 14 recurrences with 5 deaths in the treatment group and 12 recurrences and 9 deaths in the placebo group. If a high-risk tumor is estrogen- and progesterone receptor negative, it seems reasonable to allow immediate initiation of hormone therapy. Because the latent period with endometrial cancer is relatively short, a period of time under observation (5 years) without evidence of recurrence would increase the likelihood of long-term safety on an estrogen program. **We recommend that hormone therapy be avoided in patients with high-risk tumors that are receptor positive until 5 years have elapsed. The combination of estrogen-progestin is recommended in view of the potential protective action of the progestational agent. A similar approach makes sense for patients previously treated for endometrioid tumors of the ovary. In view of the fact that adenocarcinoma has been reported in patients with pelvic endometriosis and on unopposed estrogen, and that estrogen-alone may allow for recurrence of endometriosis, the combined estrogen-progestin program is also advised in patients with a past history of endometriosis.**<sup>1577,1578,1579,1580,1581,1582</sup>

# Should a Postmenopausal Woman Who Has Had Breast Cancer Use Hormones?

The argument that postmenopausal hormone therapy should not be given to women who have had breast cancer is a reasonable one. It is based on the recognition of a large body of evidence that indicates that breast cancer is often a hormone-responsive tumor. The overriding fear of many clinicians (and patients) is that metastatic cells are present (perhaps being controlled by various host defense factors) that will be susceptible to stimulation by exogenous hormones.<sup>1583</sup> However, many women who have had breast cancer are aware of the benefits of postmenopausal hormone treatment and are asking clinicians to help make this risk-benefit decision. In addition, some women suffer from such severe hot flushing and vaginal dryness that they are willing to consider hormonal treatment. Tibolone treatment of breast cancer survivors is relatively contraindicated as discussed earlier in this chapter.

The rate of recurrent breast cancer in hormone users has been reported in multiple case series with more than 1,000 breast cancer survivors.<sup>1584,1585,1586,1587,1588,1589,1590,1591,1592,1593,1594,1595,1596,1597,1598,1599,1600</sup> It is reassuring that the recurrence rates in these reports are not different from the expected rate of breast cancer recurrence. In one series, 25 and then 77 women with breast cancer ranging from in situ to stage III disease received estrogen-progestin therapy for 24–82 months; the recurrence rate was not greater than that expected.<sup>1587,1588</sup> From this group of patients, 41 breast cancer survivors receiving hormone therapy had the same outcomes when compared with 82 women selected from a cancer registry and not taking hormones.<sup>1588</sup> In a report from Australia, 90 women with a history of breast cancer who were given a combination of estrogen and progestin had lower mortality and recurrence rates; however, the dose of progestin was very high (which in itself can be therapeutic) and treatment was not randomized.<sup>1592</sup> In a follow-up of 319 women treated with estrogen after treatment for localized breast cancer, only one patient developed recurrent disease.<sup>1593</sup> In a matched-controlled series of 277 breast cancer survivors, there was no difference in the estrogen-treated group and the control group for recurrent disease.<sup>1600</sup> A series with 114 women who received hormone treatment had a low rate of recurrence.<sup>1589</sup> These patients have had both positive and negative nodes and positive and negative estrogen receptor status. Although the results conform to an incidence of recurrent disease no greater than expected, the outcomes can reflect biases in clinician and patient decision-making that can only be overcome with a proper long-term, randomized clinical trial.

A case-control study of hormone therapy after breast cancer actually found a

significant reduction in risk of recurrent disease, breast cancer mortality, and total mortality in hormone users.<sup>1601</sup> Again, these are reassuring observational data that hormone therapy after breast cancer has no adverse impact on recurrence.

A U.S. trial at the University of Texas M.D. Anderson Cancer Center provided estrogen to randomized women who had been treated for localized stage I and stage II breast cancer with either ER-negative or ER status unknown tumors.<sup>1602</sup> After 5 years of follow-up, 56 women in the trial receiving estrogen were compared with 243 women with comparable disease not receiving estrogen; there was no adverse effect of estrogen treatment on disease-free survival.<sup>1603</sup>

A multicenter, large case-control study of women younger than 55 years with breast cancer concluded that the use of oral contraceptives or postmenopausal hormone therapy either before or after diagnosis did not increase the risk of the first breast cancer or recurrent breast cancer.<sup>1604</sup> This negative finding was not changed by duration of use or age of oral contraceptive use or by BMI, duration of use, or type of postmenopausal hormone use (estrogen only or combined estrogen-progestin).

## **The HABITS Trial**

“Hormonal replacement therapy After Breast cancer—Is it Safe?” (HABITS) began in multiple centers in Sweden in May 1997, to compare breast cancer survivors treated for at least 2 years with hormone therapy with treatment other than hormones. A similar trial was initiated in Stockholm. Because recruitment was slower than anticipated, the two trials agreed in February 2002 to pool their patients and to use a joint safety and monitoring committee. In October 2003, the safety committee recommended that the trial be discontinued because there were 26 women in the treated group with new breast cancers compared with 7 in the nontreated group. The HABITS trial was terminated in December 2003.<sup>1605</sup> Confronted with this outcome, the Stockholm investigators decided to cancel their trial as well even though the hazard ratio in the Stockholm patients was 0.82 (CI = 0.35–1.9).

HABITS was a randomized but not placebo-controlled trial in which hormone therapy was compared to management without hormones in women with menopausal symptoms who had been previously treated for stage I or stage II breast cancer. Concomitant use of tamoxifen treatment was allowed in the HABITS patients but not of aromatase inhibitors. Hormone therapy consisted of the variety of products and methods on the Swedish market, but not tibolone. Most of the treated women used products with the relatively high dose of 2 mg estradiol. After 4 more years of follow-up of 442 women, there were 39 cases of new breast cancer in women using hormone therapy compared with 17 in the nontreated group, for a hazard ratio of 2.4 (CI = 1.3–4.2).<sup>1606</sup>

It is important to appreciate some significant concerns related to the study design and methodology in HABITS. The treated and nontreated groups of women were very different in terms of characteristics and behaviors. More of the women in the treated group had hormone receptor-positive cancers (62.3%) compared with the nontreated group (54.5%). Protocol deviations occurred; 11 women in the treated group never received hormones, whereas 43 in the nontreated group did receive hormones. There was a very wide range of exposure times, ranging from 0 to 80 months. About one-third of the women who received hormones changed products during the study. The method of analysis of the HABITS data was intent-to-treat, and thus the impact of these differences cannot be ascertained.

Analysis of the new breast cancers in HABITS (either local recurrences or contralateral cancers) indicated statistically significant increases only in hormone receptor-positive cancers. However, when adjusted for use of hormone therapy before diagnosis of the original breast cancer, use of tamoxifen, and hormone receptor status, the hazard ratio was 2.2 with a CI that included 1 (1.0–5.1), which by definition, while close, is not statistically significant.

The Stockholm trial reported in 2005, after a median follow-up of 4.1 years, 11 new breast cancers in the treated arm and 13 new breast cancers in the nontreated arm.<sup>1607</sup> Why there is difference between the Stockholm trial and HABITS? The HABITS investigators suggest that their patients had more node-positive disease and thus “probably” had more women with subclinical disease that would be stimulated by hormone therapy. Another possibility was more protection with higher tamoxifen use in the Stockholm trial, although the HABITS trial could detect no impact of tamoxifen. The HABITS investigators believe that another possible explanation was the greater use of norethindrone and norethindrone acetate in HABITS compared with the use of medroxyprogesterone acetate in Stockholm. All of these explanations are speculations; the difference between the two trials remains and calls into question the reliability and accuracy of the data.

The cancellation of HABITS and the Stockholm trials made it impossible for the English and Italian trials to continue recruitment, and they were also canceled. Thus, the scientific community was left with many questions, but without ongoing efforts to elucidate answers. In our view, the existing data on risk of breast cancer recurrence or new-onset cancers related to hormone therapy are far from being definitive.

**Although intuitively it seems that the risk/benefit ratio would be more favorable in the presence of negative nodes, negative receptors, and small tumors, are negative estrogen and progesterone receptor assessments by themselves sufficient to conclude that the cancer is not sensitive to hormones? And if the patient is in the high cure category, does it make any difference what the receptor**

**status is? The answers to these questions are not known. Receptor status is not absolute; it is always a relative measure and can change over the course of disease progression.**

**Patients and clinicians have to incorporate all of the previously mentioned considerations into medical decision-making. But when all is said and done, patients have to take an unknown risk if they want the benefits of hormone treatment; the prescribing clinicians too take an unknown medical-legal risk. Some patients who are burdened by severe menopausal symptoms that remain unresponsive to nonhormonal interventions may and do choose to take estrogen, judging the benefits to their quality of life with hormone use to be worth the unknown risk. Until definitive data are available from clinical trials, clinicians should support patients in this decision. Other patients will prefer to avoid any unknown risks. These patients, too, deserve support in their decision.**

# IMPLICATIONS OF HORMONE THERAPY FOR WOMEN WITH DIABETES MELLITUS

---

Estrogen can improve the metabolic changes associated with diabetes. Indeed, in prospective studies of postmenopausal women with type 2, non-insulin-dependent diabetes mellitus, estrogen-only or estrogen-progestin therapy improved all glucose metabolic parameters, including insulin resistance, the lipoprotein profile, and measurements of androgenicity.<sup>1049,1050,1466,1608,1609,1610,1611,1612</sup> One study, however, could detect no impact with transdermal administration.<sup>1610</sup> These changes should reduce the risk of cardiovascular disease, and in a very large cohort of 24,420 women from the Northern California Kaiser Permanente Diabetes Registry, current use of hormone therapy reduced the risk of myocardial infarction, but in women with a recent heart attack, an increased risk of a recurrent myocardial infarction was observed in hormone users (again a difference between primary prevention and secondary prevention).<sup>1613</sup> Tibolone also has a beneficial impact in short-term studies on insulin resistance in normal women and in women with non-insulin-dependent diabetes mellitus.<sup>720,744</sup> Raloxifene, a SERM, has no effects on glucose metabolism or insulin sensitivity in normal women but exerts a modest improvement in insulin resistance in women who are hyperinsulinemic.<sup>1614,1615</sup>

# IMPLICATIONS OF HORMONE THERAPY FOR WOMEN WITH LIVER DISEASE

---

In an evaluation of liver chemistries in a group of patients with primary biliary cirrhosis, standard hormone therapy doses produced no adverse changes over a period of 1 year.<sup>1616</sup> Estrogen treatment, either oral or transdermal, has not been associated with worsening cholestasis in women with primary biliary cirrhosis.<sup>1617,1618</sup> We recommend measurement of liver chemistries after 1 month of treatment and every 6 months, with continuing hormone therapy in the absence of deterioration.

A French cohort study concluded that hormone therapy protects against the progression of hepatic fibrosis from chronic hepatitis C.<sup>1619</sup> Most individuals with hepatitis C virus infection develop chronic disease, a major cause of worldwide morbidity and mortality from liver fibrosis. The time course is relatively slow, taking years to progress from infection to cirrhosis. Progression is increased by consumption of alcohol, excess body weight, diabetes, and the degree of fatty degeneration in the liver. The severity of liver fibrosis is greater in men, and progression in women accelerates around age 60. In vitro and animal experiments have documented a beneficial effect of estrogen on the development of fibrosis, an effect that is consistent with the data in the French study finding greater progression of fibrosis after menopause and amelioration with hormone therapy. Another French study, a retrospective survey, reported a greater rate of fibrosis progression with hepatitis C in postmenopausal and nulliparous women and a lower rate in postmenopausal women treated with hormone therapy compared with nontreated women.<sup>1620</sup>

Liver fibrosis from hepatitis C infection is not the result of viral destruction of hepatic cells. Fibrosis is a response to the inflammatory activity incited by the virus. By now, it is well known that estrogen can suppress the secretion of proinflammatory cytokines. Because of the prevalence of hepatitis C infection, these French reports are very important. Many clinicians are reluctant to prescribe hormone therapy to women with a history of liver disease. However, as long as liver enzymes are normal, there is no reason to withhold treatment, and these French studies indicate that estrogen therapy is beneficial. Postmenopausal hormone therapy should be discussed when women present with a history of hepatitis C infection.

The lesson learned from the above conditions is that estrogen-alone and estrogen-progestin treatment including contraception is acceptable as long as liver enzyme function is normal. This caveat is also true for women who have undergone organ transplantation surgery.<sup>1621</sup>

**Hormone therapy should be avoided in the setting of chronically impaired liver**

**function.**

# HORMONE TREATMENT IN THE PRESENCE OF UTERINE LEIOMYOMAS (FIBROIDS)

---

Uterine leiomyomas are monoclonal tumors that retain sensitivity to both estrogen and progestin (Chapter 3); therefore, it is appropriate to be concerned over whether leiomyomas will grow in response to postmenopausal hormone therapy. As assessed by vaginal ultrasonography, the number and size of uterine leiomyomas increased in women being treated with an intramuscular depot form of estrogen-progestin therapy.<sup>1622</sup> However, the hormonal dose in this study was relatively high, certainly higher than standard regimens. At the end of 1 year, women with small asymptomatic fibroids administered with a daily combination of 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate had no sonographic evidence of growth in contrast to an increase in size observed with transdermal estradiol (50 µg) and 5 mg medroxyprogesterone acetate daily (a response that probably reflects the effect of a higher progestin dose).<sup>1623</sup> In follow-up studies with standard doses of estrogen-progestin or tibolone, ultrasonography detected no changes in uterine or myoma volumes.<sup>1624,1625,1626</sup> Clinical experience indicates that fibroid tumors of the uterus almost always are not stimulated to grow by the commonly utilized postmenopausal doses of estrogen and progestin. Tibolone and raloxifene also do not stimulate myoma growth.<sup>757,1627,1628</sup> Interestingly, however, a vulvar leiomyoma with growth stimulated by estrogen-progestin treatment has been reported.<sup>1629</sup> A case-control study could find no statistically significant increase in the risk of uterine sarcomas associated with estrogen therapy.<sup>1630</sup> **Nevertheless, in women with known fibroids, periodic surveillance by pelvic examination and transvaginal ultrasound scans is prudent.**

# IMPLICATIONS OF HORMONE THERAPY FOR WOMEN WITH SLEEP APNEA

---

The low prevalence of sleep apnea in premenopausal women and the increased frequency after menopause suggest a hormonal link. In careful studies, however, postmenopausal hormone therapy had no significant adverse effect on sleep-disordered breathing in women with more than mild obstructive sleep apnea.<sup>1631,1632</sup> And other sleep laboratory studies found that estrogen treatment reduced difficulties with sleep-disordered breathing.<sup>1633,1634,1635</sup> The slight rise in basal body temperature induced by a progestational agent may be sufficient to disrupt the quality of sleep in some women, a problem that may be more noticeable with a sequential regimen and with nighttime administration.

# IMPLICATIONS OF HORMONE THERAPY FOR WOMEN WITH ASTHMA

---

In some women, changes in asthma activity have been noted to correlate with phases of the menstrual cycle. The impact of postmenopausal hormone therapy on asthma activity has not been well investigated, but there is an indication that estrogen has an adverse effect. A worsening in spirometry assessment was detected in asthmatics after estrogen therapy; however, the difference was judged to be subclinical, and the patients did not report any changes in their perceptions of symptoms.<sup>1636</sup> A similar study could detect no adverse effects with either discontinuation or reinitiation of estrogen treatment.<sup>1637</sup> And another study concluded that estrogen therapy improved asthma and decreased the need for glucocorticosteroid treatment.<sup>1638</sup> In a prospective assessment of a cohort of women, the use of postmenopausal hormone therapy (estrogen with or without progestin) was associated with a 50% increase in the risk of developing adult-onset asthma, and the risk was greater with long-term use and with higher doses of estrogen.<sup>1639</sup> Similar results were reported in the French E3N cohort study, except an increased risk was observed only in estrogen-alone users.<sup>1640</sup> In the Nurses' Health Study, newly diagnosed asthma was increased about twofold by hormone therapy.<sup>1641</sup> Because hormonal changes may precipitate asthmatic activity (e.g., catamenial asthma), attention should be directed to the symptomatic pattern and consideration given to the daily, continuous, combined regimen.

# MENOPAUSAL HORMONE THERAPY, DEMENTIA, AND COGNITION

---

The WHIMS analyzed the effects of hormone therapy on cognition and on risk of dementia in postmenopausal women participating in the WHI hormone trials. Contrary to earlier assumptions that menopausal estrogen therapy should offer cognitive benefit, the WHIMS concluded that estrogen-progestin and estrogen-only therapy actually increased the risk for dementia in women 65 years and older and did not prevent mild cognitive impairment.<sup>361,362,363,1642</sup> However, the only statistically significant finding in the estrogen-progestin arm was increased dementia (vascular dementia, not Alzheimer disease) in elderly women (22 cases in the treated group and 10 cases in the placebo group) who were 75 and older and who had been exposed to a relatively short term of estrogen-progestin therapy. The estrogen-only arm of the WHI contained more obese women with pre-existing cardiovascular disease, and the trend for an increase in dementia likely reflected an effect in older women with established atherosclerosis. Both timing and duration hypothesis, similar to ones proposed for cardiovascular effects of hormone therapy, emerged in the wake of WHIMS, raising questions that outcomes may differ for those women who initiate hormone therapy early in the course of menopause and in those who following early initiation continue to use hormone therapy for longer durations; hypotheses proposed that unlike WHIMS, women initiating hormone therapy proximate to final menses and who then continue to use hormones for prolonged periods may be protected against dementia. The WHI report recognized that these hypotheses could not be tested in this clinical trial because of the older age of the study participants and remoteness of hormone initiation from onset of menopause. A prospective study of a homogeneous population in Utah (thus minimizing, if not eliminating, the healthy user bias) concluded that a reduction in the risk of Alzheimer's required long-term treatment, initiated at least 10 years before symptoms of dementia appear.<sup>359</sup> Thus, any favorable effects of hormone therapy on cognition and on the risk of Alzheimer disease, if any, appear to be limited to women who initiate treatment close to onset of menopause. However, KEEPSCog, an ancillary study to KEEPS that examined the timing hypothesis as regards effects of hormone therapy initiated within 3 years of onset of menopause, similarly failed to identify cognitive benefit.<sup>369</sup>

## OTHER CONDITIONS

---

Close surveillance is indicated for some patients with seizure disorders and migraine headaches. Patients with migraine headaches often improve with strategies that minimize fluctuations in circulating hormone levels that can serve to trigger headaches. Transdermal route of estrogen administration is preferable given stable hormone profile in comparison to following oral ingestion. Conditions that do not represent contraindications include controlled hypertension, smoking, and varicose veins. The belief that estrogen is potentially harmful with each of these clinical situations is derived from old studies of high-dose oral contraceptives. Estrogen in appropriate doses is acceptable in the presence of these conditions.

No other cancers (in addition to those mentioned previously) are known to be adversely affected by hormone therapy. Postmenopausal hormone therapy can be administered to all patients with a history of cervical, ovarian, or vulvar malignancies.

Highly unusual anecdotal happenings include the following:

- Provocation of chorea by estrogen therapy in a woman with a history of Sydenham chorea<sup>1643</sup>
- Exacerbation of pulmonary leiomyomatosis by estrogen therapy<sup>1644</sup>
- Psychiatric symptoms in response to estrogen in patients with acute intermittent porphyria<sup>1645</sup>
- Idiosyncratic ocular symptoms associated with estrogen<sup>1646</sup>
- Sudden deafness and tinnitus with commencement of hormone therapy<sup>1647</sup>
- Resolution of an infection with *Trichomonas vaginalis* after discontinuation of estrogen-progestin therapy<sup>1648</sup>
- Successful treatment of Sjögren syndrome with tibolone<sup>1649</sup>

# **BEYOND SYMPTOM CONTROL**

---

Some Additional Benefits of Hormone Therapy.

