# Foreword

I was extremely pleased when I learned that the ninth edition of this textbook would once again be coming from Yale. And I reacted with a strong sense of honor and gratitude when I saw my name on the cover. It was 47 years ago at Yale when Bob Glass and Nathan Kase invited me to join them in writing a textbook on infertility and reproductive endocrinology. That manuscript, typed on a Royal portable typewriter, appeared a year later, 273 pages long for a price of \$17. Each edition grew in weight, size, and price, and so did the challenge and amount of work required.

Being associated with this book has been one of the best and most rewarding experiences in my career. It opened doors for me, not only in our own country but all over the world. Because of this book, I and my family made many new friends and visited places that otherwise would have existed only in my dreams.

It is good to see Yale Blue once again on the cover. It is also with great emotional warmth that I view the Macedonian Star on the cover, a feature that was introduced with the sixth edition of the book. The Macedonian Star is a symbol that dates from the days of Philip of Macedon and Alexander the Great. How I wish that my grandparents and father, who came from Macedonia to America in 1921, could see the cover of the ninth edition.

In the Preface to the last edition, I told a story that bears repeating. In 1999, I was standing on a street corner in New York City waiting for the change in the light. For unknown reasons, I was struck in that moment with a thought that was so strong, I was frozen in my tracks. I stood there thinking, while everyone else crossed the street, that what was written in this book could have an impact on individual patients. The force behind this thought was a sudden appreciation for the enormity of the responsibility that comes with writing a clinical book to transmit accurately the knowledge that is based on all available evidence. This important task has grown progressively larger in its scope with the explosion of scientific and medical reports in each passing decade. And yet, as always, there are physiologic events and pathologic disturbances that are not currently understood. For this reason, authors writing a clinical book must still draw upon their own experiences and offer judgments regarding the understanding and care of patients.

I hope this book, dedicated to the care of patients, continues to be used by students, residents, and clinicians. If anyone appreciates how much work goes into clinical writing, I certainly do. And so, a heart-felt thank you to my Yale colleagues for their commitment and effort in bringing the ninth edition to publication.

# Preface

It is a tremendous honor for us to author Speroff's Gynecologic Endocrinology and Infertility. This text has been considered the classic in the field. It is the resource that most of us initially used to learn reproductive physiology and endocrinology. How does one rewrite a text that is the classic in the field? Rather than be so presumptuous as to try and improve on Dr. Speroff's writing, we took the approach of updating a classic text by adding new information; we focused on changes and advances that have occurred in the field since prior editions. These include new chapters on transgender medicine and fertility preservation. We left as much as Dr. Speroff's original prose as possible. We are indebted to Dr. Speroff for entrusting us with his treatise.

This text originated in the Department of Obstetrics and Gynecology at the Yale School of Medicine. Drs. Speroff, Glass, and Kase were all faculty in the department at the time and all contributed. However, Dr. Speroff's passion for writing and education allowed him to persist through the multiple editions of the book, continually improving and expanding on the text. The book travelled with him to numerous academic institutions. Speroff's Gynecologic Endocrinology and Infertility now triumphantly returns to Yale, its place of birth, with a new set of authors on the Yale faculty. Discussion surrounding the transition occurred originally at a meeting of the Yale Obstetrics and Gynecologic Society in New Haven. At that meeting, we honored Dr. Speroff with our distinguished alumni award. When he suggested returning the book to its rightful home, we were eager to take on the challenge.

The book is indeed a group effort of all the authors and many other contributors. In addition to Dr. Speroff, the authors would like to thank Dr. Marc Fritz who led this text through several prior editions. His contributions clearly helped to keep the book current over the past several years. We also want to thank our publisher, Wolters Kluwer, for their persistence, dedication, and encouragement along the way. In particular, we thank Chris Teja and Ashley Fischer for their leadership and organizational skills without which this book would not be in print until well after its current publication date.

We hope that the readers of this book will gain as much from it as each of us previously has during our careers. Nothing will bring us more satisfaction than to inspire the next generation of women's health professionals.

# Contents

Associate Contributors

Foreword

Preface

## Section I: REPRODUCTIVE PHYSIOLOGY

- 1. Hormone Biosynthesis, Metabolism, and Mechanism of Action**  
How hormones are formed and metabolized, and how hormones work.
- 2. The Ovary—Embryology and Development**  
The ovary from conception to adult function; correlation of morphology with reproductive and steroidogenic function.
- 3. The Uterus, Endometrial Physiology, and Menstruation**  
Embryology, histology, and endocrinology of the uterus and menstruation. Anatomical abnormalities and leiomyomas.
- 4. Neuroendocrinology**  
How reproductive events are perceived, integrated, and acted upon by the central nervous system.
- 5. Regulation of the Menstrual Cycle**  
The cyclic changes of ovarian and pituitary hormones and growth factors, and what governs those changes.
- 6. Conception - Sperm and Egg Transport, Fertilization, Implantation and Early Embryogenesis**  
Physiologic events occurring on the days just before and after conception.

## **7. The Endocrinology of Pregnancy**

The steroid and protein hormones of pregnancy.

## **Section II: CLINICAL ENDOCRINOLOGY**

### **8. Normal and Abnormal Sexual Development**

Normal and abnormal sexual differentiation and the differential diagnosis of ambiguous genitalia.

### **9. Normal and Abnormal Growth and Pubertal Development**

The physiology of puberty and abnormalities that produce accelerated or retarded sexual maturation and growth problems in adolescents.

### **10. Amenorrhea**

Differential diagnosis of amenorrhea of all types utilizing procedures available to all clinicians. The problems of galactorrhea and pituitary adenomas, exercise and amenorrhea.

### **11. Chronic Anovulation and the Polycystic Ovary Syndrome**

How loss of ovulation can occur and the clinical expressions of anovulation. The polycystic ovary and hyperinsulinemia.

### **12. Hirsutism**

The biology of hair growth; the evaluation and management of hirsutism.

### **13. Reproduction and the Adrenal**

Relevance of normal adrenal function to reproductive physiology and endocrinology, and clinical and endocrine features of adrenal disorders

### **14. Menstruation-Related Disorders**

Medical problems linked to menstruation: the premenstrual syndrome, dysmenorrhea, menstrual headache, catamenial seizures,

premenstrual asthma, and catamenial pneumothorax.

**15. Abnormal Uterine Bleeding**

A physiologic basis for medical management with or without primary surgical intervention.

**16. The Breast**

The factors involved in physiologic lactation, and the differential diagnosis of galactorrhea. The endocrinology of breast cancer.