# Estrogen Therapy and Autoimmune Diseases

## Rheumatoid Arthritis

No clear conclusion is apparent from the studies of effects of estrogen on rheumatic diseases, especially rheumatoid arthritis. Some have indicated that exogenous estrogen, either in oral contraceptives or as postmenopausal therapy, protects against the onset of rheumatoid arthritis, whereas other studies find no such effect.<sup>1650,1651,1652,1653</sup> Existing data are hampered by small numbers. In a randomized, placebo-controlled clinical trial, maintenance of standard serum estradiol levels was associated with improvements in some measurements of disease activity in patients with rheumatoid arthritis.<sup>1654</sup> Reassuringly, there has been no evidence that postmenopausal hormone therapy aggravates rheumatoid arthritis or causes a flare in disease activity. **Postmenopausal hormone therapy can be safely considered in symptomatic postmenopausal women with rheumatoid arthritis. Hormone therapy can additionally be considered as a fracture risk reduction strategy in appropriately selected patients (skeletal effects of hormone therapy are discussed in the section on osteoporosis).**

## Systemic Lupus Erythematosus

In the Nurses' Health Study, the use of postmenopausal estrogen was associated with approximately a twofold increase in SLE, an observation based on 30 cases in past and current users of estrogen.<sup>1655</sup> In a follow-up of 60 postmenopausal women with stable SLE, no adverse effects of hormone therapy could be detected.<sup>1656</sup> Patients with SLE develop early atherosclerosis and those treated with glucocorticoids are especially at greater risk for osteoporosis,<sup>1657</sup> but there is a concern that exogenous estrogen will increase flares and stimulate thrombosis because of an existing hypercoagulable state in these patients. Importantly, no increase in arterial or venous thrombosis was observed with postmenopausal hormonal therapy in a longitudinal study of a large cohort of U.S. women with SLE.<sup>1658</sup> **Postmenopausal hormone therapy can be considered in patients with stable or inactive disease, without renal involvement, or high antiphospholipid antibodies, and transdermal route for estrogen administration is advised.**

# Estrogen Therapy and Osteoarthritis

Osteoarthritis is the most common form of arthritis in older people, and its prevalence increases rapidly in women after menopause. Increasing severity of osteoarthritis of the knee has been reported to be associated with increasing bone density and the current use of postmenopausal hormone therapy in middle-aged women.<sup>1659</sup> However, estrogen treatment reduced osteoarthritis in a monkey model, and a cross-sectional study concluded that current users of estrogen had a reduced prevalence of osteoarthritis of the hip, and there was protection against the severity of osteoarthritis, with a greater effect with longer duration of use.<sup>1660,1661</sup> Arthritic complaints are a major side effect of the low estrogen state induced in women with breast cancer treated with aromatase inhibitors, and osteoarthritis develops more frequently in women with the lowest levels of estrogen.<sup>1662,1663</sup> Because there are no known treatments that modify the course of osteoarthritis, this potential benefit of postmenopausal hormone therapy deserves study in appropriately designed randomized clinical trials.

# Estrogen Therapy and the Oral Cavity

Oral complaints are common among postmenopausal women. The administration of estrogen provides significant relief from oral discomfort, burning, bad taste, and dryness<sup>1664</sup>. Estrogen therapy is also associated with a reduction in periodontal disease, including gingival inflammation and bleeding.<sup>1665,1666</sup> These changes may reflect epithelial responses to estrogen by the oral mucosa, in a manner similar to that of the vaginal mucosa. Oral alveolar bone loss (which can lead to loss of teeth) is strongly correlated with osteoporosis, and the salutary effect of estrogen on skeletal bone mass (discussed later in the section on osteoporosis) is also manifested on oral bone.<sup>1667,1668</sup> In the Leisure World Cohort, tooth loss and edentia were significantly reduced in estrogen users compared with nonusers (with a reduced need for dentures), and this beneficial effect was greater with increasing duration of estrogen use.<sup>1669</sup> Approximately a 25% reduced risk of tooth loss in current users of estrogen was observed in the Nurses' Health Study.<sup>1670</sup>

# Estrogen Therapy and the Larynx

Professional singers have used hormone therapy to prevent what they view as unwanted voice changes associated with menopause.<sup>1671</sup> In prospective studies, objective voice analyses have documented a more androgenic change in voice in the early postmenopausal years with a lesser change associated with estrogen treatment; although slightly attenuated by the addition of a progestin, the overall effect of estrogen treatment is to preserve voice quality.<sup>1672,1673,1674</sup> Laryngeal cytology demonstrated epithelial maturation in women on estrogen treatment, and these women reported better voice quality and fewer voice changes compared with a control group.<sup>1675</sup>

# Estrogen Therapy and Vision

There is some evidence that estrogen therapy improves visual acuity (or lessens the visual deterioration during the early postmenopausal years), perhaps due to a beneficial effect on lacrimal fluid.<sup>1676,1677</sup> An increased prevalence of keratoconjunctivitis sicca (dry eyes) in menopausal and postmenopausal women, with symptoms of scratchiness, burning, and photophobia, is recognized by ophthalmologists.<sup>1678</sup> Although reports concluded that there was no effect or even a worsening of dry eyes with hormone therapy, a clinical trial indicated relief from dry eye symptoms with the use of topical estrogen eye drops.<sup>1679,1680,1681,1682,1683</sup>

There is evidence that postmenopausal estrogen therapy has an effect that protects against lens opacities (cataracts).<sup>1684,1685,1686,1687,1688</sup> Estrogen-alone or estrogen-progestin treatment also lowers intraocular pressure in postmenopausal women with normal eyes or glaucoma.<sup>1682,1689,1690,1691</sup> In the Nurses' Health Study, current use of estrogen-progestin, but not estrogen alone, was associated with a reduced risk of glaucoma.<sup>1692</sup>

There is modest evidence that the risk of age-related macular degeneration is reduced in estrogen users, but some studies could detect no effect.<sup>1693,1694,1695,1696,1697</sup>

# Estrogen Therapy and Age-Related Hearing Loss

Demineralization of the cochlear capsule occurs with aging and with metabolic bone diseases, such as cochlear otosclerosis. This demineralization is associated with neural hearing loss. Postmenopausal women (age 60–85 years) who have lower than average femoral neck bone mass have an increased risk of having a hearing loss.<sup>1698</sup> This association between femoral neck bone mass and age-related hearing loss suggests that prevention of bone loss with estrogen therapy might also be exerted on the cochlear capsule. In addition, estrogen may have beneficial effects on cochlear blood flow and central nervous system auditory neurons. Hearing impairment in a Turkish family was associated with an inactivating mutation for estrogen receptor- $\beta$ .<sup>1699</sup> Mouse knockout studies indicate that estrogen receptor- $\beta$  is important for the prevention of age-related hearing loss.<sup>1700</sup> Studies have documented better hearing levels in estrogen users, with an indication that the addition of a progestin attenuated the favorable effect of estrogen.<sup>1701,1702</sup> Interestingly, however, older age at menopause and longer duration of postmenopausal HT were associated with a higher risk of hearing loss.<sup>1703</sup>

# HOW LONG POSTMENOPAUSAL HORMONE THERAPY SHOULD BE CONTINUED?

---

The answer to this question is relatively straightforward. Periodic reassessments of risk-to-benefit ratio must be undertaken in hormone-using women, and **duration of therapy should be guided by the principles of “net benefit” and “do no harm.”** Clarity on persistence of the indication for which hormone therapy was initiated in the first place and overall risk profile of the user should be periodically assessed, and a woman should continue her postmenopausal hormone regimen as long as the potential for benefit outweighs that of harm. The symptom, metabolic, and skeletal effects of hormones revert early following discontinuation, with longer times needed for others may take years (e.g., dissipation in breast cancer risk) after discontinuation.

Resurgence in menopausal symptoms after discontinuing hormonal therapy is not uncommon, and resulting disruption in quality of life has been reported in at least 25% of previously treated women and, in one Swedish study, 70%.<sup>1704,1705</sup> It seems intuitively advantageous to encourage a tapering, gradual discontinuation program to minimize recurrence of menopausal symptoms, although randomized trials comparing gradual discontinuation with abrupt cessation found no benefit with a tapering regimen.<sup>1706,1707,1708,1709</sup> Neither the recurrence rate nor the severity of menopausal symptoms differs comparing the two methods.

# SHOULD WOMEN REMOTE FROM MENOPAUSE BE STARTED ON HORMONE THERAPY?

---

The positive impact of hormone therapy on the bone has been demonstrated to take place even in women older than age 65.<sup>1710,1711</sup> This is a strong argument in favor of treating women remote from menopause who have never been on estrogen and who cannot take or afford the other alternatives for bone preservation. Estrogen treatment that is not begun until after age 60 can with long-term use achieve bone densities nearly but not totally comparable with those in women taking estrogen from menopause, and estrogen use between the ages of 65 and 74 has been documented to protect against hip fractures.<sup>1712,1713</sup> **Adding a hormonal regimen to women over the age of 60 is not a trivial consideration given the known risks of thromboembolism, stroke, and cognitive deterioration that were evident in the WHI hormone trials.** This judgment requires the conclusion that a relatively youthful and vigorous elderly woman has something to gain from the choice of hormone treatment. While patients with osteoporosis may qualify, alternative effective strategies are available to minimize fracture risk, which may prove to be safer alternatives to hormone therapy in the elderly. The primary and secondary prevention trials reviewed in this chapter have strongly indicated that estrogen administered to women with established atherosclerosis is associated with an increased risk of arterial thrombosis. The mechanism, as reviewed in earlier in this chapter, is presumed to be the creation of a prothrombotic environment by the stimulation of metalloproteinase enzyme activity in unstable atherosclerotic plaques. This effect is enhanced by the production of 27-hydroxycholesterol in atherosclerotic sites, a cholesterol metabolite that competitively inhibits estrogen's beneficial actions within blood vessels. Statin treatment is known to stabilize atherosclerotic plaques rapidly, within 3 months. Although there are no studies to support this recommendation, it seems reasonable to consider initiating statin treatment for several months before starting estrogen therapy in older women.

Older women who have been deficient in estrogen for many years often experience side effects when standard doses of estrogen are initiated. Breast tenderness can be especially disturbing. Because of these side effects and the experience in the WHI with its older population, it is better to start older women with lower doses, and transdermal products that deliver low amounts of estrogen must be considered preferentially. The benefits from initiating hormone therapy in aging women must be balanced against risks for harm, and a thorough clinician-patient dialogue must place existing data in perspective including findings from the WHI hormone trials.

# CAN THE DIET PRODUCE VARIATIONS IN SYSTEMIC ESTROGEN LEVELS?

---

Oral estrogens have an extensive first-pass metabolism, both in the gastrointestinal tract and the liver. This metabolism consists chiefly of sulfation and hydroxylation. The cytochrome P-450 system catalyzes the hydroxylation of estrogen, and antioxidants can inhibit this action. Flavonoids (e.g., naringenin and quercetin) are present in high concentrations in fruits and vegetables, and grapefruit juice inhibits estrogen metabolism, producing an increase in bioavailability that is consistent with an inhibition of hydroxylation.<sup>1714,1715</sup> This raises the possibility that dietary interactions with food products could produce a clinical impact. There is great variability within individuals and between individuals in the pharmacokinetics of exogenously administered estrogen. It is possible that this variability partially reflects the dietary habits of individuals and not intrinsic metabolism.

An effect of alcohol ingestion by premenopausal women was not demonstrated on circulating levels of estrone, estradiol, DHEA-S, or SHBG in a cross-sectional study that depended on a questionnaire to assess alcohol intake.<sup>1716</sup> However, when alcohol is administered under experimental conditions, circulating estrogen concentrations are raised to high levels.<sup>113,115</sup> In a prospective cohort study of premenopausal women in Italy, higher estradiol levels were correlated with an increased alcohol intake over a 1-year period of time.<sup>1717</sup> In the last decade, the gut microbiome has emerged as an important variable capable of influencing estrogen metabolism, the metabolic and carcinogenic milieu, as well as modifying interactions between dietary factors and hormones.<sup>1718</sup>

# CLINICAL APPROACH TO POSTMENOPAUSAL HORMONE THERAPY

---

We hope that we have convinced you that menopause is a normal life event, not a disease, and that for many women, postmenopausal hormone therapy can bring about marked improvement in quality of life and, with long-term use, provide health care benefits. Postmenopausal hormone therapy should be considered for symptomatic women traversing the menopause transition and early menopause as they consider their paths for successful aging; decision to initiate hormone therapy should be made after weighing individualized risks against patient's symptom burden and indicated benefits. **It is important to appreciate that the attitude and beliefs of the clinician have a major influence on the treatment-related decisions made by patients.** As beneficial as the impact of hormonal therapy may be, we must also emphasize the large improvement in health to be gained by lifestyle changes in smoking cessation, diet, regular exercise, and control of body weight.

It is the task of an epidemiologist to derive study conclusions based on research data. It is the obligation of a clinician to make a judgment whether the epidemiologist's conclusions have clinical meaning. For example, an epidemiologist may conclude that estrogen reduces coronary artery calcification and point out that a randomized clinical trial has not proved that such a reduction lowers the risk of CHD. But it is appropriate for a clinician, knowing the correlation between coronary artery calcification and CHD, to conclude that estrogen reduction of coronary calcification will translate into less CHD. Medical judgments require more than absolute evidence from randomized trials, and medical judgments frequently do not have the luxury of postponing clinically meaningful decisions until data are conclusive.

Long-term postmenopausal hormone therapy is not precluded by the results reported by the WHI. Protection against osteoporotic fractures, reduction in incidence of colorectal cancers and possibly new-onset diabetes mellitus, and a possibility of primary prevention of CHD are some of the benefits of long-term hormone therapy. Of course, these hormone use-related benefits must be weighed against the known hormone-related risks of VTE, stroke, and breast cancer (from estrogen and progestin use). Considerations must also be given to alternative proven therapies (e.g., statins) and to support beneficial lifestyle modifications. It remains the clinician's responsibility to weigh any purported benefit against hormone therapy-related risks for each patient to ensure that patients are not subjected to undue risks.

## **The WHI Agrees with 30 Years of Research**

- Coronary heart disease: potential for protection in young postmenopausal women

- Stroke: no increase in early postmenopausal, healthy women
- VTE: twofold increase in first years of use, concentrated in those at risk
- Cancer: slightly increased risk of breast cancer or an effect on preexisting tumors; reduction in colorectal cancer
- Osteoporosis: reduction in vertebral and nonvertebral fractures
- Diabetes mellitus: reduction in new-onset diabetes

A theme has emerged from the epidemiologic confusion of the last decade. It takes healthy tissue to allow effective response to estrogen and maintenance of health. Experimental evidence in monkeys and women indicates that as endothelial cells become involved with atherosclerosis and neurons become affected with the pathologic processes, beneficial responses to estrogen diminish.<sup>359,1216,1217</sup> Maximal benefit, therefore, requires early onset of treatment, near the time of menopause.

The most effective and appropriate method to help in decision-making is to identify the specific goals and objectives of the individual patient—let your patient be your guide. Once an individual's objectives are identified, choices from multiple treatment options can be reviewed. Postmenopausal health and hormone therapy are subjects receiving enormous attention and research; therefore, decision-making should be at least an annual event, incorporating new knowledge as it appears. Approached in this fashion, the terms “short term” and “long term” and the imposition of time limits for therapy become meaningless. Clinician and patient together make an annual clinical judgment that is appropriately directed to accomplishing the individual patient's goals. **The guiding principle is the right drug in the right dose for the appropriate duration according to an individual patient's needs and tailored to the individual's unique risk profile.**

## OSTEOPOROSIS (FIGURE 17.17A, B)

---

A

B

**FIGURE 17.18** Normal (A) and osteoporotic (B) bone architecture. Osteoporosis is a disease characterized by **low bone mass** and **microarchitectural deterioration** of bone tissue leading to enhanced bone fragility and a consequent increase in fracture risk. Courtesy of World Health Organization (WHO), 1993.

Bone is a very active organ. A continuous process, called bone remodeling, involves constant resorption (osteoclastic activity) and bone formation (osteoblastic activity) (Figure 17.18). Both osteoblasts and osteoclasts are derived from bone marrow

progenitors, osteoblasts from mesenchymal stem cells and osteoclasts from hematopoietic white cell lineage. Cytokines are involved in this development process of bone turnover, which is regulated by the sex steroids. A system of cross talk exists between the bone-forming osteoblasts and the bone-resorbing osteoclasts, with many autocrine, intracrine, and paracrine signals among which RANK-L, OPG (osteoprotegerin), cathepsin, and sclerostin are prominent.

**FIGURE 17.18**

The amount of bone at any point of time reflects the balance of the osteoblastic and osteoclastic forces, influenced by a multitude of stimulating and inhibiting agents. At puberty and during the early reproductive years, net bone gain occurs, whereas aging and a loss of estrogen both lead to a dominance of osteoclastic activity and net bone loss (**Figure 17.19**). A decrease in calcium intake and/or absorption similarly results in bone loss as this lowers the serum level of ionized calcium, resulting in stimulation of parathyroid hormone (PTH) secretion in efforts to mobilize calcium from bone by direct stimulation of osteoclastic activity, a phenomenon known as secondary hyperparathyroidism. Increased PTH also stimulates the hepatic and renal activation of vitamin D in efforts to increase serum levels of calcium through intestinal calcium absorption. A deficiency in estrogen is associated with a greater responsiveness of bone to PTH. Thus, for any given level of PTH when estrogen is deficient, there is more calcium removed from bone, raising serum calcium, which, in turn, lowers circulating PTH and decreases vitamin D and intestinal absorption of calcium.

**FIGURE 17.19**

**Osteoporosis**, the most prevalent bone problem in the elderly, is characterized by both decreased bone mass and decreased bone quality, and both these factors contribute to an increased risk of fragility fractures. Osteoporosis is a major global public health problem threatening more than 44 million individuals, and it is epidemic in the United States, affecting 10 million Americans (4 times more women than men).<sup>1719</sup> In addition, about 34 million people (80% women) in the United States have low bone mass (osteopenia), and they too are also at an increased fracture.

The increase in osteoporotic fractures in the developed world is partly due to an increase in the elderly population, but not totally. A comparison of bone densities in proximal femur bones in specimens from a period of over 200 years suggested that women lose more bone today, perhaps due to less physical activity and less parity.<sup>1720</sup> Other contributing factors include a dietary decrease in calcium and an earlier and greater loss of bone because of the impact of smoking. Our Stone Age predecessors consumed a diet high in calcium, mostly from vegetable sources.<sup>1721</sup> However, the impact of the tremendous increase in the elderly population throughout the world cannot be underrated. Because of this demographic change, the number of hip fractures occurring in the world each year will increase approximately sixfold from 1990 to 2050.<sup>1722</sup>

# Pathophysiology of Osteoporosis

Osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in the risk of fractures even with little or no trauma. The skeleton consists of two bone types. Cortical bone (the bone of the peripheral skeleton) is responsible for 80% of total bone, while trabecular bone (the bone of the axial skeleton—the spinal column, the pelvis, and the proximal femur) constitutes a honeycomb structure filled with red marrow and fat, providing greater surface area per unit volume.

**The subsequent risk of fracture from osteoporosis in women will depend on bone mass at the time of menopause and the rate of bone loss following menopause.**<sup>1723</sup> The peak bone mass is influenced by heredity and endocrine factors, among which estrogens are particularly relevant. It is now recognized that there exists only a relatively narrow window of opportunity for maximizing bone mass. Almost all of the bone mass in the hip and the vertebral bodies is accumulated in young women by late adolescence (age 18), and the years immediately following menarche (11–14) are especially important.<sup>1724,1725,1726</sup> **Estrogen exposure during adolescence is vital to bone mass accrual.** Individuals who experience a late menarche are characterized by bones with lesser density and a reduction in microstructural components, a bone quality that persists to menopause and is associated with an increased risk of fractures.<sup>1727</sup> Women who experience amenorrhea during adolescence have an increased prevalence of osteoporosis.<sup>1728</sup> Calcium supplementation in prepubertal and pubertal girls improves bone accrual, an important effect that could have long-lasting beneficial consequences.<sup>1729,1730,1731,1732</sup>

Although the onset of spinal bone loss begins in the 20s, the overall change is small until periods of menopause transition and early menopause.<sup>1725,1733</sup> Bone density in the femur peaks in the mid to late 20s and begins to decrease around age 30. In general, trabecular bone resorption and formation occur 4 to 8 times as fast as cortical bone. Beyond age 30, trabecular resorption begins to exceed formation by about 0.7% per year. Bone loss accelerates after menopause as up to 5% of trabecular bone and 1–1.5% of total bone mass loss occurs per year in the first years after menopause. This accelerated loss continues for about 5 years, after which bone loss rate is considerably diminished but continues as the aging-related loss.<sup>1734</sup> For the first 20 years following cessation of menses, post-menopause-related bone loss results in as much as 50% reduction in trabecular bone and a 30% reduction in cortical bone.<sup>1735,1736</sup>

**When estrogen levels decline, bone remodeling, resorption, and formation increases.** The site of maximal bone remodeling is determined by a need to adapt to physical loads on the skeleton. Each remodeling locus is initiated by osteoclast-

mediated reabsorption and excavation of old bone, a process that takes 3–5 months, followed by osteoblast-mediated restoration and refilling. In reproductive years, the processes of bone resorption and bone formation are well balanced with resultant maintenance of net bone mass. Estrogen exerts a tonic suppression of remodeling by directing activated osteoclasts toward apoptosis and maintains a balance between osteoclastic and osteoblastic activity; in the absence of estrogen, osteoclastic activity predominates, resulting in net bone resorption. The precise mechanism of action for sex steroid protection of bones remains unknown; however, a growing body of knowledge indicates complex interactions at the molecular level, with both a classic pathway involving genomic transcription by hormone receptors and a nongenomic pathway that inhibits apoptosis (Figure 17.20).<sup>1737,1738</sup> Increased efficiency of calcium absorption, probably secondary to estrogen-induced enhancement of the availability of vitamin D, and a direct role for the estrogen receptors in the osteoblasts are likely important factors. Many estrogen-dependent growth factors and cytokines are involved in bone remodeling.<sup>1739,1740</sup> Estrogen modulates the production of bone-resorbing cytokines such as interleukin-1 and IL-6, bone-stimulating factors such as insulin-like growth factor-I, colony-stimulating factor, OPG, and proteins that are members of the transforming growth factor- $\beta$  family.<sup>1741</sup> Estrogen increases vitamin D receptors in osteoblasts, and this may be a method by which estrogen modulates vitamin D activity in bone.<sup>1742</sup> There is little evidence that estrogen affects bone by altering the circulating calcitropic hormones.<sup>1743</sup> Thus, the actions of estrogen are primarily direct effects on bone and important effects on vitamin D metabolism and renal and intestinal handling of calcium.