**17. Menopause Transition and Menopause Hormone Therapy**

Physiology of the menopause; long-term effects of estrogen on cognition, the cardiovascular system, and bone. A clinical guide for menopausal hormone therapy and patient management.

**18. Transgender Endocrinology**

Terminology, and overview of management considerations, options and approaches.

**19. Obesity**

The physiology of adipose tissue, and the problem of obesity.

**20. Reproduction and the Thyroid**

Normal and abnormal thyroid function, including a consideration of the thyroid gland in pregnancy.

**Section III: CONTRACEPTION**

**21. Family Planning, Sterilization, and Abortion**

The modern efficacy and use of contraception; the clinical methods and problems with sterilization and induced abortion.

**22. Hormonal Contraception**

A survey of the risks and benefits of hormonal (oral and nonoral) contraceptive options. Methods for patient management, including

the progestin-only minipill, options with improved compliance and emergency contraception.

**23. Long-Acting Methods of Contraception**

The advantages and disadvantages of specific long-acting contraceptive methods.

**24. Barrier Methods of Contraception and Withdrawal**

Important information for the use of the diaphragm, the cervical cap, the sponge, spermicides, and condoms. The underrated withdrawal method of contraception.

**Section IV: INFERTILITY**

**25. Female Infertility**

An approach to the problem of infertility. The proper diagnostic tests and their correct interpretation.

**26. Male Infertility**

Principles of male infertility, including analysis of semen, treatment, and therapeutic insemination.

**27. Induction of Ovulation**

Indications, strategies and options, risks, benefits, success rates, and complications for clomiphene, aromatase inhibitors, gonadotropins, dopamine agonists, GnRH.

**28. Assisted Reproductive Technologies**

An overview of the assisted reproduction technologies.

**29. Fertility Preservation**

Indications, strategies and options for fertility preservation.

**30. Recurrent Early Pregnancy Loss**

The evaluation and management of recurring spontaneous losses in

early pregnancy.

**31. Genetics**

Basic concepts of molecular biology and genetics, laboratory technologies, and clinical applications.

**32. Endometriosis**

Diagnosis and suitable treatment for the individual patient.

**33. Ectopic Pregnancy**

The diagnosis and treatment, both medical and surgical, of ectopic pregnancy.

Appendix

Selected laboratory values expressed in conventional units and the International System of Units (SI Units)

# Hormone Biosynthesis, Metabolism, and Mechanism of Action

The classical definition of a hormone is a substance that is produced in a special tissue, from which it is released into the bloodstream and travels to distant responsive cells in which the hormone exerts its characteristic effects. What was once thought of as a simple voyage is now appreciated as an odyssey that becomes more complex as new facets of the journey are unraveled in research laboratories throughout the world. Indeed, even the notion that hormones are products only of special tissues has been challenged.

Complex hormones and hormone receptors have been discovered in primitive, unicellular organisms, suggesting that endocrine glands are a late development of evolution. Hormones must have appeared even before plants and animals diverged because there are many plant substances similar to hormones and hormone receptors. The widespread capability of cells to make hormones explains the puzzling discoveries of hormones in strange places, such as gastrointestinal hormones in the brain and reproductive hormones in intestinal secretions. Furthermore, because every cell contains the genes necessary for hormonal expression, it is not surprising that dedifferentiated cancer cells can uncover gene expression and, in inappropriate locations and at inappropriate times, make hormones.

Hormones, therefore, are substances that provide a means of communication and should now be viewed broadly as chemical regulatory and signaling agents. The classic endocrine hormones travel through the bloodstream to distant sites, but cellular communication is also necessary at local sites. Paracrine, autocrine, and intracrine depict a more immediate form of communication. As compared to the distant sites of action of endocrine signals, paracrine refers to intercellular communication involving the local diffusion of regulating substances from a cell to nearby (contiguous) cells. In further contrast, autocrine and intracrine refer to forms of intracellular communication; the former involves secreted substances that act on receptors on the surface of the same cell, while the latter utilizes unsecreted substances to communicate via receptors within the same cell.

Let us follow an estradiol molecule throughout its career and in so doing gain an overview of how hormones are formed, how hormones work, and how hormones are metabolized. Estradiol begins its life span with its synthesis in a cell specially suited

for this task. For this biosynthesis to take place, the proper enzyme capability must be present along with the proper precursors. In the adult human female, the principal sources of estradiol are the granulosa cells of the developing follicle and the corpus luteum. These cells possess the ability to turn on steroidogenesis in response to specific stimuli. The stimulating agents are the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The initial step in the process that will give rise to estradiol is the transmission of the message from the stimulating agents to the steroid-producing mechanisms within the cells.

Messages that stimulate steroidogenesis must be transmitted through the cell membrane. This is necessary because gonadotropins, being large glycopeptides, do not ordinarily enter cells but must communicate with the cell by joining with specific receptors on the cell membrane. In so doing, they activate a sequence of communication. A considerable amount of investigation has been devoted to determining the methods by which this communication takes place. E. W. Sutherland, Jr., received the Nobel Prize in 1971 for proposing the concept of a second messenger.

Gonadotropin, the first messenger, activates an enzyme in the cell membrane called adenylate cyclase. This enzyme transmits the message by catalyzing the production of a second messenger within the cell, cyclic adenosine 3',5'-monophosphate (cyclic AMP). The message passes from gonadotropin to cyclic AMP, much like a baton in a relay race.

Cyclic AMP, the second messenger, initiates the process of steroidogenesis, leading to the synthesis and secretion of the hormone estradiol. This notion of message transmission has grown more and more complex with the appreciation of physiologic concepts, such as the heterogeneity of peptide hormones, the up- and down-regulation of cell membrane receptors, the regulation of adenylate cyclase activity, and the important roles for autocrine and paracrine regulating factors.

Secretion of estradiol into the bloodstream directly follows its synthesis. Once in the bloodstream, estradiol exists in two forms, bound and free. A majority of the hormone is bound to protein carriers, albumin, and sex steroid hormone-binding globulin. The biologic activity of a hormone is limited by binding in the blood, thereby avoiding extreme or sudden reactions. In addition, binding prevents unduly rapid metabolism, allowing the hormone to exist for the length of time necessary to ensure a biologic effect. This reservoir-like mechanism avoids peaks and valleys in hormone levels and allows a more steady state of hormone action.

The biologic and metabolic effects of a hormone are determined by a cell's ability to receive and retain the hormone. The estradiol that is not bound to a protein, but floats freely in the bloodstream, readily enters cells by rapid diffusion. For estradiol to produce its effect, however, it must be grasped by a receptor within the cell. The job of

the receptor is to aid in the transmission of the hormone's message to nuclear gene transcription. The result is production of messenger RNA leading to protein synthesis and a cellular response characteristic of the hormone.