## FIGURE 17.20

Estrogen is a critical hormone for skeletal health in both males and females. Males with mutations in the estrogen receptor-alpha or who have aromatase deficiencies grow slowly and have markedly reduced bone densities.<sup>1744,1745</sup> Analysis of the decline in testosterone and estrogen circulating levels with aging indicates that the amount of bioavailable estrogen circulating in the blood is the most consistent predictor of bone density in men and women.<sup>1746</sup> And most impressively, men with an aromatase deficiency, treated with estrogen, demonstrated that both androgens and estrogens are necessary in order for males to reach optimal bone mass.<sup>1747,1748</sup>

Racial differences in bone mass are well recognized. Bone mass, adjusted for body size, is greater in the black compared to white populations. It is believed that racial differences in bone density are established in childhood and early adolescence.<sup>1749,1750</sup> More than half the difference, comparing black children with white children, is due to differences in body size and composition; a significant contribution is made by bone metabolism, a smaller portion by sex hormone levels, and only 2% of the difference is unexplained.<sup>1751</sup> During adolescence, blacks absorb calcium more efficiently and bone turnover is greater with more net bone formation.<sup>1752</sup>

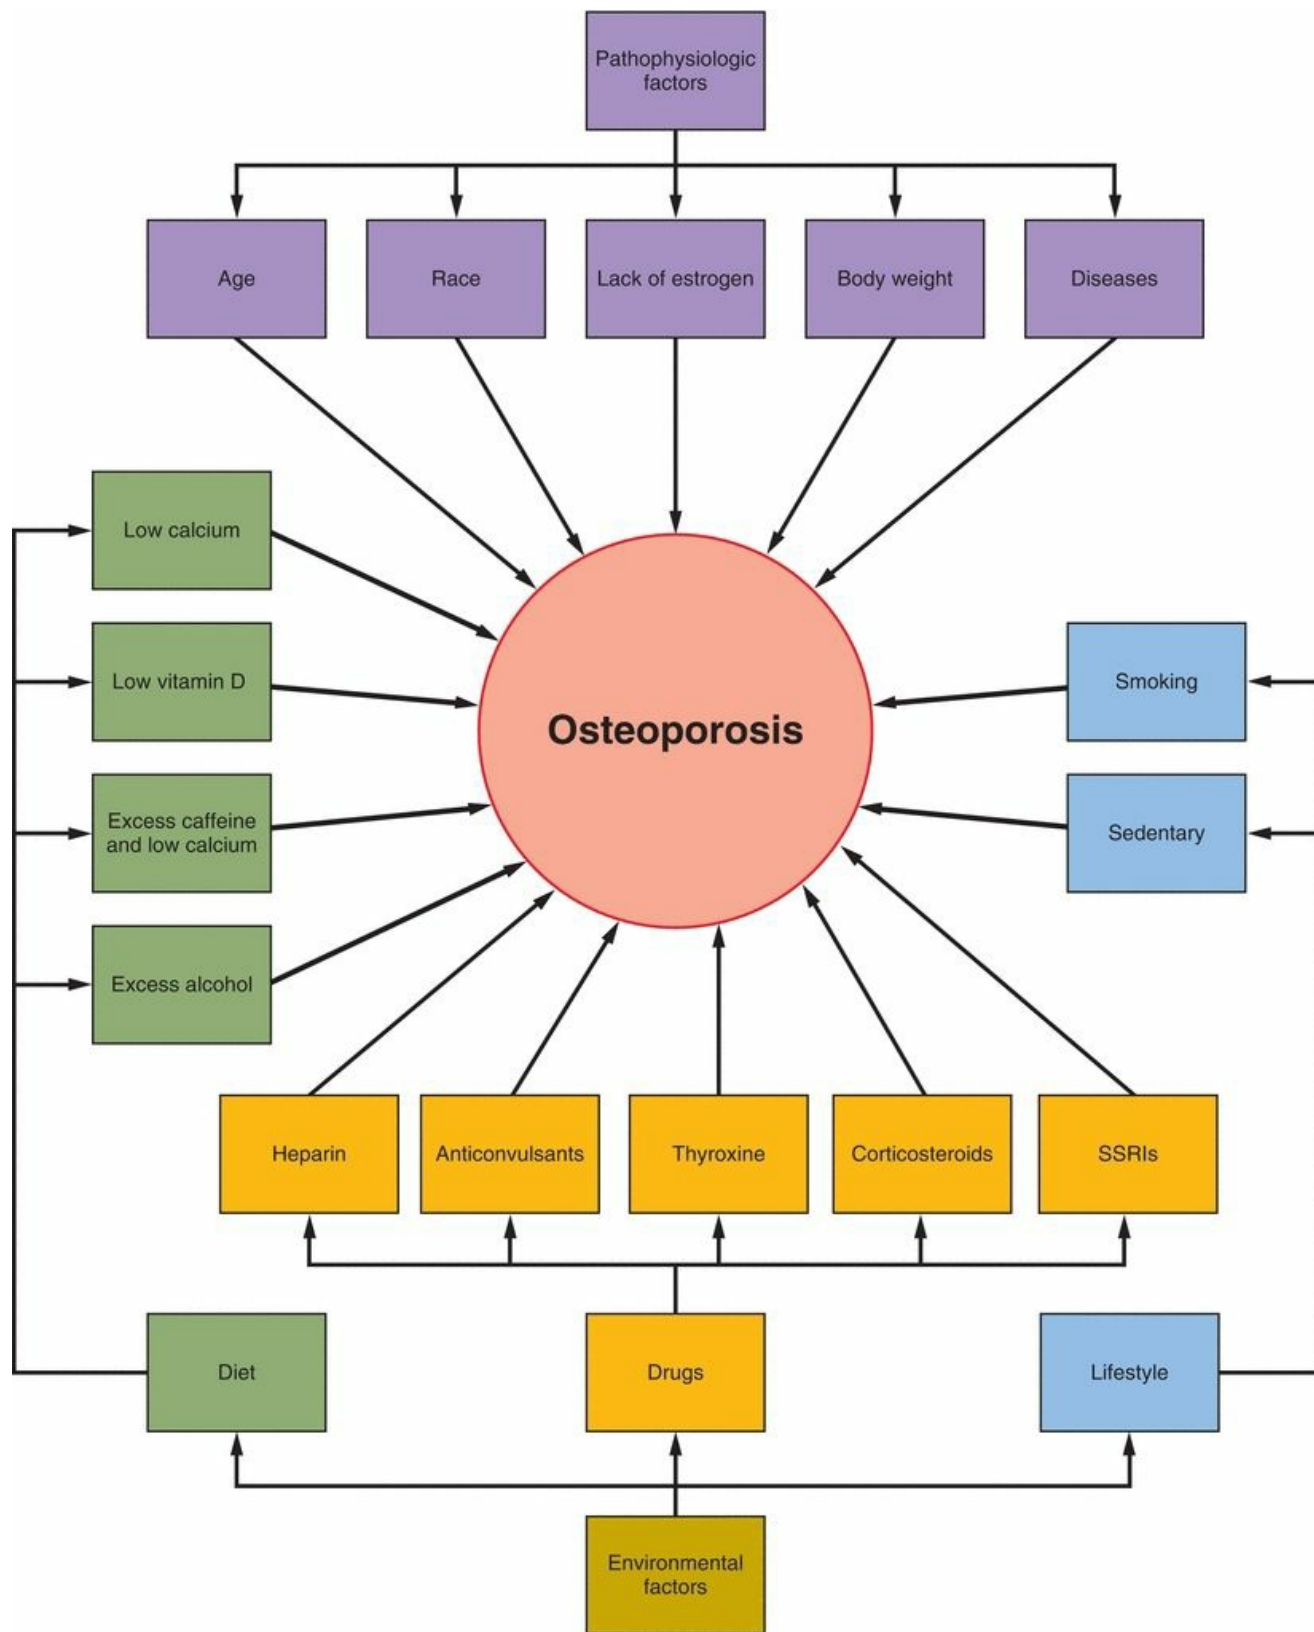

In general, bone mass is greater in black and obese women and less in white, thin, and sedentary women. Spinal bone density is similar among black and Asian women (lower in white women), and hip bone density is higher among blacks compared to white and Asian women.<sup>1753</sup> Conventional wisdom has held that Asian women have even lower bone densities than white women. The SWAN study demonstrated that this apparent difference disappeared when the data were adjusted for body size.<sup>1753,1754</sup> Both black and Asian women have higher bone density and lower fracture rates than white women. Despite the greater bone mass and lower fracture rates, the impact of osteoporotic fractures in black and Asian women is still considerable. Postmenopausal estrogen therapy is associated with improved BMD and protection against fracture risk regardless of race.<sup>1755</sup> Japanese women demonstrate the same amount and pattern of bone loss after menopause as white women.<sup>1756</sup>

Although estrogen plays a principal role in regulating bone density, genetic susceptibility for low bone mass and for bone loss are important. A study of the premenopausal daughters of women with osteoporosis revealed a reduction in bone mass, suggesting genetic influence as well as the sharing of a lifestyle that may contribute to a relatively low peak bone mass.<sup>1757</sup> **Studies of twins and mother-daughter pairs indicate that up to 70% of the variation in bone density is**

**determined by heredity.**<sup>1758</sup>

Variations in the gene that encodes the vitamin D receptor are prevalent in postmenopausal women with decreased bone densities.<sup>1759</sup> The absence of vitamin D receptor gene allelic polymorphisms was reported in older women who neither lose significant bone nor respond to calcium supplementation.<sup>1760</sup> The inherited aspects of osteoporosis are likely to be influenced by multiple susceptibility genes. For example, low bone density is associated with specific alleles of COL1A1, 1 of the 2 genes that encode the 2 polypeptides of collagen.<sup>1761</sup> Two single nucleotide polymorphisms, variants for key biologic proteins (the OPG and lipoprotein-receptor-related genes) are present in slightly over 20% of white people and are associated with an increased risk for osteoporosis.<sup>1762</sup> Clarity on genetic markers to identify individuals at increased risk for osteoporosis is still lacking and informative yield of existing efforts is, at best, limited.

The accelerated loss of bone in postmenopausal women is largely attributed to estrogen loss; 75% or more of the bone loss that occurs in women during the first 15 years after menopause is due to estrogen deficiency rather than to aging itself.<sup>1763,1764</sup> Vertebral bone is especially vulnerable, beginning to decline as early as 20 years of age.<sup>1765</sup> Vertebral bone mass is significantly decreased in perimenopausal and early postmenopausal women who have rising FSH and decreasing estrogen levels, whereas bone loss from the radius is not found until at least a year out from the menopause.<sup>1766</sup> This early loss of axial skeleton suggests that the hypoestrogenic postmenopausal state is not the only cause of vertebral osteoporosis.<sup>1767</sup> One obvious suspect is a decline in dietary intake of calcium and vitamin D in the premenopausal years; nevertheless, menopause and the loss of estrogen remain as the major contributors to bone loss. The risk of fracture, therefore, depends on 2 factors: the bone mass achieved at maturity and the subsequent rate of bone loss. **A high rate of bone loss after menopause (the “fast loser”) is highly predictive of an increased risk of fracture.** The combination of a low bone mass and fast losing is additive, and thus, these individuals are at the highest risk of fracture. Fast losing probably reflects lower endogenous estrogen levels. The bone density, which is the threshold for vertebral fractures, is only slightly below the lower limit of normal for premenopausal women.<sup>1768</sup> **Figure 17.21** outlines the various factors contributing to osteoporosis.

**FIGURE 17.21**

# Bone Loss During the Menopausal Transition

Should a clinician be concerned about bone loss and consider interventions during the perimenopausal years? A decline in BMD, as well as up-regulation of circulating and urinary levels of CTX (C-telopeptide), a marker representing degradation of bone collagen, are apparent in the menopause transition, well before the FMP. Some studies concluded that calcium supplementation of perimenopausal women retards metacarpal and lumbar bone loss.<sup>1769,1770</sup> Perimenopausal women in the SWAN study demonstrated decreasing bone densities that correlated with increasing FSH levels; however, accelerated bone loss did not occur until late in the perimenopause.<sup>1754</sup> The amount of perimenopausal bone loss is small unless estrogen levels are below normal.<sup>1771,1772,1773,1774</sup> Unlike those in perimenopause (discussed earlier in this chapter), otherwise healthy women who are anovulatory or those who demonstrate inadequate luteal phase ovarian function (and thus are exposed to less progesterone) but are not hypergonadotropic, do not have an increase in bone loss.<sup>1775,1776</sup> **Bone loss in the perimenopausal period is unlikely to be clinically consequential for the majority and interventions and treatments to prevent future osteoporosis are not necessary in perimenopausal women who have adequate estrogen levels and who are eating normally.** However, those who had failed to attain optimal peak bone mass in their younger years, an earlier onset of bone loss in the menopause transition may contribute toward an enhanced lifetime fracture risk; such women will benefit from an individualized risk assessment and consideration of timely initiation of antifracture interventions (discussed later in this chapter).

# Signs and Symptoms of Osteoporosis

Fragility fracture is a fracture that results from minimal trauma, or from a person falling from a standing height. Fragility fractures are the most common consequence of osteoporosis and commonly involved anatomical sites are the humerus, upper femur, distal forearm, and ribs. Osteoporosis is recognized as a “silent disease” that in the absence of targeted screening, may only present itself once the affected individual sustains a fracture. Osteoporosis is responsible for more than 2 million fractures per year in the United States.<sup>1719</sup> About one in two white women over age 50 will experience an osteoporosis-related fracture. Lack of estrogen and advancing age are both causative to the cumulative fracture burden of postmenopausal years. Back pain is a major clinical symptom of vertebral compression fractures. The pain with a fracture is acute, and then it decreases over 2–3 months, but lingers as chronic low back pain due to increasing lumbar lordosis. The pain subsides within 6 months unless multiple fractures produce a picture of constant pain. **Many individuals will not know they have osteoporosis until they experience a fracture.** Loss of height, kyphosis, decreased mobility and even respiratory compromise and worsening constipation are recognized disabilities resulting from fractures of the thoracolumbar spine.

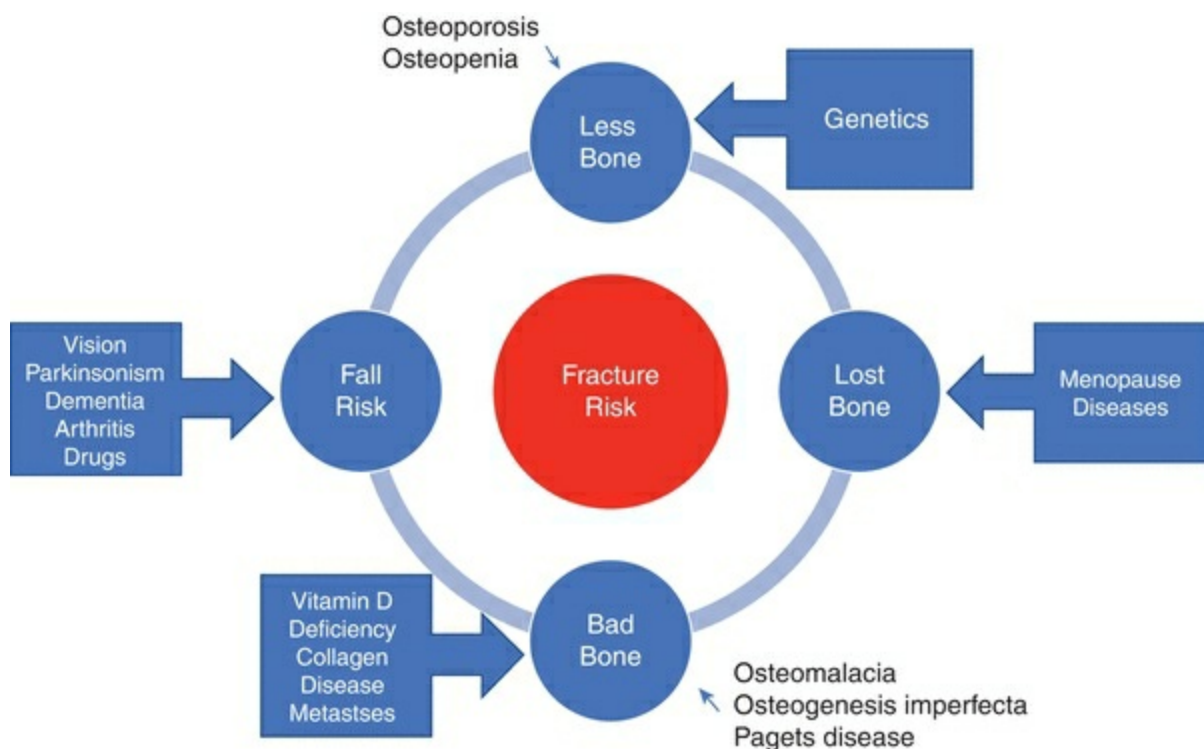

**Epidemiologic studies have revealed the following<sup>1777,1778</sup>:**

- 1. Spinal (vertebral) compression fracture.** Symptomatic spinal osteoporosis, causing pain, loss of height, postural deformities (the kyphotic dowager’s hump) with consequent pulmonary, gastrointestinal, and bladder dysfunction, is 5 times more common in white women than men. Approximately 50% of women over 65 years of age have spinal compression fractures; about two-thirds are clinically unrecognized. **Each complete compression fracture of a vertebral body causes the loss of approximately 1 cm in height.** The average untreated postmenopausal white woman can expect to shrink 2.5 inches (6.4 cm). The most common sites for vertebral fractures are the 12th thoracic and the first three lumbar vertebrae. These physical changes also have a negative impact on body image and self-esteem.
- 2. Colles fracture.** There is a 10-fold increase in distal forearm fractures in women as they progress from age 35 to 60 years. White women are more predisposed to wrist fracture than those of other races; a white woman has approximately a 15% lifetime risk of a forearm fracture. Colles fractures are the most common fractures among women until age 75, when hip fractures become more common.
- 3. Head of femur fracture.** The incidence of hip fractures increases with age in women, rising from 0.3/1,000 to 20/1,000 in white women between 45 and 85 years of age. **Eighty percent of all hip fractures are associated with osteoporosis.** White women who are 50 years old have approximately a 14%

lifetime risk of having a hip fracture; black 50-year-old women, 6%. **Hip fracture carries an increased risk of morbidity and mortality.** About 25% of patients over the age of 50 with hip fractures die due to the fracture or its complications (surgical, embolic, cardiopulmonary) within 1 year. The survivors are frequently severely disabled and may become permanent invalids. Hip fractures alone occur in about 300,000 individuals per year in the United States with a mortality of 40,000 annually and an associated cost of billions of dollars.<sup>1719</sup>

- 4. Tooth loss.** Oral alveolar bone loss (which can lead to loss of teeth) is strongly correlated with osteoporosis, and the salutary effect of estrogen on skeletal bone mass is also manifested on oral bone.<sup>1667,1779</sup> Even in women without osteoporosis, there is a correlation between spinal bone density and number of teeth.<sup>1668</sup> Tooth loss is also correlated with the use of cigarettes, a recognized contributor to bone loss. Long-term use of postmenopausal hormone therapy has been linked with fewer lost teeth.<sup>1780,1781,1782</sup>

**Individuals at an increased risk for fracture can be identified by a careful history and examination (Figure 17.22).**

**FIGURE 17.22**

**The following risk factors are especially important for women:**

- **Aging: the risk of fracture doubles every 7–8 years after age 50.**
- **Previous history of a fragility fracture.**
- **Family history of fragility fracture, particularly in first-degree relatives.**
- **Smoking.**
- **Low body weight, being small-framed and thin.**
- **Family history of osteoporosis, particularly if in first-degree relatives.**
- **Prolonged amenorrhea (hypoestrogenism).**
- **Lifelong deficient calcium and vitamin D intake.**
- **Use of bone-losing medications, such as oral steroids.**
- **Sedentary lifestyle.**
- **Excessive use of alcohol.**
- **Rheumatoid arthritis.**

Postmenopausal women who have already experienced a vertebral fracture deserve aggressive intervention. The risk of subsequent, additional vertebral fractures is substantial; 20% of women experience another vertebral fracture within 1 year after the first fracture.<sup>1783</sup> These women are also at increased risk for nonvertebral fractures.<sup>1784,1785</sup> **A complete evaluation for osteoporosis is an essential component of care for a patient presenting with a fragility fracture; as defined by the World Health Organization, a fragility fracture is one that results from an injury that would be insufficient to break a normal bone. All osteoporotic fractures are associated with an increased risk of mortality that persists for 5–10 years after the fracture.**<sup>1786</sup>

Because there are so many women with osteoporosis, a greater prevalence of depression in this population would amount to a clinical problem of considerable proportions. A cross-sectional subset in a large clinical trial reported a greater prevalence of depressive symptoms in women with fractures.<sup>1787</sup> It is well recognized that fractures secondary to osteoporosis are accompanied by a reduction in psychological and physical well-being. As far as depression goes, it is difficult to know which came first, depression or fractures, leading to subsequent depression. It has been reported that depressed people have a greater incidence of falls,<sup>1788</sup> and thus it is not unreasonable to consider that depression comes first in some people. Furthermore, depressed people are sedentary and eat poorly, factors that favor bone loss. It is speculated that chronically increased cortisol levels associated with depression might contribute to bone loss, similar to that observed with the pharmacologic administration of glucocorticoids. On the other hand, a cohort study of American women, despite finding a link between depression and fractures, failed to detect an increase in depression associated with lower bone density measurements.<sup>1788</sup> However, other studies have reported increases in depression associated with lower bone

densities.<sup>1789,1790,1791</sup>

Bone loss has been documented in an established rodent model for stress-induced depression, characterized by a decrease in osteoblastic bone formation that can be attenuated by an antidepressant drug.<sup>1792</sup> In this experimental model, osteoblastic inhibition was mediated by stress-induced stimulation of the sympathetic nervous system. Although this response is associated with an increased secretion of adrenal glucocorticoids, the evidence also indicates a direct role for sympathetic fibers in bone.

**We need to be aware that women who have experienced fractures may have depressive symptoms, and appropriate interventions can have a beneficial impact on quality of life. The important point is that depression and fractures are linked and attention to psychological well-being should be an integral part of management of individuals who have experienced fragility fractures as each condition can impact the course of the other in different patients, and both directly impact on the quality of life in all affected individuals.**

Selective serotonin reuptake inhibitors (SSRIs) are the favored treatment for depression in older adults, a problem that affects about 10% of the older population. Several earlier studies had reported an increased risk of fractures with the daily use of SSRIs; however, these earlier studies were unable to control for the various factors that influence this risk, especially falls, depression, and bone density. An excellent prospective cohort study in Canada indicated that the increase in fractures persisted after controlling for these factors.<sup>1793</sup>

There is a direct effect of SSRIs on bone. Components of the neural system are involved in bone metabolism, and serotonin receptors and serotonin transport have been identified in osteoblasts and osteocytes. The bone effects of parathyroid hormone and mechanical stimulation are modulated by the serotonin system. Mice with a mutation for the serotonin transporter develop less bone mass and strength.<sup>1794</sup> Therefore, daily SSRI use can impair bone formation, tilting the balance in favor of resorption and bone loss; indeed, decreased bone densities have been reported in both male and female SSRI users (but not in users of tricyclic antidepressants).<sup>1795,1796</sup>

# Measuring Bone Mineral Density

There is a 50–100% increase in fracture risk for each standard deviation decline in bone mass (approximately 0.1 g/cm bone mass).<sup>1797</sup> Evidence of lower bone mass at the hip is even more predictive of fracture risk; lesser bone mass one standard deviation at the hip has been associated with nearly a threefold increase in risk of fracture.<sup>1798</sup>

**Although low bone density reliably predicts the risk of fracture, increases in bone density in response to treatment do not demonstrate a direct correlation with a reduction in fractures. Therefore, a few percentage point differences achieved by various treatments may have little clinical meaning.**

The impressive correlation between fracture risk and low bone density has raised the question of whether it is of value to screen for osteoporosis. Keep in mind that because the rate of bone loss after menopause contributes equally to the risk of fracture as the total bone mass present at the time of the menopause, a normal bone density measurement at the time of menopause does not mean that the patient will not be at risk of fracture later in life. A relatively young woman with a low bone mass could be targeted for appropriate intervention; however, it is not cost-effective to attempt to screen all postmenopausal women with an expensive method, and attention is now returning to the methods of single-photon, single-energy x-ray absorptiometry and ultrasonography because measurement of bone loss at the heel, the metacarpal, and the radius using these simpler technologies can provide accurate assessment of future fracture risk.<sup>1799</sup>

Bone density measurements are certainly useful when the information will facilitate an individual to make an informed decision regarding initiating specific treatment, such as postmenopausal hormone therapy. Indeed, a decision to use hormone therapy and better maintenance of a hormone program are correlated with patients' knowledge of their bone density measurements.<sup>1800,1801</sup> In the United States, multiple organizations including the American College of Obstetricians and Gynecologists (ACOG) (2004), the U.S. Preventive Services Task Force (USPSTF), and the National Osteoporosis Foundation (NOF) are unified in their recommendations that in the absence of risk factors, postmenopausal women should be offered screening for osteoporosis by DEXA starting at age 65; earlier screening should be considered in those with risk factors especially if results of bone density test can help determine the course of management. Patients who have received long-term corticosteroid, thyroxine, anticonvulsant, or heparin treatment warrant bone mass assessment earlier than age 65. **After an initial assessment of bone density, decision to perform repeat measurements should be individualized based on results of the initial test and tailored to the patient's clinical picture;** for the majority, repeat bone density measurements to monitor bone

loss can be considered at every 2- to 5-year intervals.

## Key Points: Reasons to Measure Bone Mass

- To help patients make decisions regarding hormone therapy
- To assess response to therapy in selected patients, for example, smokers, and women with eating disorders
- To assess bone mass in patients being treated long term with glucocorticoids, thyroid hormone, anticonvulsants, or heparin
- To confirm the diagnosis and assess the severity of osteoporosis to aid in treatment decisions and to monitor efficacy of therapy
- To assess bone mass in postmenopausal women who present with fractures, who have one or more risk factors for osteoporosis, or who are over age 65
- Recording standing height will detect any decrease that should raise concerns regarding possibility of underlying osteoporosis
- Bone mass should be measured in postmenopausal women who present with fractures, who have one or more risk factors for osteoporosis, or who are over age 65

Standard x-rays do not provide an early assessment of fracture risk; 30–40% of bone must be lost before radiographic changes become apparent. Photon absorptiometry measures the transmission of photons through bone. Single-photon absorptiometry uses a <sup>131</sup>I source of energy or, more recently, miniature x-ray tubes. These methods can reliably measure bone density in the radius and the calcaneus and are relatively inexpensive. These measurements correlate with vertebral bone density and predict the risk of future fracture, particularly in older women.<sup>1799</sup> Dual-energy absorptiometry employs different photons from two energy sources. Dual-energy x-ray absorptiometry (DEXA) provides good precision for all sites of osteoporotic fractures, and the radiation dose is much less than for a standard chest x-ray. Whole-body scans by DEXA can measure total body calcium, lean body mass, and fat mass. **DEXA remains the gold standard technology for bone density measurement in routine clinical practice.** Quantitative CT for bone density measurements can be performed on most commercial computed tomography systems; however, radiation exposure is higher than with DEXA, and measurements of the femur are not available, although very accurate measurements of the spine are possible.

For high precision, the best information is provided by the DEXA technique (together with sophisticated software to give a precision of 1%), measuring the three

sites of greatest interest, the radius, the hip, and the spine.<sup>1802</sup> Better accuracy is gained by three-site assessments because there can be differences among the anatomical sites. In other words, a normal value at one site does not preclude a low bone density at another site. For practical clinical use (and for screening), measurements are made at the lumbar spine, the hip, and the femoral neck. Serial measurements are best made at least 2 years apart to allow meaning interpretation of interval data. Measurement of the bone density at the radius or calcaneus is more cost-effective, using single-source x-ray absorptiometry, and can be used for screening. It is anticipated that ultrasonography will prove to be a low-cost, effective method for bone mass assessment, particularly in high-risk populations.<sup>1803</sup> Ultrasonographic measurements of the calcaneus have been reported to be as accurate as femoral neck measurements by DEXA in predicting the risk of hip fractures.<sup>1804,1805</sup> However, peripheral measurements are not accurate for monitoring response to treatment.

## Terminology (Table 17.15)

**TABLE 17.15 Definitions Based on Bone Mineral Density**

Normal	0 to $-1$ SD from the T-score reference standard (84% of the population)
Osteopenia	T-score between $-1$ and $-2.5$ SD
Osteoporosis	T-score at or below $-2.5$ SD

- **T-score:** Standard deviations between patient and average peak young adult bone mass. The more negative, the greater the risk of fracture.
- **Z score:** Standard deviations between patient and average bone mass for same sex, age, and ethnicity.

In postmenopausal women, fracture risk assessment based on DEXA depends on interpretation of the T-score (i.e., how her bone mass compares to that of a young skeleton) (see Table 17.15). In contrast to postmenopausal women, interpretation of bone density measurement in premenopausal woman should be based on the Z

score (i.e., how her bone mass compares to her age- and sex-matched healthy individuals in the population). In postmenopausal women, T-scores of less than or equal to  $-2.5$  are consistent with a diagnosis of osteoporosis, whereas in premenopausal women, Z scores of equal to or less than  $-2.0$  reflect low bone mass and identify premenopausal women who are at risk for future fracture. A bone density Z score that is lower than  $-2.0$  (2.5% of normal population of same age) at any age should prompt consideration for diagnostic evaluation for potential causes of bone loss.

# Diagnostic Tests

Patients with osteoporosis should be screened for underlying conditions that can lead to bone loss:

1. Serum parathyroid hormone, calcium, phosphorus, and alkaline phosphatase: for primary hyperparathyroidism
2. Renal function tests: for secondary hyperparathyroidism with chronic renal failure
3. Serum 25-hydroxyvitamin D: for vitamin D deficiency
4. Thyroid function tests: for hyperthyroidism and excessive thyroid hormone treatment
5. Blood count and smear, sedimentation rate, and protein electrophoresis: for multiple myeloma, leukemia, or lymphoma
6. Careful history and, when indicated, appropriate laboratory studies to rule out long-term use of bone-losing medications, alcohol abuse, metastatic cancer, and chronic liver disease

Excess thyroxine treatment can cause bone loss. However, retrospective studies of thyroid function and bone mass have not produced uniform conclusions.<sup>1806</sup> In the Study of Osteoporotic Fractures, women with a previous history of hyperthyroidism had an increased risk of subsequent hip fractures, and women taking thyroid hormone also had an increased risk of fracture (which did not reach statistical significance).<sup>1807</sup> However, in a prospective assessment of TSH levels in the Study of Osteoporotic Fractures, no association could be detected between low TSH and bone loss.<sup>1808</sup> A recent meta-analysis provides evidence of increased fracture risk for the spine, hip, and wrist in both subclinical hyperthyroidism and subclinical hypothyroidism.<sup>1809</sup> **It is thus prudent to screen for thyroid dysfunction in postmenopausal women with osteoporosis as well as those with osteopenia and maintain TSH levels within the normal range.**

## Should Osteopenia Be Treated?

The term “low bone mass” is now preferred to the older term “osteopenia,” as defined by bone density T-scores between  $-1.0$  and  $-2.5$ . Approximately 40% of American postmenopausal women have bone densities in the range of osteopenia. It is logical to expect a continuum of fracture risk extending from normal bone density to osteoporosis, and a longitudinal American study observed that osteopenia was associated with a 1.8-fold higher rate of fracture (compared with a 4-fold higher rate with osteoporosis).<sup>1810</sup> Experts argue, however, that most women with osteopenia simply have lower than average bone mass but will not have progressive bone loss and, in the absence of risk

factors, may not require any bone-specific interventions beyond lifestyle modifications that include attention to diet, calcium and vitamin D intake, and weight-bearing exercise. Consideration for treatment depends on the demonstration of continued bone loss as determined by declining bone density on serial measurements. **We support preventive drug therapy for postmenopausal women with evidence of low bone mass in the presence of one or more risk factors for fracture or documented progressive bone loss.**

## **FRAX, the World Health Organization Fracture Risk Assessment Tool**

The World Health Organization fracture risk assessment tool, FRAX, is updated and calibrated according to risk in different geographic areas. This tool is available online for free use from the National Osteoporosis Foundation ([http://www.nof.org/frax\\_update.htm](http://www.nof.org/frax_update.htm)) or directly from the FRAX website (<http://www.shef.ac.uk/FRAX/>).<sup>1811,1812</sup> This algorithm predicts the likelihood for an older individual to experience a fragility fracture over a period of 10 years because of low bone mass. The National Osteoporosis Foundation concluded that treatment is cost-effective if FRAX predicts a 10-year hip fracture probability of at least 3% or an overall risk of any osteoporotic fracture greater than 20%.<sup>1813</sup> The clinical application of FRAX produces no major changes in already-existing guidelines.<sup>1814</sup> An osteoporotic bone density and historical risk factors continue to be important factors indicating the need for treatment. **FRAX is useful in identifying which individuals with osteopenia merit treatment;** nevertheless, a careful evaluation of risk factors as reviewed in this chapter continues to be a reliable method to indicate fracture risk in an individual with low bone mass. For example, long-term use of corticosteroid or treatment with aromatase inhibitors (e.g., in the management of postmenopausal breast cancer) identifies individuals in whom bone loss prevention should be considered regardless of the bone density. In addition, fracture risk calculation by FRAX utilizes bone density at the hip, but not at the spine. The decision to initiate antifracture treatment as well as choice of treatment in a patient with low bone density at the spine but with normal hip bone density requires careful consideration of the individual's history and risk factors. FRAX does not replace good medical judgment. **We support preventive drug therapy for postmenopausal women with evidence of low bone mass and a 10-year hip fracture probability of 3% or higher or a 10-year fracture probability of 20% or higher for any osteoporosis-related fracture according to FRAX.**

## **Biochemical Markers of Bone Turnover**

There are many serum and urinary biochemical markers of bone turnover (see [Table 17.16](#)). Some of the biomarkers (such as hydroxyproline, pyridinoline, and deoxypyridinoline cross-links of collagen, telopeptides of collagen, and serum cross-linked telopeptides) reflect the activity of the osteoclasts, whereas others (such as osteocalcin, bone-specific alkaline phosphatase, and procollagen peptide) reflect the activity of the osteoblasts.

## **Table 17.16 Bone Turnover Markers**

## Bone Resorption Markers

## Bone Formation Markers

### Urinary

- Hydroxyproline
- Pyridinoline (PYD)
- Deoxypyridinoline (DPD)
- N-telopeptide (NTX)
- C-telopeptide (CTX)

### Serum

- CTX
- Bone sialoprotein (BSP)
- Tartrate resistant acid phosphatase (TRAP)

### Serum

- Alkaline phosphatase
- Bone-specific alkaline phosphatase
- Osteocalcin
- Type 1 procollagen
  - C1NP
  - P1NP

The urinary tests use a second-morning voided urine specimen, and the immunoassays measure hydroxyproline, pyridinoline, deoxypyridinoline, the collagen cross-linked N-telopeptides, or the collagen cross-linked C-telopeptides.<sup>1815</sup> These are structural proteins released by osteoclastic resorption of bone. **A measurement of bone turnover markers provides a snapshot in time of the current state of bone metabolism.** Because of individual variability, marker measurements correlate poorly with BMD; however, changes in these markers quickly indicate responses to therapy.<sup>1816</sup> Therefore, it has been proposed that efficacy of therapy (with either hormones or other antiresorptive agents) can be judged by comparing a baseline value with a single follow-up measurement after 1–3 months of treatment.<sup>1817</sup> A lesser decrease in the serum or urinary cross-linked peptides indicates a less than optimal bone response, raising concerns about compliance with therapy as well as identifying patients for further evaluation and specific added treatment. How reliable, practical, and cost-effective this approach is for routine clinical use is a reasonable question. Up-regulation of bone resorption markers identifies a state of excessive bone loss, which if left unchecked will result in progressive decline in bone mass. Notably, fracture risk is higher in individuals with evidence of low bone density and up-regulated bone loss

compared to either alone. **Single, random measurements of bone markers are not useful in predicting future bone loss, and bone turnover markers are insensitive indicators of response to raloxifene and calcitonin. Measurement of bone turnover markers is best confined to clinical trials, except in special situations as noted in this chapter.**

# TREATMENT OPTIONS FOR FRACTURE RISK REDUCTION

---

# Menopausal Hormone Treatment

Hormone therapy is an effective bone-protecting strategy that improves BMD and offers fracture risk reduction. Antifracture efficacy of hormone therapy is now documented by randomized, placebo-controlled clinical trials.<sup>1818,1819,1820</sup> The WHI (discussed in detail earlier in this chapter) reported fracture outcomes based on an average of 5.6 years of follow-up, comparing placebo treatment with daily 0.625 mg conjugated estrogen and 2.5 mg medroxyprogesterone acetate (similar results were also reported in the estrogen-only arm of the clinical trial)<sup>1179,1820</sup> (Table 17.17).

## TABLE 17.17 WHI—Fracture Outcomes

	Estrogen-Progestin	Placebo	Hazard Ratio
Osteoporotic fractures	733 cases	896 cases	0.76 (0.69–0.83)
Spinal fractures	41	60	0.65 (0.46–0.92)
Hip fractures	52	73	0.67 (0.47–0.96)
Lower arm/wrist fractures	189	245	0.71 (0.59–0.85)

The Kaplan-Meier estimates of the impact of hormone therapy in WHI indicated that the reduction in fractures continued to increase over time, suggesting that a very powerful effect would be achieved with treatment of a long duration. In addition, spinal fractures included only clinically symptomatic fractures (known to represent about one-third of vertebral fractures); again, the overall effect was probably greater if all vertebral fractures had been included. The beneficial effect was achieved even though the use of a bisphosphonate increased from 1% at baseline to about 6% in the estrogen-progestin group and 10% in the placebo group. The effect would have been even greater if bisphosphonates had not been prescribed by the participants' clinicians. In the WHI, hormone therapy decreased the risk of hip fracture by 60% among women with adequate calcium intake at baseline, but not in those with a lower intake. This underscores the importance of emphasizing to patients the consequences of inadequate calcium and vitamin D intake. The impact of hormone therapy was greater in leaner women, as one would expect. **Thus, the results of the WHI provide us with clinical trial evidence for a therapy that protects against fractures in a population not selected for having osteoporosis.** Hormone therapy use in the United States declined by at least 50% following the initial publications from the WHI, and this decrease was paralleled by a significant increase in the incidence of fractures among postmenopausal women!<sup>1821</sup>

Estrogen therapy stabilizes the bone turnover in favor of net bone gain through suppression of bone resorption. Besides inhibiting osteoclastic resorption activity, estrogen increases intestinal calcium absorption, increases 1,25-dihydroxyvitamin D

(the active form of vitamin D), increases renal conservation of calcium, and supports the survival of osteoblasts. With estrogen therapy, one can expect a 50–60% decrease in fractures of the arm and hip,<sup>501, 1713, 1822, 1823</sup> and when estrogen is supplemented with calcium, an 80% reduction in vertebral compression fractures can be observed.<sup>525</sup> This reduction is seen primarily in patients who have taken estrogen for more than 5 years.<sup>1129, 1710</sup> **Protection against fractures wanes with advancing age, and long-term estrogen use is necessary to maximally reduce the risk of fracture after age 75.**

Because most osteoporotic fractures occur late in life, women and clinicians must understand that the short-term use of estrogen immediately after menopause cannot be expected to offer sustained protection against fractures in the seventh and eighth decades of life. Some long-term protection is achieved with 7–10 years of estrogen therapy after menopause, but the impact is minimal after age 75.<sup>1824</sup> In a prospective cohort study of women 65 years of age and older, in those who had stopped using estrogen, and in those who were over 75 and had stopped estrogen after more than 10 years use, there was no substantial effect on the risk for fractures.<sup>1711</sup> Any substantial fracture risk reduction effect from hormone therapy requires treatment initiation within 5 years of onset of menopause and for current use to extend into the elderly years. **The protective effect of estrogen rapidly dissipates after treatment is stopped because estrogen withdrawal is followed by rapid bone loss.** In the 3- to 5-year period following loss of estrogen, whether after menopause or after cessation of estrogen therapy, there is an accelerated loss of bone.<sup>1825, 1826, 1827, 1828, 1829</sup> The PEPI trial, however, found that this rate of bone loss was comparable to that in women not on hormone therapy,<sup>1830</sup> but in a Swedish case-control study, most of the beneficial effect of hormone therapy was lost 5 years after discontinuing treatment.<sup>501</sup> An American randomized trial concluded that elderly women who stopped taking hormones lost most of the bone density gained while on hormone therapy.<sup>1831</sup> Two reports documented that less than 4 years of exposure to estrogen is followed by a period of time, perhaps 10 years, when bone density is better and fractures are less prevalent than nonusers of hormone therapy.<sup>1832, 1833</sup> This protection is not as great as that obtained with long-term hormone use, and beneficial effects should not be expected after age 70, when fractures are most prevalent.