Once estradiol has accomplished its mission, it is eventually released back into the bloodstream. It is possible that estradiol can perform its duty several times before being cleared from the circulation by metabolism. On the other hand, many molecules are metabolized without ever having the chance to produce an effect. Unlike estradiol, other hormones, such as testosterone, can either work directly or are metabolized and altered within the cell in which an effect is produced. In the latter case, a metabolite is released into the bloodstream as an inactive compound. Clearance of steroids from the blood varies according to the structure of the molecules.

Cells that are capable of clearing estradiol from the circulation accomplish this by biochemical means (conversion to estrone and estriol, moderately effective and very weak estrogens, respectively) and conjugation to products that are water soluble and excreted in the urine and bile (sulfo- and glucuroconjugates).

Thus, a steroid hormone has a varied career packed into a short lifetime. In this chapter, we will review the important segments of this life span in greater detail, as well as explore the mechanisms by which tropic hormones regulate steroid hormones.

# STEROID HORMONE NOMENCLATURE

---

All steroid hormones are of basically similar structure with relatively minor chemical differences leading to striking alterations in biochemical activity. The basic structure is the perhydrocyclopentanophenanthrene molecule. It is composed of three 6-carbon rings and one 5-carbon ring. One 6-carbon ring is benzene, two of the 6-carbon rings are naphthalene, and three 6-carbon rings are phenanthrene; add a cyclopentane (5-carbon ring), and you have the perhydrocyclopentanophenanthrene structure of the steroid nucleus.

The sex steroids are divided into three main groups according to the number of carbon atoms they possess. The 21-carbon series includes the corticoids as well as the progestins, and the basic structure is the **pregnane** nucleus. The 19-carbon series includes all the androgens and is based on the **androstane** nucleus, whereas the estrogens are 18-carbon steroids based on the **estrane** nucleus (**Figure 1.1**).

**FIGURE 1.1**

There are six centers of asymmetry on the basic ring structure, and there are 64 possible isomers. Almost all naturally occurring and active steroids are nearly flat, and substituents below and above the plane of the ring are designated alpha ( $\alpha$ ) (dotted line) and beta ( $\beta$ ) (solid line), respectively. Changes in the position of only one substituent can lead to inactive isomers. For example, 17-epitestosterone is considerably weaker than testosterone; the only difference being a hydroxyl group in the  $\alpha$ -position at C-17 rather than in the  $\beta$ -position ([Figure 1.2](#)).

**FIGURE 1.2**

The convention of naming steroids uses the number of carbon atoms to designate the basic name (e.g., pregnane, androstane, or estrane). The basic name is preceded by numbers that indicate the position of double bonds, and the name is altered as follows to indicate one, two, or three double bonds: -ene, -diene, and -triene. Following the basic name, hydroxyl groups are indicated by the number of the carbon attachment, and one, two, or (Figure 1.3) three hydroxyl groups are designated -ol, -diol, or -triol. Ketone groups are listed last with numbers of carbon attachments, and one, two, or three groups designated -one, -dione, or -trione. Special designations include deoxy- (elimination of oxygen), nor- (elimination of carbon), and  $\Delta$ - (location of double bond).

**FIGURE 1.3**

# STEROIDOGENESIS

---

The production of all three major groups of sex steroids is achieved through a common pathway, which begins with the cholesterol molecule. In this section, we will discuss this biosynthesis from the production and uptake of cholesterol through the synthesis of each of the sex steroids.

# LIPOPROTEINS AND CHOLESTEROL

---

Cholesterol is the basic building block in steroidogenesis. All steroid-producing organs except the placenta can synthesize cholesterol from acetate. Progestins, androgens, and estrogens, therefore, can be synthesized in situ in the various ovarian tissue compartments from the 2-carbon acetate molecule via cholesterol as the common steroid precursor. However, in situ synthesis cannot meet the demand, and, therefore, the major resource is blood cholesterol that enters the ovarian cells and can be inserted into the biosynthetic pathway or stored in esterified form for later use. The cellular entry of cholesterol is mediated via a cell membrane receptor for low-density lipoprotein (LDL), the bloodstream carrier for cholesterol.

Lipoproteins are large molecules that facilitate the transport of nonpolar fats in a polar solvent, the blood plasma. There are five major categories of lipoproteins according to their charge and density (flotation during ultracentrifugation). They are derived from each other in the following cascade of decreasing size and increasing density.

# Chylomicrons

Large, cholesterol (10%)- and triglyceride (90%)-carrying particles formed in the intestine after a fatty meal.

# **Very-Low-Density Lipoproteins**

Also carry cholesterol, but mostly triglyceride; more dense than chylomicrons.

# **Intermediate-Density Lipoproteins (IDLs)**

Formed (for a transient existence) with the removal of some of the triglyceride from the interior of very-low-density lipoprotein (VLDL) particles.

# **Low-Density Lipoproteins**

The end products of VLDL catabolism, formed after further removal of triglyceride leaving approximately 50% cholesterol; the major carriers (two-thirds) of cholesterol in the plasma (and thus a strong relationship exists between elevated LDL levels and cardiovascular disease).

# High-Density Lipoproteins

The smallest and most dense of the lipoproteins with the highest protein and phospholipid content; high-density lipoprotein (HDL) levels are inversely associated with atherosclerosis (high levels are protective). HDL can be further separated into a lighter fraction (HDL<sub>2</sub>) and a denser fraction (HDL<sub>3</sub>).

The lipoproteins contain four ingredients: (1) cholesterol in two forms, free cholesterol on the surface of the spherical lipoprotein molecule and esterified cholesterol in the molecule's interior; (2) triglycerides in the interior of the sphere; (3) phospholipid; and (4) protein in electrically charged substances on the surface of the sphere and responsible for miscibility with plasma and water. The surface proteins, called **apoproteins**, constitute the sites that bind to the lipoprotein receptor molecules on the cell surfaces. The principal surface protein of LDL is apoprotein B, and apoprotein A-1 is the principal apoprotein of HDL.

Lipids for peripheral tissues are provided by the secretion of VLDL by the liver. Triglycerides are liberated from VLDL by lipoprotein lipase located in the capillary endothelial cells as well as a lipase enzyme located on the endothelial cells in liver sinusoids. In this process, the surface components (free cholesterol, phospholipids, and apoproteins) are transferred to HDL. Finally, the VLDL is converted to LDL, which plays an important role of transporting cholesterol to cells throughout the body. The hepatic lipase enzyme is sensitive to sex steroid changes; it is suppressed by estrogen and stimulated by androgens (**Figure 1.4**).