Maximal protection against osteoporotic fractures, therefore, requires lifelong therapy; even some long-term protection requires 10 or more years of treatment, and some protection against fractures is lost within 5 years of discontinuation.<sup>1712, 1834</sup> Standard doses of systemic estrogens that are commonly utilized for symptom control offer skeletal benefit, regardless of route of administration.<sup>501</sup> A study of women randomized to treatment either with continuous transdermal delivery of estradiol 50 mg daily or oral estrogen demonstrated that both equally prevented postmenopausal bone

loss.<sup>1835</sup>

In the PEPI trial, at the end of 3 years, the women receiving hormone treatment had experienced about a 5% gain in BMD in the spine and 2% in the hip compared with approximately a 2% loss in the placebo group.<sup>574</sup> How long does this gain in bone density continue in hormone-using women? In a 10-year follow-up study of women receiving estrogen-progestin therapy, the spinal bone density steadily increased, reaching a level 13% over baseline after 10 years of treatment.<sup>1836</sup> In another cohort study, hormone users did experience a loss of bone at the hip over a 10-year period of time; however, the incidence of hip, wrist, and vertebral fractures was significantly reduced in the hormone users.<sup>1837</sup>

The idea of postponing treatment to prevent osteoporosis until later in life has some merit. Changes in bone density in the early postmenopausal years have no major effect on fractures later in life, except in individuals who already have low bone density. This amounts to only 5% of women in their early postmenopausal years, and most of this 5% will have risk factors such as smoking, history of fracture at a younger age, lean body mass, or excessive alcohol consumption. The positive impact of hormone therapy on bone has been demonstrated in women over age 65 and even over age 75.<sup>1129, 1710, 1711, 1824, 1838, 1839, 1840</sup> This may be a strong argument in favor of treating very old women with estrogen for skeletal benefit, as estrogen use between the ages of 65 and 74 has been documented to protect against fractures.<sup>1713</sup> However, starting hormone treatment later in life and solely for the benefit of bones is a controversial issue. The WHI hormone trials should serve as a reminder that we must strive to balance purported benefits of hormone therapy against risks that are enhanced in aging populations, such as stroke. A large cohort study could detect no significant impact on nonspinal fractures.<sup>1711</sup> In a later analysis of this same cohort, some reduction in fracture risk was observed in women starting hormone therapy after age 60, but a statistically significant reduction was present only in those who started treatment before age 60 and remained on it.<sup>1841</sup>

Older studies suggested that a dose of 0.625 mg of conjugated estrogens is necessary to preserve bone density.<sup>1842</sup> The conventional wisdom has stated that an estradiol blood level of 40–60 pg/mL is required to protect against bone loss.<sup>1843, 1844</sup> We now know that any amount of estrogen can have an impact, although it is very likely that some degree of protection is lost when doses are less than the equivalent of 0.625 mg conjugated estrogens or 1.0 mg estradiol.

The rate of bone loss and the incidence of hip and vertebral fracture is inversely related to the circulating estrogen levels in older women.<sup>1845, 1846</sup> Estradiol levels as low as 10 pg/mL have a beneficial impact on bone density and fracture rates compared

with values below 5 pg/mL. **Thus, any increment in estrogen, even within the usual postmenopausal range, will exert protective effects.** This explains how a positive effect on bone was observed even with the utilization of the vaginal ring that delivers a very small amount of estradiol with minimal systemic absorption.<sup>558</sup>

A lower dose of 0.3 mg daily of conjugated estrogens or 0.5 mg estradiol prevented loss of vertebral trabecular bone when combined with calcium supplementation (to achieve a total intake of 1,500 mg daily).<sup>576, 1847, 1850</sup> In a small study without calcium supplementation, daily administration of 0.3 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate produced a slight increase in lumbar bone density with a lesser effect on the hip.<sup>1851</sup> Even a dose of estradiol as low as 0.25 mg/day produced an increase in bone density.<sup>579</sup>

The Women's Health, Osteoporosis, Progestin, Estrogen (HOPE) trial involved 800 postmenopausal women in a dose-response evaluation of conjugated estrogens and medroxyprogesterone acetate. The lowest dose, 0.3 mg conjugated estrogens, either unopposed or combined with 1.5 mg medroxyprogesterone acetate, produced a gain in bone density.<sup>577</sup> A major concern with lower doses is the possibility that there will be a significant percentage of nonresponders (discussed later). Nevertheless, a lower dose of estrogen may be more acceptable (fewer side effects) in elderly women.

Certain progestational agents have been reported to act independently, in a manner similar to estrogen, to reduce bone resorption.<sup>1852</sup> When added to estrogen, progestins can lead to an apparent synergistic increase in bone formation associated with a positive balance of calcium.<sup>1853, 1854, 1855, 1856</sup> On the other hand, other studies have failed to find a greater impact on bone, comparing estrogen alone to estrogen plus a progestin.<sup>1711</sup> These different results are explained by the fact that the synergistic result of combining estrogen with a progestin is determined by the type of progestin, being limited to members of the 19-nortestosterone (norethindrone) family.<sup>571</sup> This could reflect an increase in free estrogen levels because of a reduction in SHBG. Careful studies indicate that the addition of medroxyprogesterone provides an additional effect on bone density only in women with established, significant osteoporosis.<sup>1856, 1857, 1858</sup>

In the PEPI trial, at the end of 3 years, there was little difference comparing treatment with estrogen only to the groups receiving either sequential or continuous combinations of estrogen and medroxyprogesterone acetate or micronized progesterone.<sup>574</sup> Thus, the daily, continuous combination of estrogen-progestin is equally efficacious in maintaining bone density as the sequential regimens, although at least one study has indicated a slightly greater response in the lumbar spine with continuous treatment.<sup>571, 610, 1859, 1860</sup>

The addition of testosterone to an estrogen therapy program has been reported to

provide no additional beneficial impact on bone or on relief from hot flushes.<sup>613, 617</sup> Others have demonstrated a greater increase in bone density with an estrogen-androgen combination compared with estrogen alone, although the blood estrogen levels achieved were higher than those associated with standard postmenopausal hormone therapy.<sup>615</sup> In another study, only a very pharmacologic dose of methyltestosterone added to the bone density achieved with estrogen alone.<sup>618</sup>

**We support the consideration of early initiation of menopausal hormone therapy in early menopausal women with evidence of low bone mass as a fracture risk reduction strategy, but caution that consideration for prolonged use of hormone regimens in postmenopausal women must be individualized. If long-term use of menopausal hormone therapy is chosen as the preferred approach to fracture risk reduction, prescribers are cautioned on the importance of periodic reassessments and timely adoption of risk reduction strategies (such as switching from oral to transdermal route and reduction in dose of estrogen) to ensure that patients electing to be treated with hormones achieve protection against osteoporotic fractures while mitigating estrogen-related risks. Testosterone should not be prescribed with the expectation that androgen treatment will improve bone health.**

## **Follow-Up Assessment of Hormone-Treated Women**

Either a stable bone density or an increase indicates successful treatment; however, not all women will maintain or gain bone density on postmenopausal hormone therapy; in one study, 12% of treated women lost bone despite apparently good compliance.<sup>500</sup> In the PEPI 3-year clinical trial, where compliance rates were probably maximal, 4% of treated women lost bone in the spine and 6% in the hip.<sup>574</sup> **It is worthwhile to repeat bone density assessment following initiation of hormone therapy for skeletal benefit to assess response in treated women when they are in their late 60s.** This problem of poor response is discussed near the end of this section.

# Selective Estrogen Receptor Modulators

## Raloxifene

Raloxifene is the prototype SERM that is commonly utilized in the management of osteoporosis. SERMs act as agonists-antagonists at the level of estrogen receptors and can have selective actions on specific target tissues. Raloxifene produces favorable estrogen-like responses in bone and on lipids, but unlike estrogen, it is neutral at the level of the endometrium.<sup>649, 650</sup> In contrast to estrogen, raloxifene also has proven efficacy in reducing risk for breast cancer. The changes in bone remodeling produced by raloxifene are consistent with an estrogen agonist effect.<sup>1861</sup> As with estrogen therapy, discontinuation of raloxifene treatment is followed by a resumption of bone loss.<sup>1862</sup>

The increase in bone density associated with raloxifene, 60 mg daily, is less than that seen with bisphosphonate, alendronate.<sup>1863, 1864, 1865</sup> The MORE study of raloxifene administration to osteoporotic women reported results from 8 years of follow-up.<sup>653, 654</sup> Women with low bone density T-scores had approximately a 50% reduction in vertebral fractures with raloxifene treatment; those with previous vertebral fractures had approximately a 35% reduction. However, **there has been no evidence of a reduction in hip or wrist fractures with raloxifene use.** Although the reduction in vertebral fractures is similar to that seen with alendronate and estrogen, why is there no decrease in hip fractures, despite a bone density response that is only slightly less than that associated with alendronate? There are at least two possible explanations. The study was of insufficient duration to demonstrate an impact in a population that was relatively young for hip fractures. Or a weaker impact on bone density produces a lesser effect in the hip, which has a combination of cortical and trabecular bone that is less responsive compared with the spine with its large content of trabecular bone.

A reduction in vertebral fractures with raloxifene that is equivalent to that with estrogen or bisphosphonates despite a lesser increase in bone density is strong evidence that fracture risk and reduction are not simply reflections just of bone density. Thus, a few percentage point differences comparing bone densities between two therapies do not translate into a difference in fracture protection. For this reason, fracture data are important, and we cannot conclude that small differences predict lesser or better performances in fracture protection. Another example is the greater gain in bone density associated with combination treatment with alendronate and estrogen; a greater gain in bone density does not necessarily mean a greater protection against fractures. Similar to estrogen, use of raloxifene has been associated with a small but real risk for thrombotic events. **In our view, raloxifene is an option for prevention of osteoporosis-related spinal fractures, especially for those who are deemed at an enhanced risk for both**

**breast cancer and spine fracture risk. We recommend, however, periodic evaluation of bone density in the hip, as if ongoing site-specific bone loss continues despite compliance with raloxifene, patient and clinician should consider another treatment option that offers broader skeletal benefits at the level of the hip as well as the spine.**

## **Bazedoxifene**

BZA is a third-generation SERM, with tissue-specific estrogen agonist-antagonist effects. It has favorable effects on bone and lipids, but does not affect the endometrium or the breast. BZA in a dose of 20 mg daily decreased the risk of all clinical fractures in a randomized clinical trial, with a potency comparable to other antiresorptive agents in postmenopausal women at high risk for fractures.<sup>670, 671</sup> In a subgroup of women at higher risk for fractures, BZA had a reduced risk of nonvertebral fractures (50% reduction with 20 mg), compared with both raloxifene and placebo. The only adverse event that differed with treatment was an increase in venous thrombosis with treatment compared with placebo. The results of this trial indicate that the effect of BZA on bone should be comparable to that of estrogen and bisphosphonates.

The reduction of nonvertebral fractures with BZA compared with raloxifene should not be ignored. We have known for some time that even with 8 years of follow-up, raloxifene has no impact on the risk of hip fractures. This is likely because raloxifene is less potent, and thus the hip with a mixture of cortical and trabecular bone is more resistant to raloxifene's effects, compared with the spinal column that is composed of sensitive, trabecular bone. As discussed earlier in this chapter, BZA partnered with conjugated estrogen is the first TSEC to be made available in the United States for menopause management. The idea is to gain the benefits of estrogen (BZA has little impact on hot flashes), protect the endometrium and possibly the breast, and enhance some actions of estrogen, such as a reduction in fractures. This approach to postmenopausal hormone therapy has eliminated a concomitant need for progestational agents in hormone-using postmenopausal women with an intact uterus. **In our opinion, the combination of BZA and estrogen is a promising option for reducing risk of osteoporosis; its efficacy in reducing fracture risk however remains unclear, and future studies are awaited to determine how risk reduction benefit of TSEC against fractures, if any, compares to that of traditional hormone therapy.**

# Calcium Supplementation

There has been considerable confusion over whether calcium supplementation by itself can offer protection against postmenopausal osteoporosis. This is partly due to the fact that calcium studies were performed in women who were in the very early postmenopausal years, in the midst of the rapid loss of calcium associated with estrogen deficiency, and this estrogen effect overwhelmed any responses to calcium. Studies that involved women beyond this early stage of the postmenopausal period indicated a positive impact of calcium supplementation.<sup>1866, 1867, 1868, 1869</sup>

Calcium absorption decreases with age because of a decrease in biologically active vitamin D and becomes significantly impaired after menopause. A positive calcium balance is mandatory to achieve adequate prevention against osteoporosis. Calcium supplementation (1,000 mg/day) reduces bone loss and decreases fractures, especially in individuals with low daily intakes.<sup>1870, 1871</sup> Estrogen acts to improve calcium absorption by increasing the levels of 1,25-dihydroxyvitamin D and makes it possible to utilize effective supplemental calcium in lower doses (**Figure 17.23**).

**FIGURE 17.23**

## Key Points: Calcium Supplementation

- In order to remain in zero calcium balance, postmenopausal women require a total of 1,200 mg elemental calcium (through diet and supplements) per day.<sup>1870, 1872, 1873</sup>
- Because the average woman without any dietary restrictions receives about 500–700 mg of calcium in her diet, the minimal daily supplement for women on estrogen equals an additional 500 mg.

High-dose calcium supplementation can unmask asymptomatic hyperparathyroidism, causing abnormally high calcium blood levels and an increased risk for renal stones.<sup>1874, 1875</sup> Assessment of dietary intake and restrictions should be undertaken at routine clinical visits, and recommendations on dose of supplementation should be individualized based on dietary intake. Women receiving calcium supplementation in excess of 500 mg daily should have their blood levels of calcium and phosphorus measured yearly for the first 2 years. If normal, no further surveillance is necessary.

Even with the commonly used therapeutic doses of calcium, nearly 40% of postmenopausal women have inefficient absorption.<sup>1876</sup> Estrogen improves calcium absorption and allows the utilization of supplemental calcium in effective doses without the side effects associated with higher doses (constipation and flatulence) that diminish compliance. **We must emphasize that although calcium supplementation is important, it cannot provide the same degree of protection against osteoporosis as that achieved by hormonal therapy or raloxifene or agents discussed later in this section.**<sup>1877, 1878</sup> Nevertheless, the beneficial impact of estrogen on bone is reduced in the absence of calcium supplementation.<sup>1848</sup> Skeletal harm from low calcium intake in the aging population gets compounded if there is coexisting insufficient dietary intake of proteins.<sup>1879</sup>

Improved calcium intake in adolescents results in significant increases in bone density and skeletal mass, providing protection against osteoporosis later in life.<sup>1880, 1881</sup> Calcium supplementation is far more important during adolescence than in the reproductive years when bone formation is minimal. Under age 25, during the years of bone accumulation, the recommended daily calcium intake is 1,300 mg.<sup>1882</sup> This amount, 1,300 mg/day, is also recommended during pregnancy and lactation. Most calcium comes from dairy products; relying on other foods is not easy because it requires a high intake volume of other foods to provide the same amount of calcium in normal daily servings of dairy products (Table 17.18). Foods with high amounts of oxalate and

phytate, such as spinach, rhubarb, beans, peas, wheat bran, and beet greens, reduce calcium absorption.

## **TABLE 17.18 Calcium Content of Foods**

## Calcium Content of Foods

Yogurt (1 cup)	415 mg
Yogurt with fruit (1 cup)	345 mg
Juice fortified with calcium (1 cup)	300 mg
Milk (1 cup)	300 mg plus 100 IU vitamin D
Ice cream (1 cup)	175 mg
Cottage cheese (1 cup)	140 mg
Romano cheese (1 oz)	300 mg
Parmesan cheese (1 oz)	335 mg
Cheddar cheese (1 oz)	205 mg
Swiss cheese (1 oz)	270 mg
Mozzarella cheese (1 oz)	207 mg
Tofu (1 cup)	150 mg
Broccoli, cooked (1 cup)	140 mg
Beans, cooked (1 cup)	80 mg

There are dozens of calcium supplements on the market, containing calcium carbonate,

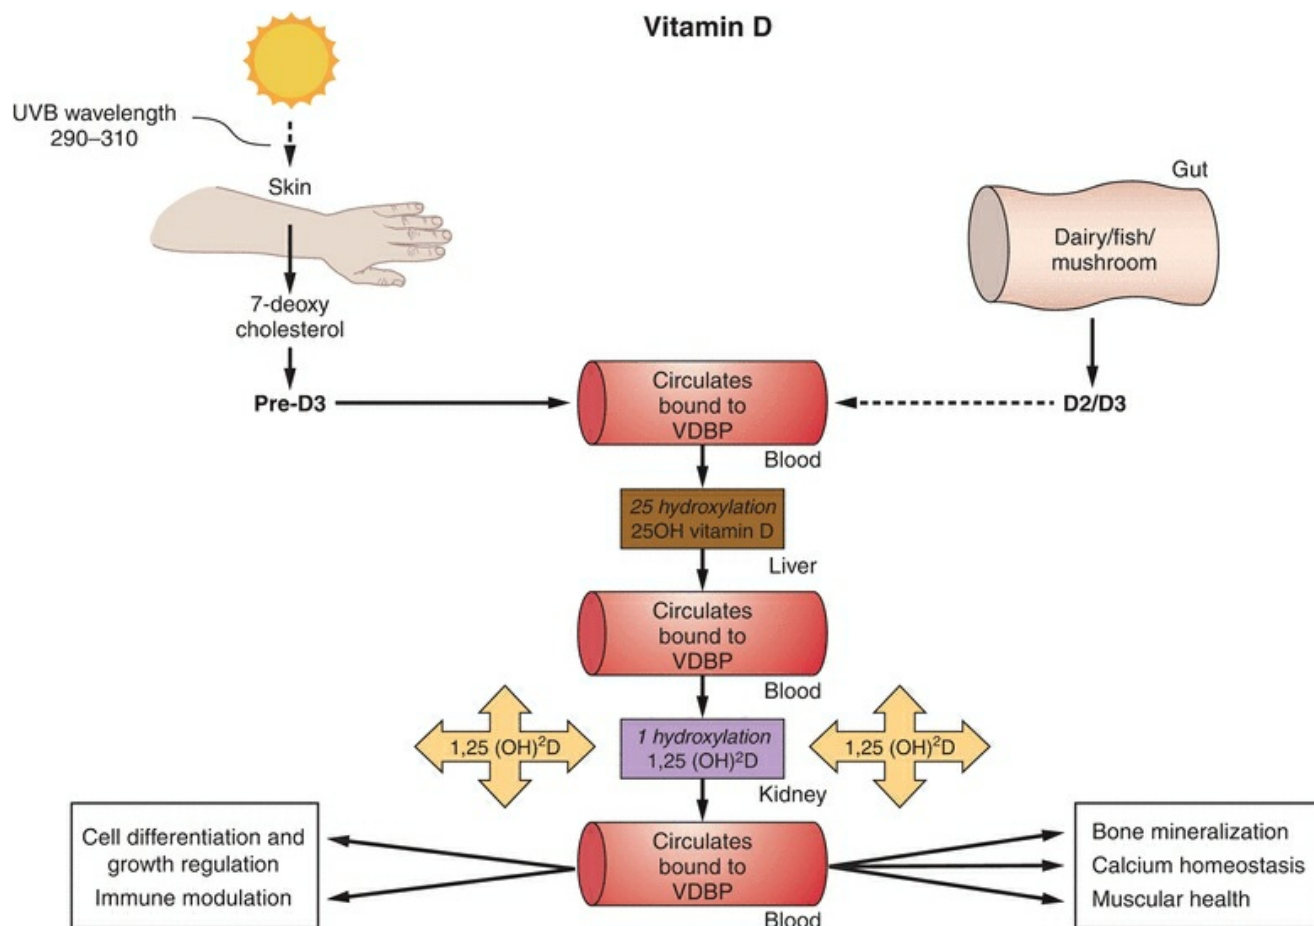

calcium lactate, calcium phosphate, or calcium gluconate. Calcium carbonate tablets are the cheapest and contain the most elemental calcium (40%). Calcium lactate tablets contain 13% calcium, calcium citrate 23%, and calcium gluconate only 9%. The calcium carbonate antacids are excellent, inexpensive sources. Be aware that aluminum-containing antacids such as Maalox, Mylanta, Gelusil, and Riopan can inhibit gastrointestinal absorption of calcium. Bone meal and dolomite as sources of calcium should be avoided because they are contaminated with lead. Calcium carbonate derived from “natural” sources (such as oyster shell), brand-name formulations, and even “refined” products can also contain lead.<sup>1883</sup> It is worth looking for specific products labeled as tested and containing no lead, having “purified” or “USP Verified Mark” on the label. Calcium citrate does not require gastric acid for absorption and is the best choice for older patients with reduced gastric acid production. Calcium supplementation is most efficient when single doses do not exceed 500 mg and when taken with a meal. **Excess calcium supplementation (especially not with meals) is associated with a slight increase in risk for kidney stones.**<sup>1874,1884</sup>

# Vitamin D

Changes in vitamin D and calcium metabolism accompany aging and contribute to the aging-related increase in skeletal fragility.<sup>1885,1886</sup> There is an age-related decrease in the ability of tissues to convert the major circulating form of vitamin D, 25-hydroxyvitamin D to the active form of vitamin D (1,25-dihydroxycholecalciferol, better known as 1,25-dihydroxyvitamin D), and there is a decrease in the ability of the intestine to absorb dietary vitamin D. Exposure of the skin to ultraviolet rays in sunlight stimulates the formation of cholecalciferol (vitamin D<sub>3</sub>). One dose of sunlight that produces erythema is equivalent to 10,000–25,000 IU of vitamin D. Excessive exposure to sunlight cannot cause toxic levels of vitamin D because any excess in vitamin D<sub>3</sub> is inactivated by ultraviolet radiation.

Vitamin D<sub>2</sub> (ergocalciferol) in commercial supplements has been replaced with the more effective vitamin D<sub>3</sub> (cholecalciferol), which is more than 3 times the potency of vitamin D<sub>2</sub>.<sup>1887</sup> Cholecalciferol and ergocalciferol are converted in the liver to calcitriol (25-hydroxyvitamin D), the major circulating metabolite that is active in stimulating the absorption of calcium and phosphate from the gastrointestinal tract. The circulating level of 25-hydroxyvitamin D and renal conversion to its active form, 1,25-dihydroxyvitamin D, are regulated by calcium, phosphorous, and parathyroid hormone (**Figure 17.24**).

**FIGURE 17.24**

The importance of optimization of vitamin D status through lifestyle modifications and judicious use of supplementation in aging populations cannot be minimized. For postmenopausal women, the recommended daily allowance for vitamin D is 600 IU.<sup>1882</sup> However, it is important to appreciate that RDA doses are inadequate to achieve correction of underlying vitamin D deficiency, and there is sufficient evidence to support safety of daily intake of 1,000–2,000 units of vitamin D in addition to calcium supplementation. Older studies that failed to document a beneficial impact of vitamin D supplementation were handicapped by doses that were too low and in the setting of inadequate calcium intake.<sup>1888</sup> A pooled analysis of 68,500 patients in seven major vitamin D fracture trials concluded that vitamin D in appropriate doses coupled with calcium supplementation reduced fractures at all sites in men and women.<sup>1889</sup>

Because adequate and active vitamin D depends on cutaneous generation mediated by sun exposure, women in the winter months can easily be relatively vitamin D deficient and lose bone.<sup>1890</sup> In far northern and southern areas, the winter sunlight is

inadequate to stimulate dermal activation. But even in areas of the world where there is adequate sun exposure, inadequate dietary intake and an indoor lifestyle yield a significant number of women with abnormally low levels of circulating 25-hydroxyvitamin D.<sup>1891</sup> In addition, clothing and sunscreens prevent the cutaneous production of vitamin D<sub>3</sub>. The NHANES documented a rising prevalence of vitamin D insufficiency in the United States over the last two decades.<sup>1892</sup> **If uncertain regarding vitamin D supplementation, the serum level of 25-hydroxyvitamin D can be measured; although the Institute of Medicine (IOM) in the United States has lowered the threshold to define vitamin D deficiency to less than 20 ng/mL, the U.S. Endocrine Society maintains that a level below 30 ng/mL is abnormal.**<sup>1822,1893</sup>

The benefit of vitamin D supplementation is clear in older postmenopausal women, and the lack of side effects encourages us to recommend vitamin D supplementation as part of the overall program for osteoporosis prevention in younger postmenopausal women. But keep in mind that effective bone response to vitamin D requires adequate calcium intake.

One caution regarding vitamins: excessive intake of vitamin A, specifically retinol, was reported to be associated with an increased rate of hip fractures in the women not using hormone therapy in the Nurses' Health Study; it would be better to avoid obtaining vitamin D by taking more than one multivitamin tablet daily.<sup>1894</sup> It has been argued that excess retinol intake may explain the higher rate of fractures in Scandinavia.<sup>1895</sup>

The WHI conducted a randomized trial of calcium and vitamin D supplementation.<sup>1896</sup> The 36,282 postmenopausal women were part of the WHI clinical trials involving postmenopausal hormone therapy or dietary modification. The average follow-up was 7 years. Thirty-seven percent of the women were age 50–59, 45.5% were 60–59, and 17.5% were 70–79. The treated group was supplemented with 1,000 mg calcium and 400 IU vitamin D daily. Overall analysis indicated no significant reduction in fractures with calcium/vitamin D treatment. The women treated with calcium/vitamin D had a 17% greater risk of kidney stones. However, a closer look reveals some good news:

- Correcting for compliance by analyzing just those women who continued their medication revealed a statistically significant 29% reduction in risk for hip fractures. Only 59% of the treated women at the end of the trial were taking the intended dose.
- Women who were 60 years and older had a 21% significant reduction in hip fractures.
- The reduction in hip fractures was greatest (42%) in those women who combined calcium/vitamin D supplementation with postmenopausal hormone therapy.

The population at greatest risk for fractures (the oldest women in the WHI study) actually benefited, and the study confirmed something already known that hormone therapy combined with calcium/vitamin D supplementation achieves the best results. Keep in mind that the women in this study were not at high risk for fractures. Indeed, whole-body and spinal bone density increased in the placebo group. This is hard to explain; the average postmenopausal untreated woman loses spinal bone density. In this study, only hip bone density demonstrated a loss, and thus, it is not surprising that significant benefits were demonstrated only with hip fractures. The fact that most of these women were overweight probably contributed to the protection against bone loss in the spine. In a population of women losing bone density in both the hip and spine, and in women with other risk factors for fractures, calcium/vitamin D supplementation should yield even better results than those reported by the WHI, including a reduction in spinal and arm fractures. Degenerative joint disease and resulting osteophytes can convey false reassurance of improved bone density on radiologic imaging including DEXA, and this may have contributed to the improved spine bone density observed in the WHI placebo group.

What about the kidney stones? The women in the WHI trial were allowed to continue their own programs of supplementation. Thus, many took calcium and multivitamins (which contain 400 IU vitamin D). The average daily calcium intake of the study population was 1,100–1,200 mg, twofold higher than the average American woman. The WHI does not provide data to answer this most important question: was the small increase in kidney stones observed in women who were taking excessive amounts of calcium and vitamin D?

The WHI has published multiple findings from the calcium/vitamin D randomized trial. The conclusions are uniformly negative, summarized as follows:

- The incidence of invasive breast cancer was similar in the treated and placebo groups. The risk of breast cancer was not associated with baseline 25-hydroxyvitamin D levels.<sup>1897</sup>
- Calcium and vitamin D supplementation did not protect against a decline in physical functioning or performance.<sup>1898</sup>
- The incidence of newly diagnosed diabetes was the same in the treated and placebo groups.<sup>1899</sup>
- Myocardial infarction and stroke events were similar in the treated and placebo groups.<sup>1900</sup>
- Calcium and vitamin D supplementation had no effect on blood pressure or the risk of developing hypertension.<sup>1901</sup>

The WHI also reported the effects on overall mortality in their randomized trial of

calcium and vitamin D supplementation.<sup>1902</sup> After an average follow-up of 7 years, there was no impact on total mortality (744 deaths in treated women and 807 deaths in the placebo group). There was a nonsignificant reduction (about 10%) in risks for stroke and cancer mortality. Comparing the women older than 70 to those younger than age 70, there was a lower risk for mortality in the younger group, but this did not achieve statistical significance. When analysis was restricted to those participants who were adherent to therapy, the results for overall mortality and for the younger women were essentially unchanged. However, a nested case-control study assessed the results according to serum 25-hydroxyvitamin D levels at baseline; the results indicated that women with the lowest levels had a higher risk for death. The WHI investigators concluded that their results weakly support the hypothesis that calcium and vitamin D supplementation modestly reduces cancer and cardiovascular mortality. Overall, the results indicated no major benefit of calcium and vitamin D supplementation on the risk of death due to cancer or cardiovascular disease.

Smaller trials and observational studies of vitamin D supplementation have demonstrated reductions in total mortality, reductions in blood pressure and cholesterol levels, and reduced risks of stroke and CHD. Vitamin D insufficiency has been linked to a wide spectrum of problems, including an increase in autoimmune diseases such as rheumatoid arthritis, upper respiratory tract infections, diabetes mellitus, multiple sclerosis, cancer, and cardiovascular disease. Low levels of serum 25-hydroxyvitamin D have been reported to be associated with higher all-cause mortality, greater prevalence of breast cancer, peripheral arterial disease, and higher cardiovascular mortality.<sup>1903,1904,1905,1906,1907</sup> It is proposed that many tissues produce locally the active 1,25-dihydroxyvitamin D that exerts beneficial effects on cell regulation and differentiation before being inactivated within cells without reaching the circulation and interfering with calcium metabolism.<sup>1886</sup>

What could explain the lack of strong agreement between the WHI results and the rest of the literature? The answer can be found in the characteristics of the women in the WHI and the doses of calcium and vitamin D used for supplementation. The women in the WHI were not at high risk for fractures, and most of the women were overweight. Only one-third of the participants had a low calcium intake at entry to the study, and 29% were already taking calcium supplementation. As previously noted, the average daily calcium intake of the study population was 1,100–1,200 mg, twofold higher than the average American woman.<sup>1896</sup> Low serum levels of 25-hydroxyvitamin D were found in only 25% of the women in whom it was measured.

The negative publicity associated with the WHI publications has obscured the importance of fracture risk in women. In the observational arm of the WHI, the risk of fracture was compared to the risks of cardiovascular events and breast cancer in a

prospective cohort of 83,724 women, aged 70–79.<sup>1908</sup> **The recorded events indicated that the number of women who experienced a fracture in 1 year's time exceeded the combined number of women experiencing invasive breast cancer or cardiovascular disease (except in blacks in whom cardiovascular events dominated).** And don't forget that in the WHI, the women adherent to their calcium/vitamin D supplementation had a 29% reduction in risk for hip fractures, and the reduction in hip fractures (42%) was greatest in those women who combined calcium/vitamin D supplementation with hormone therapy.<sup>1896</sup>

Because 60% of individuals who live in northern latitudes have low serum levels of 25-hydroxyvitamin D, the WHI results do not rule out the possibility of beneficial effects of adequate supplementation in a large segment of our population.<sup>1909</sup> The WHI nested case-control study documented that the risk of hip fracture steadily increases in women as their serum levels of 25-hydroxyvitamin D decrease.<sup>1910</sup>

**Vitamin D is essential for adequate calcium absorption and maximal bone protection, but remember that supplemental vitamin D requires adequate calcium intake.**<sup>1888,1889</sup> Calcium absorption decreases and parathyroid hormone increases as the levels of 25-hydroxyvitamin D fall below 30 ng/mL. Multiple studies have demonstrated that vitamin D together with calcium supplementation in older men and women reduces the rate of fractures.<sup>1877,1911,1912</sup> Normal vitamin D levels are important for muscle functioning; vitamin D supplementation alone and in combination with calcium lowers the risk of falling and improves lower extremity function in older men and women.<sup>1913,1914</sup> **We believe that vitamin D and calcium supplementation are simple yet critical strategies that offer risk reduction against fragility fractures through mechanisms that include positive effects on BMD, on bone quality, and possibly on muscular function. Supplementation strategies must utilize dietary sources as well as supplements, and dosing regimens should be individualized to the needs of the population at risk.**

## Key Points: Vitamin D

- Clinicians should be vigilant toward identifying populations at risk for vitamin D deficiency and be more aggressive in confirming their impression through monitoring serum levels of 25-hydroxyvitamin D. While a level less than 20 ng/mL is a definitive indication of vitamin D deficiency, any value less than 30 ng/mL is below normal and must be interpreted in the context of the overall picture. We believe that this measurement should be part of every older individual's annual medical assessment.

- The choice of vitamin D supplementation dose and regimen should be dictated by the severity of deficiency, and periodic surveillance is advised to ensure effectiveness of chosen regimen and to safeguard against a small but real risk of overdosing. It takes about 3 months after initiation of supplementation for serum levels of 25-hydroxyvitamin D to reach a new steady state after a change in dose.
- Patients who lose bone despite adequate treatment for bone loss must have serum 25-hydroxyvitamin D and calcium measurements because inadequate calcium and vitamin D can be an easily correctable reason for suboptimal response to effective regimens.

Given these facts, how can we determine how much vitamin D to give to an individual patient? A collection of bone experts reached a consensus by considering the amount of vitamin D supplementation required to change blood levels of 25-hydroxyvitamin D and parathyroid hormone, correlating this information with the levels of vitamin D required to prevent bone loss.<sup>1915</sup> The U.S. IOM recommends intake of 600 IU as the daily allowance of vitamin D for postmenopausal women until age 70, with an increase in recommended allowance to 800 IU daily for women 71 and older. However, in women with documented evidence of vitamin D deficiency (serum 25-hydroxyvitamin D < 30 ng/mL), doses as high as 1,500–2,000 IU/day can be safely utilized to achieve levels required to maintain the optimal serum level of 25-hydroxyvitamin D, greater than 30 ng/mL. Short durations (3 months) of higher-dose regimens are often utilized to achieve restoration of low level of 25-hydroxyvitamin D to normal, such as 50,000 IU vitamin D<sub>2</sub> (available as prescribed formulation in the United States) administered once or twice weekly for 3–6 months followed by switch to lower-dose daily regimens of 600–2,000 IUs. Toxic doses of vitamin D (enough to produce hypercalcemia) are far beyond these recommendations.

# Bisphosphonates

Bisphosphonates are effective in preventing bone loss by enhancing osteoclast apoptosis and inhibiting bone resorption. The bisphosphonates share a basic phosphate-carbon-phosphate core and bind avidly to the bone mineral calcium where they remain for many years, making bone less susceptible to osteoclastic action. The first generation of bisphosphonates (etidronate) also inhibited bone mineralization, and therefore intermittent therapy was necessary. The newer generations of bisphosphonates allow bone formation to occur while inhibiting bone resorption and make it possible to use continuous therapy rather than intermittent therapy.

**Diagnostic screening with the laboratory tests previously noted is important before the administration of bone-specific drugs in order to avoid inappropriate treatment in the presence of a secondary cause for osteoporosis, especially renal disease.**

Oral bisphosphonates must be taken on an empty stomach with a full glass only of water, no other liquid, at least 30 minutes before any other food or liquid intake in order to achieve adequate absorption. A failure to remain upright for at least 30–60 minutes and until after the first food intake of the day after ingesting bisphosphonates can result in esophageal injuries, such as esophagitis, esophageal ulcers, and esophageal erosions with bleeding.<sup>1916</sup> Upper gastrointestinal problems in clinical trials (with carefully instructed and monitored subjects) are similar comparing alendronate treatment with placebo, indicating that improper usage is the culprit.<sup>1917,1918</sup> Risedronate (Actonel), 5 mg daily, is as effective as alendronate (Fosamax) for the prevention of bone loss, provides similar protection against fractures, and may be better tolerated.<sup>1919,1920,1921,1922,1923</sup> Other equally effective bisphosphonates include ibandronate (Boniva) and zoledronic acid (Reclast, Aclasta). Notably, zoledronic acid administered as a single 5-mg dose intravenously protects against bone loss for at least 2 years.<sup>1924,1925</sup>

The mechanism for the gastrointestinal reactions is an interference with the normal healing process that repairs trauma associated with eating. With less frequent exposure, this healing is allowed to proceed unimpeded. Periodic administration with equivalent bone efficacy is possible because of the high affinity of bisphosphonates for bone. Thus, weekly administration of alendronate and risedronate, each in a dose of 35 mg for prevention and 70 mg for treatment, reduces side effects and produces similar increases in bone density compared with a daily regimen.<sup>1926,1927,1928,1929,1930</sup>

In women with osteoporosis, alendronate (10 mg daily) administration reduced the risk of all subsequent fractures by 30% and vertebral fractures by 50% in 3–4 years of treatment.<sup>1931,1932,1933</sup> In normal postmenopausal women, alendronate increased bone

density in both the spine and the hip, and the 5-mg dose (the preferred dose for preventive treatment) was more effective than 2.5 mg.<sup>1934,1935</sup> In the data derived from follow-up of 4,432 women for an average of 4.2 years, a statistically significant reduced risk of fracture was demonstrated only in women with initial T-scores of  $-2.5$  or less, a 36% reduction in all fractures and a 50% reduction in vertebral fractures.<sup>1936</sup>

Bisphosphonate treatment obviously benefits women who already have a low bone density or previous vertebral fractures. Risedronate reduces vertebral and hip fractures in women with osteoporosis with an impact similar to that of alendronate.<sup>1921,1937</sup> After 5 years of treatment with risedronate, the risk of new vertebral fracture decreased by 59%, an improvement from the 49% reduction reported after 3 years.<sup>1938</sup> Ibandronate reduced vertebral fractures by about 60% over 3 years; zoledronic acid reduced vertebral fractures by 70% and hip fractures by 41% over 3 years.<sup>1939,1940</sup>

The EPIC (Early Postmenopausal Interventional Cohort) study concluded that over a 4-year period of time, alendronate and hormone therapy in the United States produce similar bone density results. The greater increase noted in Europe with hormone therapy probably reflects the use of 19-nortestosterone progestins, which are known to have an additive effect on bone density when combined with estrogen. Combining bisphosphonate and hormone therapy produces an added gain in bone density. When women who were already taking hormone therapy also received alendronate (10 mg) for 1 year, the gain in bone density ranged from 0.9% in the femoral neck to 2.6% in the spine.<sup>1941</sup> In women with osteopenia, combined therapy with alendronate 10 mg and 0.625 mg conjugated estrogens produced a 1–2% greater gain in bone density over a 2-year period of treatment; similar results were reported in a 1-year trial with risedronate.<sup>1942,1943</sup> **There are no data available on whether addition of a bisphosphonate to estrogen regimen improves antifracture efficacy of either agent alone. Furthermore, there is a theoretical concern that oversuppression of resorption can ultimately yield more brittle bones.**

Compliance with alendronate has been overestimated by the clinical trials. It is well-recognized that participants in clinical trials are better motivated, are better supported, and perform better. In the Kaiser Permanente Medical Care Program in California, about one-third of patients had acid-related complaints, and one in eight required treatment.<sup>1944</sup> About 50% of the Kaiser patients did not comply with instructions, and about 50% discontinued therapy by 1 year.<sup>1944,1945</sup> Analysis of general pharmaceutical claims databases in the United States revealed that only 43% refilled their first prescription, and after 2 years, only 20% were adherent to treatment.<sup>1946</sup> Bone density measurements are recommended to assess compliance and to provide motivation for continuation; compliance can also be assessed by measuring bone markers prior to

initiation of therapy and then repeating assessment 1–3 months later; a 30% decrease in bone markers is anticipated if patients are compliant with prescribed strategy and there are no major issues of malabsorption. Programs with good patient support have reported long-term compliance with hormone therapy: 65% at 7.5 years in an Australian population and 61% at 7 years in the United Kingdom.<sup>1947,1948</sup>

Because of the apparent benefits associated with alendronate therapy, the clinical trials were halted after 4 years, although follow-up has indicated persistent gains in BMD through 10 years of use.<sup>1949</sup> There is evidence that a bisphosphonate already in the bone can recirculate when bone containing the bisphosphonate is remodeled.<sup>1950</sup> Thus, perhaps long-term treatment with this class of agents is unnecessary. Comparing bone loss after discontinuation of treatment, accelerated bone loss occurs after estrogen and raloxifene, but a residual effect on bone density is maintained for up to 7 years after alendronate is discontinued<sup>1862,1951,1952,1953</sup> (Table 17.19).