**FIGURE 1.4**

LDL is removed from the blood by cellular receptors that recognize one of the surface apoproteins. The lipoprotein bound to the cell membrane receptor is internalized and degraded. Intracellular levels of cholesterol are partly regulated by the up- and down-regulation of cell membrane LDL receptors. When these LDL receptors are saturated or deficient, LDL is taken up by “scavenger” cells (most likely derived from macrophages) in other tissues, notably the arterial intima. Thus, these cells can become the nidus for atherosclerotic plaques.

HDL is secreted by the liver and intestine or is a product of the degradation of VLDL. Cholesteryl ester molecules move to form a core in a small spherical particle, the HDL<sub>3</sub> particle. These particles accept additional free cholesterol, perhaps mediated by receptors that recognize apoprotein A-1. With uptake of cholesterol, the particle size increases to form HDL<sub>2</sub>, the fraction that reflects changes in diet and hormones. HDL<sub>3</sub> levels remain relatively stable.

The protein moieties of the lipoprotein particles are strongly related to the risk of cardiovascular disease, and genetic abnormalities in their synthesis or structure can

result in atherogenic conditions. The lipoproteins are a major reason for the disparity in atherosclerosis risk between men and women. Throughout adulthood, the blood HDL cholesterol level is about 10 mg/dL higher in women, and this difference continues through the postmenopausal years. Total and LDL cholesterol levels are lower in premenopausal women than in men, but after menopause, they rise rapidly.

The protective nature of HDL is due to its ability to pick up free cholesterol from cells or other circulating lipoproteins. This lipid-rich HDL is known as HDL<sub>3</sub>, which is then converted to the larger, less dense particle, HDL<sub>2</sub>. Thus, HDL converts lipid-rich scavenger cells (macrophages residing in arterial walls) back to their low-lipid state and carries the excess cholesterol to sites (mainly liver) where it can be metabolized. Another method by which HDL removes cholesterol from the body focuses on the uptake of free cholesterol from cell membranes. The free cholesterol is esterified and moves to the core of the HDL particle. Thus, HDL can remove cholesterol by delivering cholesterol to sites for utilization (steroid-producing cells) or metabolism and excretion (liver).

For good cardiovascular health, the blood concentration of cholesterol must be kept low, and its escape from the bloodstream must be prevented. The problem of cholesterol transport is solved by esterifying the cholesterol and packaging the ester within the cores of plasma lipoproteins. The delivery of cholesterol to cells is in turn solved by lipoprotein receptors. After binding the lipoprotein with its package of esterified cholesterol, the complex is delivered into the cell by receptor-mediated endocytosis (discussed later in this chapter), in which the lysosomes liberate cholesterol for use by the cell.

Major protection against atherosclerosis depends on the high affinity of the receptor for LDL and the ability of the receptor to recycle multiple times, thus allowing large amounts of cholesterol to be delivered while maintaining a healthy low blood level of LDL. Cells can control their uptake of cholesterol by increasing or decreasing the number of LDL receptors according to the intracellular cholesterol levels. Thus, a high-cholesterol diet influences the liver to reduce the number of LDL receptors on its cells, causing an elevated blood level of LDL. Statins protect against atherosclerosis by reducing cholesterol biosynthesis, increasing LDL receptors in the liver, and lowering circulating levels of LDL cholesterol.

# STEROID BIOSYNTHETIC PATHWAY

---

The overall steroid biosynthesis pathway shown in [Figure 1.5](#) is based primarily on the pioneering work of Kenneth J. Ryan and his coworkers.<sup>1,2</sup> These pathways follow a fundamental pattern displayed by all steroid-producing endocrine organs. As a result, it should be no surprise that the normal human ovary produces all three classes of sex steroids: estrogens, progestins, and androgens. The importance of ovarian androgens is appreciated, not only as obligate precursors to estrogens but also as clinically important secretory products. The ovary differs from the testis in its fundamental complement of critical enzymes and, hence, its distribution of secretory products. The ovary is distinguished from the adrenal gland in that it is deficient in 21-hydroxylase and 11 $\beta$ -hydroxylase reactions. Glucocorticoids and mineralocorticoids, therefore, are not produced in normal ovarian tissue.

## FIGURE 1.5

During steroidogenesis, the number of carbon atoms in cholesterol or any other steroid molecule can be reduced but never increased. The following reactions can take place:

- 1. Cleavage of a side chain (desmolase reaction)**
- 2. Conversion of hydroxy groups into ketones or ketones into hydroxy groups (dehydrogenase reactions)**
- 3. Addition of hydroxy group (hydroxylation reaction)**
- 4. Creation of double bonds (removal of hydrogen)**
- 5. Addition of hydrogen to reduce double bonds (saturation)**

The traditional view of steroidogenesis was that each step was mediated by many enzymes, with differences from tissue to tissue. A fundamental simplicity to the system emerged when the responsible complementary DNAs and genes were cloned.<sup>3,4,5</sup>

Steroidogenic enzymes are either dehydrogenases or members of the cytochrome P450 group of oxidases. Cytochrome P450 is a generic term for a family of oxidative enzymes, termed 450 because of a pigment (450) absorbance shift when reduced. P450 enzymes can metabolize many substrates; for example, in the liver, P450 enzymes metabolize toxins and environmental pollutants. The human genome contains genes for 57 cytochrome P450 enzymes; 7 of these enzymes localize to the mitochondria and 50 to the endoplasmic reticulum (the major site for metabolic clearance). The following distinct P450 enzymes are involved in steroidogenesis: P450scc is the cholesterol side-chain cleavage enzyme; P450c11 mediates 11-hydroxylase, 18-hydroxylase, and 19-methyloxidase; P450c17 mediates 17-hydroxylase and 17,20-lyase; P450c21 mediates 21-hydroxylase; and P450arom mediates aromatization of androgens to estrogens ([Table 1.1](#)). Marked differences in the exon-intron organization of the P450 genes are compatible with an ancient origin; thus, the superfamily of P450 genes diverged more than 1.5 billion years ago.