## **TABLE 17.19 Bisphosphonates—Recommended Dosages**

	For Prevention	For Treatment
Alendronate	5 mg daily; 35 mg weekly	10 mg daily, 70 mg weekly
Risedronate	5 mg daily	5 mg daily
	35 mg weekly	35 mg weekly
	75 mg daily for 2 d each month	75 mg daily for 2 d each month
Ibandronate	150 mg monthly	150 mg monthly
	2.5 mg daily	2.5 mg daily
		150 mg monthly
Zoledronic acid	5 mg IV every 2 y	3 mg IV every 3 mo
		5 mg IV annually

## How Long Should Bisphosphonate Treatment Be Continued?

In an extension of the alendronate Fracture Intervention Trial (FIT), the participants were randomized after 5 years of treatment either to another 5 years of treatment or placebo.<sup>1954</sup> The group that discontinued alendronate treatment (5 or 10 mg/day) experienced small losses of BMD over 5 years. The levels, however, remained above the pretreatment levels 10 years previously. There were no differences in nonvertebral fractures between the treatment and placebo groups, but there was a twofold higher rate of clinically recognizable vertebral fractures in the placebo group (5.3% vs. 2.4%). It was concluded that for most women, a period of drug holiday may be safely considered

after 5-year treatment with alendronate and that long-term treatment beyond 5 years should be limited to high-risk women (women with existing vertebral fractures or very low bone densities).

The rate of hip fracture among women who discontinued bisphosphonate therapy was compared with women who remained on treatment.<sup>1955</sup> The study group consisted of 9,063 users who had been compliant for at least 2 years. The hip fracture rate about doubled in the women who discontinued treatment compared with those who did not. After discontinuation for a year or longer, the risk of hip fracture increased by 9 months in women with low compliance rates. In women with high compliance rates for 2 or 3 years, there were no significant differences in fracture risk after discontinuation for up to 1 year later. Why is there this lingering effect?

The unique tight binding of bisphosphonates to bone matrix causes this class of drugs to remain in the body for decades. This is believed to be the explanation for why there is no rapid bone loss after discontinuing bisphosphonate treatment in contrast to the rapid loss that follows the termination of treatments such as estrogen or raloxifene or denosumab (discussed later). This is also the reason why concerns have been raised regarding long-term treatment because when bone remodeling releases bound bisphosphonate, it is free to be active again, and as a result, the endogenous bisphosphonate is added to the administered bisphosphonate, raising dosage exposure. The potential risk that has been long recognized is that prolonged exposure to bisphosphonates or excessive dosage would oversuppress bone resorption, thus oversuppressing bone turnover, a phenomenon referred to as adynamic bone that ultimately affects the biomechanical strength of bone and allows microcracks to accumulate. A unique type of fracture of the femur, commonly referred to as “atypical fracture,” is characterized by a transverse fracture in an area marked by hypertrophy of the cortex and has been associated with long-term use of bisphosphonates.<sup>1956</sup>

## **Bisphosphonates and Osteonecrosis of the Jaw**

Osteonecrosis of the jaw (ONJ) is a rare complication that has been described with long-term use of potent antiresorptive agents, including bisphosphonates and denosumab.<sup>1957</sup> In an analysis of information from the Surveillance, Epidemiology, and End Results (SEER) databank linked to Medicare claims, 16,703 cancer patients were identified who were treated with IV bisphosphonates (pamidronate and zoledronic acid) from 1995 to 2003.<sup>1958</sup> When 14,349 treated patients were matched with 28,698 controls, the treated group had a threefold increased risk of jaw or facial bone surgery and a very large increased risk of osteomyelitis of the jaw. The estimated absolute risk equaled 5.48 events per 100 patients over 6 years. In addition, the risk increased with increasing cumulative dose. The absolute risk is much less in noncancer patients being

treated with bisphosphonates for the management of osteoporosis, in whom the incidence of ONJ is estimated at 0.001–0.01%, minimally higher than in the general population.<sup>1957</sup>

The mechanism underlying ONJ in bisphosphonate users is uncertain beyond the recognition that infection and blood flow changes are involved. It is postulated that a compromised healing ability of the bone because of inhibition of bone turnover leads to sequestered osteomyelitis and necrosis. Studies have suggested that the risk of ONJ is greater in patients treated with zoledronic acid compared with pamidronate.<sup>1959,1960,1961</sup> Awareness of this problem has led to increased attention to oral hygiene and the avoidance of tooth extractions in the high-risk population of cancer patients receiving bisphosphonate treatment.

The risk of osteomyelitis and ONJ and face has been recognized for several years, but continues to be controversial. To be sure, most of the cases have been in cancer patients, usually treated with intravenous high doses, but this complication was also reported in patients receiving oral bisphosphonate treatment for osteoporosis, with no history or evidence of malignancy.<sup>1961,1962</sup> Experts in the field point out that many clinicians specializing in osteoporosis have never seen a case. **The incidence of ONJ with oral bisphosphonates is somewhere from 1 in 10,000 to 1 in 100,000.** They further argue that a true cause-and-effect relationship would require appropriate controlled studies, and two are ongoing. But clinical decision-making cannot be delayed until data are available, and it is by no means certain that the ongoing trials will yield definitive results on such a rare event. Patients should be cautioned regarding this rare problem and urged to practice good dental care. **We recommend consideration for dental evaluation and cleaning for patients in whom initiation of bisphosphonates for management of osteoporosis is being considered, prior to initiation of therapy, attention to oral hygiene during the course of treatment, and ongoing periodical surveillance.**<sup>1963</sup>

## **Bisphosphonates and Atrial Fibrillation**

An increase in the incidence of new-onset atrial fibrillation has been linked with the use of bisphosphonates, more so with intravenous than oral regimens.<sup>1964</sup> A meta-analysis presented at the meeting of the American College of Chest Physicians in October 2008 estimated that atrial fibrillation is observed in 2.5–3% of individuals treated with bisphosphonates and that 1–2% experience hospitalization or death. A case-control study concluded atrial fibrillation could be attributed to bisphosphonates in 3% of previous or current users.<sup>1965</sup> These positive reports were followed by a series of consistently negative studies. A larger Danish case-control study concluded that there

was no link between atrial fibrillation and the use of bisphosphonates.<sup>1966</sup> A Danish cohort study of fracture patients found no increase in the risks of stroke or myocardial infarction and concluded that an increase in atrial fibrillation could be attributed to the use of bisphosphonates in individuals already at increased risk for cardiovascular events.<sup>1967</sup> In two large American cohort databases of patients undergoing coronary angiography, there was no increase in atrial fibrillation or myocardial infarction associated with bisphosphonate treatment.<sup>1968</sup> A retrospective cohort study from Taiwan compared bisphosphonate use with the use of raloxifene and reported a similar rate of atrial fibrillation in both treatment groups.<sup>1969</sup> An apparent increase in atrial fibrillation can be attributed to the fact that most bisphosphonate users are older, have more cardiovascular disease, and are at greater risk for atrial fibrillation. Nonetheless, caution is advised in the elderly and those at risk, such as those with known hypertensive disorders, ischemic heart disease, cardiomyopathy, and valvular heart disease.

## **Bisphosphonates and Esophageal Cancer**

In a Letter to the Editor in the January 1, 2009, issue of the New England Journal of Medicine, the FDA reported 23 cases (8 fatal) of esophageal cancer in patients being treated with alendronate.<sup>1970</sup> As of 2009, a total of 31 cases of esophageal cancer had been collected in Europe and Japan associated with alendronate, risedronate, ibandronate, and etidronate. Although this is a small number of cases with drugs that have been used for more than a decade by millions of people, the concern has added credibility because of the well-recognized side effect of esophageal injury with oral bisphosphonates. Nevertheless, the FDA report was anecdotal in nature, with no comparison group. In response, American and European comparisons of treated patients to the U.S. expected incidence of esophageal cancer or to nontreated patients in national databases in the United Kingdom and Denmark failed to detect an increase in esophageal cancer in bisphosphonate-treated patients.<sup>1971,1972</sup> A meta-analysis of 11 studies published in 2015 was similarly reassuring and failed to identify any evidence to support an increase in risk of upper gastrointestinal cancers with the use of bisphosphonates.<sup>1973</sup>

## **Bisphosphonates and Pain**

The FDA has informed clinicians that patients taking bisphosphonates rarely experience severe bone, joint, or muscle pain that is relieved when treatment stops; discontinuation of bisphosphonate treatment and consideration for an alternative agent are advised in this setting.

---

## Key Points: Treatment with Bisphosphonates

- Bisphosphonate treatment is best reserved for older postmenopausal women. It is not a drug class of choice for the prevention of osteoporosis in relatively young postmenopausal women in whom hormone therapy may be preferentially considered as a first-line approach for osteoporosis prevention and fracture risk reduction.
- In all except very high-risk patients being treated with bisphosphonates, it would be wise to consider a time limit for duration of exposure. Bone density should be measured after 2–4 years of treatment, and a period of “drug holiday” should be considered after 5 years of use for those who are not deemed at a markedly high fracture risk. Patients should be followed by monitoring of bone density, with a resumption of treatment in those who rapidly lose bone or in those who accumulate a loss of 5–10% in 1 year.
- The onset of severe pain at any site is an indication to discontinue bisphosphonate treatment.
- In the absence of demonstrated fracture reduction benefit, the increased cost and likely increase in adverse events from a combination regimen (such as estrogen and bisphosphonate), such an approach is not currently recommended.

# Denosumab

Denosumab (Prolia) is a human monoclonal antibody to RANKL and is one of the newest of the available antifracture agents that was approved for the treatment of osteoporosis in high-risk patients. RANKL (nuclear factor kappa B ligand) is secreted by osteoblasts and binds to its receptor, RANK, on the surface of osteoclasts, stimulating the osteoclasts to mature and to resorb bone. OPG is a soluble receptor that is produced by the osteoblasts and that acts as a sponge to bind circulating RANKL, thereby preventing the RANK-mediated activation of osteoclasts; in the absence of RANK signaling, osteoclasts undergo apoptosis. An agent that could act like OPG, therefore, would prevent bone loss. Denosumab works like OPG, but rather than competing with RANK for its activator RANKL, it binds with great affinity to RANKL, thus preventing activation of RANK. The antiresorptive effects of denosumab are thus distinct from those of bisphosphonates and estrogens. Denosumab prevents both maturation and survival of osteoclasts and active bone resorption by osteoclasts.

The impact of denosumab on bone density has been evaluated in phase 2 clinical trials.<sup>1974</sup> The participants were postmenopausal women up to age 80 who had osteoporosis based on low T-scores. For the first 2 years, the patients were randomized to one of seven denosumab doses, alendronate, or placebo. After 2 years, patients in 5 of the treated groups were continued for 2 more years on 60 mg daily given subcutaneously only once every 6 months. One treatment arm was discontinued, and then after a year, treatment was resumed with 60 mg denosumab every 6 months. One treatment arm was discontinued after 2 years and followed. Two hundred and sixty-two women completed the study. Long-term treatment increased bone density in the spine and hip, whereas the placebo group continued to lose bone density. A reduction in markers for bone turnover was sustained. The group that discontinued treatment after 2 years lost bone density; after a year, retreatment with denosumab restored the bone to the level of the gain achieved in the first 2 years, levels similar to the groups who continued treatment for 4 years. No significant differences in the treatment and placebo groups were noted for adverse events. Similar results have been reported in a phase 3 trial with 332 women in 21 centers in Canada and the United States.<sup>1975</sup> In a large, 3-year, worldwide multicenter trial involving 7,868 women with osteoporosis, the Fracture Reduction Evaluation of Denosumab in Osteoporosis Every 6 Months (FREEDOM) trial, treatment with 60 mg denosumab subcutaneously every 6 months reduced vertebral fractures by 68%, hip fractures by 40%, and other nonvertebral fractures by 20%.<sup>1976</sup> A separate phase 3 trial concluded that denosumab treatment increased BMD at the hip and spine significantly more than alendronate.<sup>1977</sup> There were no differences in major adverse events in these trials, including osteonecrosis, or indications of suppressed immune function; however, eczema and cellulitis were

significantly increased in the worldwide study.<sup>1976</sup> The data representing 10 years of denosumab exposure (3 years of exposure in the FREEDOM trial plus 7-year exposure in the open-label extension study) offer reassurance regarding safety and efficacy of long-term use. Not only did the incidence of fractures in the long-term users remain comparable to that observed during the FREEDOM trial; additionally, there was evidence of ongoing improvement in BMD during the 10-year period of exposure. Adverse event profile was similarly comparable to that encountered in the 3-year FREEDOM trial.<sup>1978</sup>

How do the results compare with bisphosphonates? The increase in bone density at the spine and hip is greater with denosumab, and total body bone density, as exemplified by the radius, increases with denosumab, but not with bisphosphonates. **After discontinuation of denosumab, however bone loss begins immediately and the concept of drug holiday does not hold for denosumab. Prescribing information warns of the possibility of an increased risk of multiple vertebral fractures following discontinuation.**<sup>1979</sup> This quick reversibility contrasts with bisphosphonates which bind tightly to bone, remaining in bone for decades and maintaining a long-term effect. The 6-month dosing regimen of denosumab and subcutaneous route of administration offer convenience. Alternatively, the requirement for subcutaneous administration might seem to be an obstacle to some, but on the other hand, a required visit to the office might increase continuation rates. **Given that data on safety and ongoing efficacy of denosumab beyond 10 years of use are wanting, in our opinion, it is prudent to then consider switching to a bisphosphonate to ensure that the skeletal benefit gained from denosumab use persists beyond its discontinuation.**

# Calcitonin

Calcitonin regulates plasma calcium by inhibiting bone resorption and has been long recognized to offer fracture risk reduction. The antifracture efficacy of calcitonin is inferior to the agents discussed earlier. In a randomized 5-year trial, calcitonin treatment reduced spinal fractures with less of an effect (about 33%) compared with estrogen, alendronate, and raloxifene and had no reduction in hip fractures.<sup>1980</sup> Studies with intranasal delivery of salmon calcitonin (200 IU daily) indicate it can increase bone density. Human calcitonin is available, but recombinant salmon calcitonin (Fortical and Miacalcin) is more potent. Calcitonin treatment should be combined with vitamin D and calcium supplementation. The lack of a dose response and a high drop-out rate raised questions regarding the potency and efficacy of calcitonin in preventing fractures. Calcitonin however still has a place for use in patients who are unable to tolerate alternative agents, as well as for patients with intractable back pain, given its analgesic potential.<sup>1981</sup>

# Fluoride

The addition of fluoride, a potent stimulator of bone formation, can offer significant protection against osteoporosis. The clinical response depends on the formulation and dose. Slow-release sodium fluoride (25 mg b.i.d. given 12 of every 14 months) combined with calcium supplementation reduced the vertebral fracture rate with essentially no side effects.<sup>1982</sup> Treatment is recommended for no longer than 4 years to avoid the toxic accumulation of fluoride in bone.<sup>1983</sup> This treatment is reserved for patients with established postmenopausal osteoporosis; however, a commercial preparation has not yet been approved.

# Strontium

A divalent strontium salt of ranelic acid acts through uncoupling and rebalancing of the bone turnover in favor of net bone formation. A dose of 2 g of strontium ranelate is dissolved in water and taken at bedtime. Clinical trials indicate that a reduction in spinal and nonvertebral fractures is achieved comparable to antiresorptive agents.<sup>1984,1985</sup> Antifracture efficacy has been reported with up to 8 years of use. The main side effect is nausea and diarrhea that usually resolves in a few months. In pooled analyses, an increased risk of VTE was associated with strontium ranelate relative to placebo over 5 years of treatment, and ongoing caution is advised. Strontium is not approved for the management of osteoporosis in the United States, but oral strontium ranelate is available in many countries (Protelos, Protos, Protaxos, Bivalos, Osseor) for use in the management of osteoporosis.<sup>1986</sup>

# Tibolone

Tibolone is structurally related to the 19-nortestosterone progestins used clinically in oral contraceptives. Its chemistry, mechanisms of action, and clinical effects are discussed in detail earlier in this chapter. Tibolone prevents bone loss in postmenopausal women as effectively as estrogen or estrogen-progestin therapy.<sup>705,723,1987,1988,1989,1990,1991</sup> In a large U.S. dose-response study with doses ranging from 0.3 to 2.5 mg daily, only the 1.25- and 2.5-mg doses produced progressive bone density increases in the femoral neck. Indeed, the impact on bone was essentially the same for the two highest doses, 1.25 and 2.5 mg. Although the 1.25-mg dose is acceptable for the prevention of bone loss, the 2.5-mg dose is more effective for the alleviation of hot flashes.<sup>698</sup>

The beneficial impact on bone can be attributed to tibolone's estrogenic metabolites acting through the estrogen receptor because it is blocked by an antiestrogen, but not by an antiandrogen or an antiprogestin.<sup>1992</sup> Tibolone prevents the bone loss associated with GnRH agonist treatment (and the side effect of hot flushing).<sup>760,1993</sup> The BMD data are similar to those associated with hormonal and alendronate therapy.

The LIFT (Long-term Intervention on Fractures with Tibolone) study was a randomized, placebo-controlled multicenter trial in 22 countries of tibolone, 1.25 mg, given daily over 3 years.<sup>777</sup> The 4,538 women who participated in the trial were age 60–85, all at high risk of fractures because of osteoporosis, and all treated with calcium and vitamin D supplementation. The study was stopped in February 2006 after a mean treatment of 34 months because of an increased risk of stroke. The risks of all events were assessed after 5 years of follow-up. The reduction of fractures was about 4 times as great in women who already had a vertebral fracture upon entry to the study compared with women who had not had a fracture at baseline. It is noteworthy that the number of falls in the treated group was 25% less. The increase in stroke was greater in the oldest women (over age 70).

Based on previous bone density studies, the results of the LIFT trial on fracture reduction were not unexpected. The magnitude of the effect is roughly comparable to those with estrogen, bisphosphonates, and raloxifene (with the important exception being a lack of effect of raloxifene on hip fractures). A reduction of breast cancer was comparable to that reported with tamoxifen and raloxifene, but this was not a primary endpoint of the study.

The reported risk of stroke is similar to that observed with estrogen. In the WHI, no increase in stroke was observed in women under age 60 who had an absence of stroke risk factors. **It seems prudent to avoid the use of tibolone in elderly women and in women who are at risk for stroke** (specifically those with hypertension, smoking,

diabetes, or atrial fibrillation). The OPAL (Osteoporosis Prevention and Arterial effects of tibolone) study was a 3-year, randomized, double-blind trial in six U.S. centers and five European centers, treating 866 postmenopausal women with either 2.5 mg tibolone daily, 0.625/2.5 mg daily of conjugated estrogens/medroxyprogesterone acetate, or placebo.<sup>741</sup> Unfortunately, the OPAL trial did not achieve its goal of providing robust data on cardiovascular effects, due to the older age of the women and the notably different results in American and European women. There continues to be good reason to believe that tibolone will have a neutral effect in terms of CHD.

In summary, tibolone treatment of postmenopausal women is as effective as estrogen therapy in relieving hot flushes, preventing bone loss, and increasing vaginal lubrication and stimulates libido to a greater degree than estrogen. There is less breast tenderness and mastalgia with tibolone. Endometrial safety has been reported to be comparable to that achieved with continuous combined estrogen-progestin regimens and with a lower rate of breakthrough bleeding. The standard dose of tibolone for many years was 2.5 mg daily, but the new studies support the use of the lower dose, 1.25 mg, with no apparent loss of bone efficacy. Tibolone continues to be an appropriate choice for hormonal therapy, suitable for many postmenopausal women.