### TABLE 1.1 Cytochrome P450 Enzymes

<b>Enzyme</b>	<b>Cellular Location</b>	<b>Reactions</b>
P450scc	Mitochondria	Cholesterol side-chain cleavage
P450c11	Mitochondria	11-Hydroxylase 18-Hydroxylase 19-Methyloxidase
P450c17	Endoplasmic reticulum	17-Hydroxylase, 17,20-lyase
P450c21	Endoplasmic reticulum	21-Hydroxylase
P450arom	Endoplasmic reticulum	Aromatase

The structural knowledge of the P450 enzymes that has been derived from amino acid and nucleotide sequencing studies demonstrated that all the steps between cholesterol and pregnenolone were mediated by a single protein, P450scc, bound to the inner mitochondrial membrane. Cloning data revealed that this protein is encoded by the CYP11A1 gene on chromosome 15. These experiments indicated that multiple steps did not require multiple enzymes. Differing activity in different tissues may reflect posttranslational modifications. In addition, P450-encoding genes contain tissue-specific promoter sequences, which is another reason that regulatory mechanisms can differ in different tissues (e.g., placenta and ovary). CYP11A1 mutations are very rare, producing impaired steroidogenesis in both the adrenal glands and the gonads and causing abnormal sexual development and adrenal failure.<sup>6</sup>

Conversion of cholesterol to pregnenolone involves hydroxylation at the carbon 20 and 22 positions, with subsequent cleavage of the side chain. Conversion of cholesterol to pregnenolone by P450scc takes place within the mitochondria. It is one of the principal effects of tropic hormone stimulation, which also causes the uptake of the cholesterol substrate for this step in the ovary. The tropic hormones from the anterior

pituitary bind to the cell surface receptor of the G protein system, activate adenylate cyclase, and increase intracellular cyclic AMP. Cyclic AMP activity leads to gene transcription that encodes the steroidogenic enzymes and accessory proteins. In a process that is faster than gene transcription, cyclic AMP stimulates the hydrolysis of cholesteryl esters and the transport of free cholesterol to the mitochondria.

The cholesterol used for steroid synthesis is derived from circulating LDLs, followed by the mobilization and transport of intracellular stores.<sup>5,7,8</sup> LDL cholesterol esters are incorporated into the cell by tropic hormone stimulation of endocytosis via clathrin-coated pits (a mechanism discussed later in this chapter). Cholesterol is stored in the cell in the ester form or as free cholesterol. Indeed, the rate-limiting step in steroidogenesis is the transfer of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane where fully active P450<sub>scc</sub> waits for substrate. The rate-limiting transfer of hydrophobic cholesterol through the aqueous space between the outer and inner mitochondrial membranes is mediated by protein activation stimulated by the tropic hormone. Long-term, chronic steroidogenesis requires gene transcription and protein synthesis, but short-term, acute responses occur independently of new RNA synthesis (although protein synthesis is still necessary—specifically the proteins that regulate cholesterol transfer across the mitochondrial membrane).

Several proteins have been characterized and proposed as regulators of acute intracellular cholesterol transfer. Sterol carrier protein 2 (SCP2) is able to bind and transfer cholesterol between compartments within a cell. Another candidate is a small molecule, steroidogenesis activator polypeptide (SAP), and still another is peripheral benzodiazepine receptor (PBR), which affects cholesterol flux through a pore structure. But the most studied and favored protein as a regulator of acute cholesterol transfer is **steroidogenic acute regulatory (StAR) protein**.<sup>9,10,11,12,13</sup> StAR messenger RNA and proteins are induced concomitantly with acute steroidogenesis in response to cyclic AMP stimulation. StAR protein increases steroid production and is imported and localized in the mitochondria. Congenital lipoid adrenal hyperplasia (an autosomal recessive disorder) is a failure in adrenal and gonadal steroidogenesis due to a variety of mutations in the StAR gene.<sup>14,15</sup> With several of these mutations, a low level of steroidogenesis is possible, even permitting feminization at puberty, but continuing tropic hormonal stimulation results in an accumulation of intracellular lipid deposits that destroy steroidogenic capability.<sup>16</sup> Mutations of the StAR gene are the only inherited disorder of steroidogenesis not caused by a defect in one of the steroidogenic enzymes.

StAR is required for adrenal and gonadal steroidogenesis (for which it mediates the transport of cholesterol into mitochondria) and, therefore, is necessary for normal male sexual differentiation. StAR moves cholesterol from the outer mitochondrial membrane

to the inner mitochondrial membrane where it can enter the steroidogenic pathway by being converted to pregnenolone. A group of proteins structurally related to StAR have been identified, designated StARD4, StARD5, and StARD6. StARD4 is responsible for binding free cholesterol as it is produced in the cytoplasm and transporting it to the outer mitochondrial membrane.<sup>12</sup> Because steroid-producing cells do not store large amounts of hormones, acute increases in secretion depend on this system to produce rapid synthesis.

Once pregnenolone is formed, further steroid synthesis in the ovary can proceed by one of two pathways, either via  $\Delta^5$ -3 $\beta$ -hydroxysteroids or via the  $\Delta^4$ -3-ketone pathway. The first (the  $\Delta^5$  pathway) proceeds by way of pregnenolone and dehydroepiandrosterone (DHEA) and the second (the  $\Delta^4$  pathway) via progesterone and 17 $\alpha$ -hydroxyprogesterone.

The conversion of pregnenolone to progesterone involves two steps: the 3 $\beta$ -hydroxysteroid dehydrogenase and  $\Delta^{4-5}$  isomerase reactions that convert the 3-hydroxyl group to a ketone and transfer the double bond from the 5–6 position to the 4–5 position. The 3 $\beta$ -hydroxysteroid dehydrogenase enzyme catalyzes both the dehydrogenation and isomerization reactions and exists in two forms (type I and type II), encoded by two separate genes on chromosome 1 (the type I gene is expressed in the placenta, breast, and other nonglandular tissues, while the type II gene is expressed in the gonads and the adrenal glands). Once the  $\Delta^{4-5}$  ketone is formed, progesterone is hydroxylated at the 17 position to form 17 $\alpha$ -hydroxyprogesterone. 17 $\alpha$ -Hydroxyprogesterone is the immediate precursor of the C-19 (19 carbons) series of androgens in this pathway. By peroxide formation at C-20, followed by epoxidation of the C-17, C-20 carbons, the side chain is split off, forming androstenedione. The 17-ketone may be reduced to a 17 $\beta$ -hydroxy to form testosterone by the 17 $\beta$ -hydroxysteroid dehydrogenase reaction. Both C-19 steroids (androstenedione and testosterone) can be converted to corresponding C-18 phenolic steroid estrogens (estrone and estradiol) by microsomal reactions in a process referred to as aromatization. This process includes hydroxylation of the angular 19-methyl group, followed by oxidation, loss of the 19-carbon as formaldehyde, and ring A aromatization (dehydrogenation). As an alternative, pregnenolone can be directly converted to the  $\Delta^5$ -3 $\beta$ -hydroxy C-19 steroid, DHEA, by 17 $\alpha$ -hydroxylation followed by cleavage of the side chain. With formation of the  $\Delta^4$ -3-ketone, DHEA is converted into androstenedione.

The four reactions involved in converting pregnenolone and progesterone to their 17-hydroxylated products are mediated by a single enzyme, P450c17, bound to smooth endoplasmic reticulum and encoded by the CYP17A1 gene on chromosome 10q24.32. 17-Hydroxylase and 17,20-lyase were historically thought to be separate enzymes; however, these two different functions of the single P450c17 enzyme are not genetic or

structural but represent the effect of posttranslational influencing factors.<sup>17</sup> In the adrenal gland pathway to cortisol, very little 17,20-lyase activity is expressed. In the ovarian theca cells, the testicular Leydig cells, and the adrenal reticularis, both 17-hydroxylase and 17,20-lyase activities are expressed, directing the steroidogenic pathway via DHEA. In the corpus luteum, the principal pathway is via progesterone.

Hydroxylation of progesterone and 17 $\alpha$ -hydroxyprogesterone is mediated by the P450c21 protein, also known as 21-hydroxylase. Characterization of this protein and gene cloning indicate that its encoding gene, CYP21, is located on chromosome 6p21.3. An inactive pseudogene, CYP21P, is nearby. Many of the mutations that affect CYP21 and cause congenital adrenal hyperplasia are gene conversions involving recombinations between CYP21 and inactivating mutations in CYP21P.

Aromatization is mediated by P450arom found in the endoplasmic reticulum.<sup>18,19</sup> Aromatase cytochrome P450 is encoded by the CYP19A1 (cytochrome P450; family 19—denoting oxidation of the C-19 methyl group; subfamily A; polypeptide 1) gene on chromosome 15q21.1. Aromatization in different tissues with different substrates is the result of the single P450arom enzyme encoded by this single gene. Aromatase deficiency because of an inactivating mutation of CYP19A1 is very rare; only a handful of cases have been reported.<sup>20</sup> Affected females present at birth with virilization because the placenta cannot convert fetal adrenal androgens to estrogens; thus, maternal virilization during the pregnancy is usually also present.

Aromatase transcription is regulated by several promoter sites that respond to cytokines, cyclic nucleotides, gonadotropins, glucocorticoids, and growth factors.<sup>21</sup> Tissue-specific expression is regulated by tissue-specific promoters that allow the extremes of highly regulated expression in the ovary in response to cyclic AMP and gonadotropins, expression in adipose tissue stimulated by prostaglandin E<sub>2</sub>, and nonregulated expression in the placenta and adipose. Very specific inhibitors of P450arom have been developed, called “aromatase inhibitors,” that allow intense blockage of estrogen production, with clinical applications that include the treatment of breast cancer (e.g., anastrozole and letrozole) and ovulation induction. The aromatase complex also includes NADPH-cytochrome P450 reductase, a ubiquitous flavoprotein involved in reduction reactions.

The 17 $\beta$ -hydroxysteroid dehydrogenase and 5 $\alpha$ -reductase reactions are mediated by non-P450 enzymes. The 17 $\beta$ -hydroxysteroid dehydrogenase is bound to the endoplasmic reticulum and the 5 $\alpha$ -reductase to the nuclear membrane. The 17 $\beta$ -hydroxysteroid dehydrogenase enzymes convert estrone to estradiol, androstenedione to testosterone, and DHEA to androstenediol, and vice versa. Eight different isozymes have been cloned and characterized.<sup>22</sup> The type 1 enzyme is active in the placenta and granulosa cells, converting estrone to estradiol. The type 2 and 4 enzymes, found in many tissues, form

androstenedione and estrone from testosterone and estradiol, respectively. The type 3 and 5 enzymes in the testis reduce androstenedione to testosterone. The type 6 enzyme may be found only in rodents, and the type 7 and 8 enzymes are widespread, but have limited activity. Thus, types 1, 3, and 5 form active estrogens and androgens, whereas types 2 and 4 produce weaker products, a form of inactivation. This is important, for example, in protecting the fetus against testosterone and estradiol in the maternal circulation. The cell-specific production of each of these isoforms is a method for regulating the local concentration of estrogens and androgens.

# ESTROGENS

---

Androgens are the precursors of estrogens.  $17\beta$ -Hydroxysteroid dehydrogenase activity converts androstenedione to testosterone, which is not a major secretory product of the normal ovary. It is rapidly demethylated at the C-19 position and aromatized to estradiol, the major estrogen secreted by the human ovary. This process involves the well-characterized “two-cell system” described at length in [Chapter 5](#), ([Figure 1.6](#)). Estradiol also arises to a major degree from androstenedione via estrone, and estrone itself is secreted in significant daily amounts. Estriol is the peripheral metabolite of estrone and estradiol and not a secretory product of the ovary. The formation of estriol is typical of general metabolic “detoxification” (i.e., the conversion of biologically active material to less active forms) ([Figure 1.7](#)).