# Teriparatide

Parathyroid hormone increases bone formation. Teriparatide (Forteo) is the recombinant human 1–34 amino acid fragment of parathyroid hormone. Another Canadian preparation encompasses the 1–84 sequence. This is the only treatment, besides fluoride, that directly stimulates osteoblasts to form new bone. Given to postmenopausal women with osteoporosis in a once-daily, subcutaneous dose of 20 mg, teriparatide produces a greater increase in bone density and possibly a greater reduction in fractures compared with estrogen or alendronate.<sup>1994,1995</sup> Statistically significant reductions in both vertebral and nonvertebral fractures were observed in randomized controlled trials. A recent meta-analysis offers reassuring evidence of efficacy of teriparatide in reducing hip fractures by 56% in patients with osteoporosis.<sup>1996</sup> **Because of the expense and difficulty in self-administration, treatment with the parathyroid fragment is best directed to individuals with serious osteoporosis and at high risk for fractures.** After a relatively short period of treatment, no more than 2 years, the gain in bone can be maintained with one of the antiresorptive agents.<sup>1997,1998,1999,2000</sup>

# Alternative Therapies to Prevent Bone Loss

Phytoestrogens are effective in preventing bone loss in rats, but not in monkeys.<sup>2001,2002,2003</sup> In women, some studies demonstrated at best a slight effect on spinal bone, but most found no benefit in either the spine or hip.<sup>878,2004,2005,2006</sup> Flaxseed supplementation had no effect on biomarkers of bone metabolism.<sup>2007</sup> The difference between hip fracture incidence in Japanese and American women may be due to structural and/or genetic differences, not dietary intake of soy.<sup>2008</sup>

Ipriflavone is a synthetic isoflavone; it is methylated dehydroxydaidzein, which is metabolized to daidzein. Studies with ipriflavone demonstrated prevention of bone loss over a year.<sup>2009,2010,2011,2012</sup> Overall, the effect on bone was not as great as that observed with a standard dose of estrogen, or alendronate, perhaps not great enough to yield a benefit. A 4-year randomized trial in Europe assessed the effect of ipriflavone on bone density, urinary markers, and vertebral fractures in 474 women and could find no difference in the treated group compared with the placebo group.<sup>2013</sup>

Equol is a bacterial metabolite, and the only hormonally active metabolite, of the soy phytoestrogen, daidzein. At least in vitro, equol stimulates gene transcription with both estrogen receptors and with a greater potency than any other isoflavone.<sup>2014</sup> Equol formation is totally dependent on intestinal microflora. The most important observation regarding equol is that most adults do not produce equol, even when challenged with high doses of soy.<sup>934</sup> This is a contrast to nonhuman primates and other animals; all that have been studied produce high levels of equol. Thus, there are two human populations: equol producers and nonequol producers. The key question is whether equol producers receive greater clinical effects from phytoestrogens than nonequol producers. As noted, thus far the clinical effects of isoflavones on bone have not been impressive. In a 2-year randomized trial of postmenopausal women, isoflavone-rich soy milk increased spinal bone mass in the 45% of the subjects who were equol producers, with essentially no effect in nonequol producers.<sup>934</sup> Similar results were obtained in a Japanese trial testing the effect of isoflavone treatment in equol producers and nonproducers.<sup>2015</sup> Therefore, the population destined to receive a benefit from soy intake may be limited to equol producers. Studies need to be repeated measuring the responses in individuals who are identified as equol producers or nonequol producers. If the population destined to receive a benefit from soy intake is limited to equol producers, a convenient, inexpensive method must be developed to identify equol production. It may be possible to convert nonproducers to producers. A more straightforward approach is to administer equol itself. Daidzein yields two forms in equol producers, the R-equol inactive isomer and S-equol, the active isomer that binds to estrogen receptor- $\beta$ . S-equol has been synthesized and its administration is effective for the treatment of menopausal

symptoms.<sup>936</sup> Another alternative is the S-equol supplement made by incubating equol-producing bacteria with soy isoflavones.<sup>937,938</sup> It is absorbed readily with high bioavailability; low doses must be administered twice daily because of a relatively short half-life.

# Statins

Statin treatment is, of course, a mainstay in programs designed to prevent cardiovascular disease. Prompted by animal experiments indicating that statins increase bone formation, case-control studies reported that statin treatment was associated with a reduced risk of fracture.<sup>2016,2017</sup> However, analysis of a randomized trial of statin therapy and cardiovascular disease failed to detect an effect on fracture risk, and a cohort study reported that an apparent beneficial effect of statin on fracture risk was influenced by various confounding factors.<sup>2018,2019</sup> In the prospective cohort arm of the WHI, bone densities and fracture rates were similar comparing statin users with nonusers.<sup>2020</sup> A recent systematic review and meta-analysis assessed the efficacy of statins on bone density, on markers of bone turnover, and on fracture risk by examining data from 33 clinical trials.<sup>2021</sup> Statin use was associated with a decreased risk of overall fractures (OR = 0.81; 95% CI = 0.73–0.89) and hip fractures (OR = 0.75; 95% CI = 0.60–0.92). Statin use was associated with statistically significantly higher bone density parameters at the total hip and the lumbar spine and with improved bone formation marker, osteocalcin. Interestingly, skeletal benefits of statins demonstrated a gender differential being more robust in males compared to women users. **Based on existing evidence, statin users should be reassured regarding the potential for skeletal benefit, but statins should not replace proven effective medications to prevent or treat osteoporosis.**

# Thiazide Diuretics

Older women are often treated with thiazides for hypertension. Thiazides reduce the urinary loss of calcium and induce a positive calcium balance, and treatment is associated with a higher bone density. It is useful to know that estrogen and thiazides are additive; a significantly higher bone density is achieved with combined use.<sup>2022</sup> A recent meta-analysis that included 2,193,160 participants from 11 cohort studies evaluated the relationship between thiazide diuretic use and fracture. Users of thiazide diuretics experienced a statistically significant 14% reduction in the risk of all fractures and 18% reduction in risk of hip fracture compared to nonusers.<sup>2023</sup> **Based on existing evidence, users of thiazide diuretics should be reassured regarding the potential for skeletal benefit, but thiazides should not replace proven effective medications to prevent or treat osteoporosis.**

# Lifestyle Modifications

Lifestyle can have a beneficial effect on bone density as well as reduce fracture risk. Physical activity (weight-bearing), as little as 30 minutes a day for 3 days a week, will increase the mineral content of bone in older women.<sup>2024</sup> To be effective, exercise must exert a load on bone, especially the spine.<sup>2025</sup> Ordinary walking, while beneficial for balance and for overall health, alone will not suffice for improving bone density.<sup>2026</sup> Even brisk walking achieves a significant increase in bone density only in the calcaneus, the site subjected to stress with walking.<sup>2027</sup> However, brisk walking may slow the rate of bone loss in the hip.<sup>2028</sup> In other words, weight lifting is better for the spine than is ordinary walking, although running probably helps hip bone mass. The activities that are beneficial are running, weight training, aerobics, stair climbing, and sports other than swimming. The effect of weight-bearing exercise on bone density is additive when combined with hormone therapy.<sup>2029</sup> Although ordinary walking has little impact on bone density, it is still reasonable to expect walking to have an overall beneficial effect on the risk of fracture. Walking improves the cardiovascular status of patients and reduces body mass. These changes plus the exercise itself improve balance and decrease the risk of falling. For these reasons, walking, even after adjusting for bone density and body weight, is associated with a reduced risk of hip fracture.<sup>1807,2030</sup>

The impact of exercise on bone is significantly less than that achieved by hormone therapy.<sup>1876</sup> Women require the full combination of pharmacologic therapy, calcium and vitamin D supplementation, and exercise in order to minimize the risk of fractures. For each of these, the beneficial impact lasts only as long as the therapy is continued.

**Cigarette smoking and excessive alcohol consumption are associated with an increased risk of osteoporosis.** The magnitude of bone loss associated with cigarette smoking is consistent with a 40–45% increase in the risk of hip fracture.<sup>2031</sup> Women who smoke also enter menopause earlier and lose bone at a greater rate in the first years of the postmenopausal period.<sup>2032</sup>

A high coffee intake has been reported to be associated with an increased risk of osteoporosis.<sup>2033</sup> However, this increase in risk is dependent on dietary calcium intake. In women who drank at least one glass of milk (300 mg calcium) per day throughout most of their lives, increasing caffeinated coffee intake was not associated with a lower bone density.<sup>2034</sup> Repeatedly, we see the importance of teaching children and adolescents the merit of an adequate calcium intake; drinking nonfat milk throughout life is good for you. An adequate calcium intake compensates for “calcium robbers,” such as caffeine and soft drinks. A British study concluded that an increase of only 300 mL of milk per day in adolescents increased bone density without an increase in weight or

body fat.<sup>1881</sup>

**Remember that not all fractures are solely due to osteoporosis.** Drug side effects, impaired vision, neurologic dysfunction, and muscular conditions all put patients at risk because more than 90% of fractures occur following a fall<sup>1755</sup> (**Figure 17.25**).

Data from **McClung MR**, Do current management strategies and guidelines adequately address fracture risk? *Bone* 38(2 Suppl 2):S13, 2006.

Interventions that reduce the odds of falling and enhance the ability to withstand the impact of a fall are important.<sup>2035</sup> This includes patient education regarding hazards in the home, monitoring drug use, adequate nutrition, and a good exercise program. In addition, there is evidence that estrogen with or without added progestin improves muscle strength and balance.<sup>268,269,270,271,272,273</sup> On the other hand, some studies have not been able to document an increase in muscle strength or improvements in balance.<sup>2029,2036,2037,2038,2039</sup> Furthermore, the increase in muscle mass and strength in response to weight-bearing exercise was the same when hormone users were compared with nonusers.<sup>2040</sup> Nevertheless, a cohort study reported 71% fewer falls in early postmenopausal hormone users and 43% in late postmenopausal hormone users.<sup>2041</sup> Use of hip guards has been shown to reduce risk of hip fractures in institutionalized elderly, but not in ambulant populations.<sup>2042</sup>

# Bone-Losing Medications

Clinicians should always remember that exposure to excessive thyroid and glucocorticoid hormones is associated with osteoporosis and an increased rate of fractures. The bone loss associated with glucocorticoid treatment is significantly prevented by hormone or bisphosphonate therapy.<sup>2043,2044,2045,2046</sup> **Excessive thyroid effects can be avoided by periodic (at least annually) monitoring treatment dosage with TSH levels.** Specific preventive treatment should also be offered to patients using long-term anticonvulsants or heparin.

Considerable publicity has successfully raised clinical consciousness regarding the increased risk of fractures associated with the use of corticosteroids. We should similarly recognize the increased risk of fractures with the daily use of SSRIs. The Canadian Multicentre Osteoporosis Study Research Group reported the effect of daily SSRIs in a prospective cohort study in seven regional centers of 5,008 adults over the age of 50.<sup>1793</sup> After adjusting for age, hip bone density, fractures at baseline, and estrogen use in women, daily SSRI use was associated with a twofold increased risk of fragility fractures. Daily use of SSRIs was also associated with about a twofold increased risk of falling, and these individuals had lower bone densities. Controlling for falls and lower bone density still left an increased risk of fractures in SSRI users that began after 1–1.5 years of use.

Does this side effect of SSRIs make sense? Is it the SSRI or the lifestyle associated with clinical depression? Serotonin does not cross the blood-brain barrier; in the brain, serotonin activity is the result of synthesis, reuptake, and binding to a 5-hydroxytryptophan receptor, which is inhibited by SSRIs. Most of the circulating serotonin comes from synthesis in the duodenum by specialized neuroendocrine cells. Locally released serotonin stimulates intestinal peristalsis, whereas the serotonin entering the circulation is taken up by platelets or serotonin can reach a target tissue like bone, linking bone formation to the gut. Mice with a mutation for the serotonin transporter protein develop less bone mass and strength.<sup>1794</sup> Serotonin receptors and serotonin transport have been identified in osteoblasts and osteocytes. The bone effects of parathyroid hormone and mechanical stimulation are modulated by the serotonin system. Therefore, daily SSRI use can impair bone formation, tilting the balance in favor of resorption and bone loss, and decreased bone densities have been reported in both male and female SSRI users (but not in users of tricyclic antidepressants).<sup>1795,1796</sup>

It is not always easy to know which came first, depression or fractures, leading to subsequent depression. It has been reported that depressed people and SSRI users have a greater incidence of falls,<sup>1788</sup> and thus it is not unreasonable to consider that depression comes first in some people. However, orthostatic hypotension and syncope

are more common in SSRI users, and this could also contribute to the greater prevalence of falls.

Depressed people are sedentary and eat poorly, factors that favor bone loss. Some have speculated that increased cortisol levels associated with depression might lead to bone loss, similar to that observed with the pharmacologic administration of corticosteroids. On the other hand, American studies, despite finding a link between depression and fractures, failed to detect an increase in depression associated with lower bone density measurements.<sup>1787,1788</sup> However, other studies have reported increases in depression associated with lower bone densities.<sup>1789,1790,1791</sup>

Obviously, this is an unsettled picture, but we should be more aware of the possible increased risk of fractures with the daily use of SSRIs. Interventions that reduce the odds of falling and enhance the ability to withstand the impact of a fall are important. This includes patient education regarding hazards in the home, monitoring drug use, adequate nutrition, and a good exercise program. Aggressive monitoring of bone density is warranted; adequate calcium and vitamin D supplementation are necessary, and until more studies clarify this problem, it seems reasonable to consider treatment with one of the antiresorptive agents.

Proton pump–inhibiting drugs used to treat gastroesophageal reflux impair intestinal calcium absorption, resulting in secondary hyperparathyroidism and bone loss. Long-term use of omeprazole has been linked to an increase in hip fractures in case-control studies.<sup>2047,2048</sup> These drugs should be added to the list of bone-losing medications that require careful monitoring of bone density and antiresorptive treatment when indicated. The list includes, of course, any treatment that produces a hypoestrogenic state, for example, an aromatase inhibitor.

Thiazolidinediones used to treat diabetes are associated with an increase in bone loss and fractures.<sup>2049,2050</sup> Bone density measurements and careful assessment for fracture risk are important components of health care for these diabetic women, with emphasis on adequate calcium and vitamin D supplementation and appropriate treatment with one of the antiresorptive agents where indicated.

## Key Points: Bone-Losing Medications

- Glucocorticoid treatment (more than 3 months)
- Exposure to excessive thyroxine (suppressed TSH levels)
- SSRI therapy for depression
- Proton pump–inhibiting drugs
- Aromatase inhibitors

- Thiazolidinediones

# Management of a Nonresponder

**Response to treatment is assessed by repeating BMD assessment.** Treatment efficacy is reflected in stable or improved BMD repeated at a minimum interval of 1 year from baseline study. **It is important to appreciate that the number to focus on when assessing interval change is of the actual BMD that is reported in  $\text{g/cm}^2$ , and not the T-scores.** There are two reasons to question the prevalence of nonresponse to treatment. The first reason is the argument that the results of single bone density measurements display the phenomenon of regression to the mean (extreme results are in part due to random error). Analysis of the hip and spinal bone density data from the randomized clinical trials assessing the effects of alendronate and raloxifene in postmenopausal women with osteoporosis revealed that women who lost BMD after 1 year of treatment were likely to gain bone during the second year.<sup>2051</sup> The more extreme the measurement after 1 year of treatment, the more likely the next year's measurement indicated a reversal. Therefore, it has been recommended that bone treatments should not be discontinued when measurements after 1 year indicate loss of bone density because repeat results are usually closer to the mean. Once a lack of response is identified based on repeat bone density assessment, the next step should be to inquire about compliance, particularly with prescribed oral agents, and assess serum 25-hydroxyvitamin D and calcium levels as vitamin D deficiency is a common mechanism for failure of antifracture treatments. Optimal vitamin D levels are necessary to maximize the response to any antiresorption agent.<sup>2052</sup> This emphasizes the need to titer the dose of vitamin D supplementation by measuring the circulating level of 25-hydroxyvitamin D. A value less than 30 ng/mL is below normal; less than 20 ng/mL is a definitive indication of vitamin D deficiency. Assessment of bone turnover markers can allow insights into compliance as well as effectiveness as a minimum of 30% reduction in markers of bone resorption should occur with the use of estrogens, raloxifene, bisphosphonates, and denosumab.

**We advocate monitoring of treatment response with the use of repeat bone density measurements, as well as support a consideration of assessing bone markers within 1–3 months following initiation of antifracture therapy to reflect compliance and treatment efficacy, at least in the short term. Clinicians must be aware that interpretation of treatment efficacy must be based on BMD ( $\text{g/cm}^2$ ), and not T-scores (Table 17.20).**

## TABLE 17.20 Is Antifracture Treatment Working?

## **Bone mineral density monitoring**

- A minimal time interval of 1 y is needed to allow detection of any meaningful change in bone density
- Use the same device and facility if feasible
- Compare absolute bone mass ( $\text{g}/\text{cm}^2$ ) and not T-scores
- Pay attention to the facility and devise specific least significant difference (LSD) to determine if interval change is of clinical relevance
- Consider lateral imaging if suspecting vertebral fracture

---

## **Monitoring using bone markers?**

- Can be considered in patients where concern for noncompliance or lack of efficacy is high
  - If checked before starting treatment and 3 mo after treatment is initiated, a >30% change (drop) is consistent with compliance and suggests treatment efficacy
-

# Assessing Blood Estrogen Levels in Hormone Users

On the average, about 10–15% of women may lose bone despite being prescribed hormone therapy. **Because of the precision error with bone density measurements, a change of at least 3–5% is necessary to be clinically significant.** A Finnish 5-year clinical trial reported a prevalence of poor response based on bone density of 11% for spinal bone and 26% for the hip.<sup>2053</sup> As expected, smoking and low body weight were common findings among the poor responders, but the most impressive characteristics were lower estradiol and higher FSH levels. It is only logical that there exists a group of women who metabolize and clear administered estrogens at a greater rate and thus require a higher dose to sustain a protective effect on bone. Indeed, considerable variation in estradiol levels has been documented in individuals receiving both oral and transdermal hormone therapies.<sup>504,2054</sup> Marketing presentations by the pharmaceutical companies provide mean levels, suggesting stable and smooth maintenance of blood levels; however, the ranges, which are wide, are not revealed. An aim of individualizing hormone therapy is to determine the appropriate dose for the intended objective; in the case of bone, antiresorptive effects are apparent when serum estradiol levels exceed 20 pg/mL and are optimized with estradiol in 40–60 pg/mL range. In patients using hormone therapy for osteoporosis prevention or management, if repeat bone density assessment demonstrates evidence of ongoing bone loss, proceeding with assessing serum estradiol level is an appropriate next step. A practical range for a blood sample derived during office hours from a patient taking her medication at night is 50–100 pg/mL. To minimize variation, we encourage clinicians to always use the same laboratory, after first establishing the values obtained using standard doses of estradiol in their own practices. The reliability of blood estrogen measurements is questionable when CEEs are the treatment being used, although some assays can provide reproducible results because of cross-reactions with the specific antibody in the assay.

As clinicians and the pharmaceutical industry promote lower doses of estrogen in order to minimize estrogen-related risks, a greater rate of poor response as measured by bone density can be expected. For otherwise healthy women without significant risk for cerebrovascular and cardiovascular harm, up-titration of estrogen dose can be safely considered if evidence of lack of skeletal response is encountered. Safety of such an approach can be ensured by monitoring of serum concentrations of estradiol. We would further emphasize that appropriate detection and investigation will confirm that a relatively low blood estradiol level is the cause of most cases of poor bone response to hormone treatment. An acidic vaginal pH (<4.5) correlates with an appropriate dose of estrogen administration and is a very simple and inexpensive way of assessing

adequacy of dosing.<sup>242,539</sup>

**In a woman demonstrated to be losing bone despite hormone therapy, the following steps are recommended as shown in [Table 17.21](#).**

## **TABLE 17.21 Recommendations for Losing Bone Despite Hormone Therapy**

**1. Check compliance and dose by measuring blood estrogen levels; adjust dose titration based on serum estradiol measurements. Consider the use of vaginal pH measurements**

---

**2. Rule out other causes of bone loss**

*Chronic disease:*

- Renal and hepatic
- Multiple myeloma

*Endocrine diseases:*

- Excess glucocorticoids
- Hyperthyroidism
- Hyperparathyroidism
- Inadequate estrogen dosing

*Drugs:*

- Heparin, anticonvulsants, glucocorticoids
- SSRIs, proton pump inhibitors, thiazolidinediones

*Nutritional:*

- Calcium, phosphate, vitamin D deficiencies

*Toxic exposures:*

- High intake of alcohol
- Smoking

---