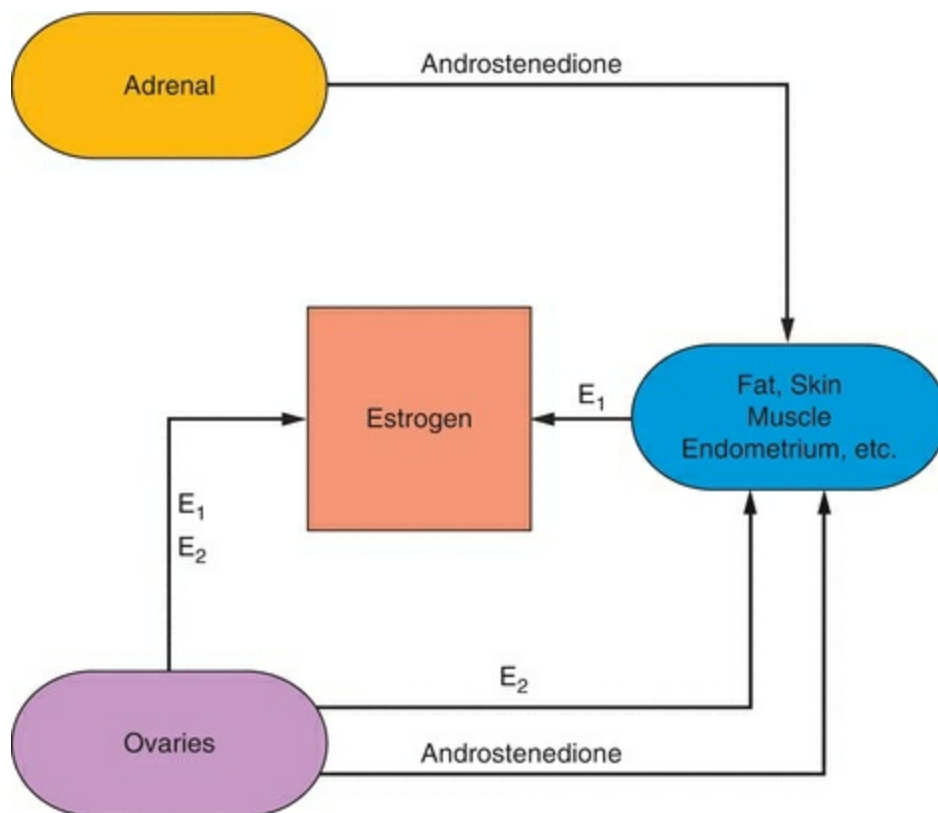

**FIGURE 1.6**

**FIGURE 1.7**

The conversion of steroids in peripheral tissues is not always a form of inactivation. Free androgens are peripherally converted to free estrogens, for example, in the skin and adipose cells. The location of the adipose cells influences their activity. Women with central obesity produce more androgens.<sup>23</sup> The work of Siiteri and MacDonald<sup>24</sup> demonstrated that enough estrogen can be derived from circulating androgens to produce bleeding in the postmenopausal woman. In the female, the adrenal gland remains the major source of circulating androgens, particularly androstenedione (**Figure 1.8**). In the male, almost all of the circulating estrogens are derived from peripheral conversion of androgens. The precursor androgens consist principally of androstenedione, DHEA, and dehydroepiandrosterone sulfate.

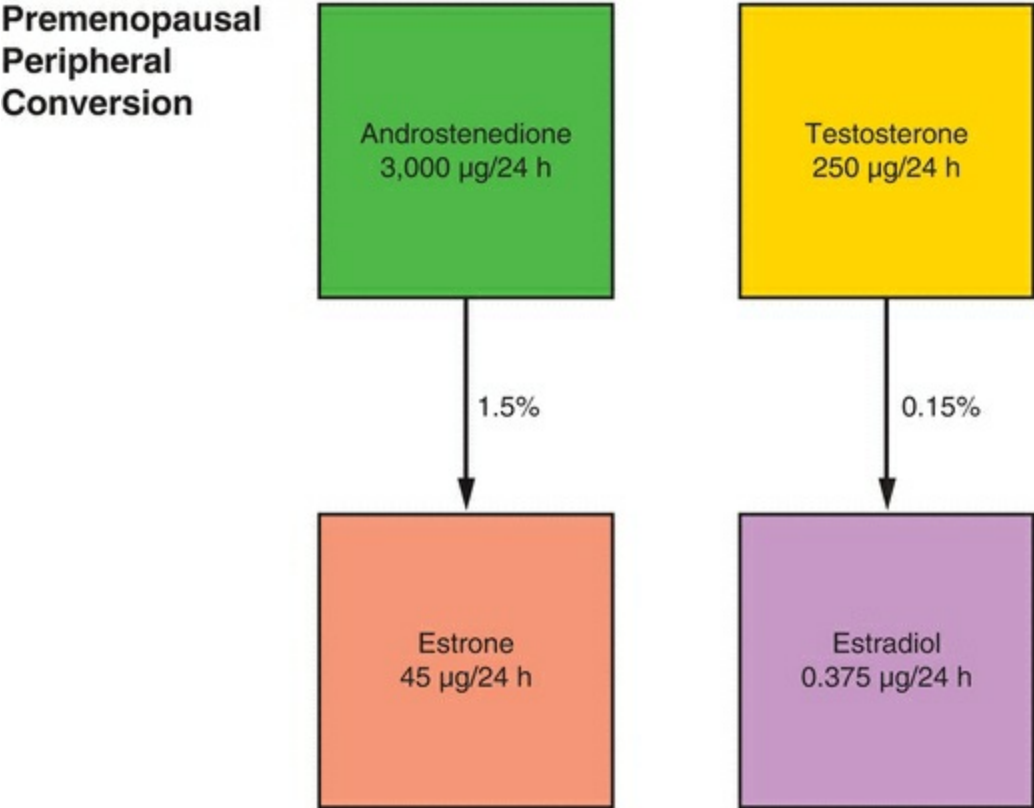

**FIGURE 1.8**

It can be seen, therefore, that the pattern of circulating steroids in the female is influenced by the activity of various processes outside the ovary. Because of the peripheral contribution to steroid levels, the term secretion rate is reserved for direct organ secretion, whereas production rate includes organ secretion plus peripheral contribution via conversion of precursors. The metabolic clearance rate (MCR) equals the volume of blood that is cleared of the hormone per unit of time. The blood production rate (PR) then equals the MCR multiplied by the concentration of the hormone in the blood.

$$\begin{aligned} \text{MCR} &= \text{Liters/Day} \\ \text{PR} &= \text{MCR} \times \text{Concentration (Liters/Day} \times \text{Amount/Liter} \\ &= \text{Amount/Day)} \end{aligned}$$

In the normal nonpregnant female, estradiol is produced at the rate of 100–300  $\mu\text{g/day}$ , but it circulates and functions within cells in concentrations of  $\text{pg/mL}$ . The production of androstenedione is about 3  $\text{mg/day}$ , and the peripheral conversion (about 1%) of androstenedione to estrone accounts for about 20–30% of the estrone produced per day. Because androstenedione is secreted in milligram amounts, even a small percent conversion to estrogen results in a significant contribution to estrogens, which exist and function in the circulation in picogram amounts. Thus, the circulating estrogens in the

female are the sum of direct ovarian secretion of estradiol and estrone, plus peripheral conversion of C-19 precursors (**Figure 1.9**).

**FIGURE 1.9**

# PROGESTERONE

Peripheral conversion of steroids to progesterone is not seen in the nonpregnant female; rather, the progesterone production rate is a combination of secretion from the adrenal and the ovaries. Including the small contribution from the adrenal, the blood production rate of progesterone in the preovulatory phase is less than 1 mg/day. During the luteal phase, production increases to 20–30 mg/day.

In the preovulatory phase in adult females, in all prepubertal females, and in the normal male, the blood levels of progesterone are at the lower limits of immunoassay sensitivity: less than 1 ng/mL. After ovulation, that is, during the luteal phase, progesterone ranges from 3 to 15 ng/mL. In congenital adrenal hyperplasia, progesterone blood levels can be as high as 50 times above normal. Pregnanediol and Pregnanetriol are metabolites of progesterone that are excreted in the urine ([Figure 1.10](#)).

**FIGURE 1.10**

# ANDROGENS

---

The major androgen products of the ovary are DHEA and androstenedione (and only a little testosterone), which are secreted mainly by stromal tissue derived from theca cells. With excessive accumulation of stromal tissue or in the presence of an androgen-producing tumor, testosterone becomes a significant secretory product. Occasionally, a nonfunctioning tumor can induce stromal proliferation and increased androgen production. The normal accumulation of stromal tissue at midcycle results in a rise in circulating levels of androstenedione and testosterone at the time of ovulation.

The adrenal cortex produces three groups of steroid hormones: the glucocorticoids, the mineralocorticoids, and the sex steroids. The adrenal sex steroids represent intermediate by-products in the synthesis of glucocorticoids and mineralocorticoids, and excessive secretion of the sex steroids occurs only with neoplastic cells or in association with enzyme deficiencies. Under normal circumstances, adrenal gland production of the sex steroids is less significant than gonadal production of androgens and estrogens. About one-half of the daily production of DHEA and androstenedione comes from the adrenal gland. The other half of androstenedione is secreted by the ovary, while the other half of DHEA is secreted almost equally from the ovary and peripheral tissues. The production rate of testosterone in the normal female is 0.2–0.3 mg/day, and approximately 50% arises from peripheral conversion of androstenedione (and a small amount from DHEA) to testosterone, whereas 25% is secreted by the ovary and 25% by the adrenal.

Reduction of the  $\Delta^4$  unsaturation (an irreversible pathway) in testosterone is very significant, producing derivatives very different in their spatial configuration and activity. The  $5\beta$ -derivatives are not androgenic, and this is not a clinically important pathway; however, the  $5\alpha$ -derivative (a very active pathway) is extremely potent. Indeed, dihydrotestosterone (DHT), the  $5\alpha$ -derivative, is the principal androgenic hormone in a variety of target tissues and is formed within the target tissue itself.

In men, the majority of DHT is derived from testosterone that enters a target cell and is converted by means of  $5\alpha$ -reductase. In women, because the production rate of androstenedione is greater than testosterone, DHT is primarily derived from androstenedione and partly from DHEA.<sup>25</sup> Thus, in women, the skin production of DHT is predominantly influenced by androstenedione. DHT is by definition an intracrine hormone, formed and acting within target tissues.<sup>26</sup> The  $5\alpha$ -reductase enzyme exists in two forms, type I and II, each encoded by a separate gene, with the type I enzyme found in the skin and the type II reductase predominantly expressed in reproductive tissues<sup>27</sup>.

DHT is largely metabolized intracellularly; hence, the blood DHT is only about one-tenth the level of circulating testosterone. In tissues sensitive to DHT (which

includes hair follicles), only DHT enters the nucleus to provide the androgen message. DHT also can perform androgenic actions within cells that do not possess the ability to convert testosterone to DHT. DHT is further reduced by a 3 $\alpha$ -keto-reductase to androstenediol, which is relatively inactive. The metabolite of androstenediol, 3 $\alpha$ -androstenediol glucuronide, is the major metabolite of DHT and can be measured in the plasma, indicating the amount of target tissue conversion of testosterone to DHT (Figure 1.11).

**FIGURE 1.11**

Not all androgen-sensitive tissues require the prior conversion of testosterone to DHT. In the process of masculine differentiation, the development of the Wolffian duct structures (epididymis, the vas deferens, and the seminal vesicle) is dependent on testosterone as the intracellular mediator, whereas development of the urogenital sinus and urogenital tubercle into the male external genitalia, urethra, and prostate requires

the conversion of testosterone to DHT.<sup>28</sup> Muscle development is under the direct control of testosterone. Testosterone is also aromatized to a significant extent in the brain, liver, and breast, and in some circumstances (e.g., in the brain), androgenic messages can be transmitted via estrogen.

# BLOOD TRANSPORT OF STEROIDS

---

While circulating in the blood, a majority of the principal sex steroids (i.e., estradiol and testosterone) is bound to a protein carrier known as sex hormone-binding globulin (SHBG), which is produced mainly in the liver. Additionally, 30% is loosely bound to albumin, and a very small percentage binds to corticosteroid-binding globulin, leaving only about 1% unbound and free. Hyperthyroidism, pregnancy, and estrogen administration all increase SHBG levels, whereas corticoids, androgens, progestins, growth hormone, insulin, and insulin-like growth factor I (IGF-I) decrease SHBG.

The circulating level of SHBG is inversely related to body weight, and, thus, significant weight gain can decrease SHBG and produce important changes in the unbound levels of the sex steroids. Additionally, circulating SHBG levels are reduced in the setting of insulin resistance and hyperinsulinemia<sup>29,30</sup>; this, in fact, may be the major mechanism that mediates the impact of increased body weight on SHBG. The relationship between levels of insulin and SHBG is so strong that SHBG concentrations are a marker for hyperinsulinemic insulin resistance, and a low level of SHBG is a predictor for the development of type 2 diabetes mellitus.<sup>31</sup>

The distribution of body fat also has a strong influence on SHBG levels. Android or central fat is located in the abdominal wall and visceral-mesenteric locations. This fat distribution is associated with hyperinsulinemia, hyperandrogenism, and decreased levels of SHBG.<sup>32</sup> The common mechanism for these changes is probably the hyperinsulinemia.

While SHBG is a homodimeric glycoprotein composed of two monomers, it contains a single binding site for androgens and estrogens. Its encoding gene has been localized to the short arm of chromosome 17.<sup>33</sup> Genetic studies have revealed that the SHBG gene also encodes the androgen-binding protein present in the seminiferous tubules, synthesized by the Sertoli cells.<sup>34,35</sup> Dimerization is believed to be necessary to form the single steroid-binding site. Specific genetic abnormalities with decreased or abnormal SHBG have not been reported. SHBG gene expression has now been identified in other tissues (brain, placenta, and endometrium), although a biologic significance has not been determined.

As previously mentioned, SHBG is decreased by androgens; hence, the binding capacity in men is lower than that in normal women. The binding globulin level in women with increased androgen production is also depressed. Androgenic effects are dependent on the unbound fraction that can move freely from the vascular compartment into the target cells. Routine assays determine the total hormone concentration, bound plus free. Thus, a total testosterone concentration can be in the normal range in a woman who is hirsute, but because the binding globulin level is depressed by the androgen

effects, the percent-free and active testosterone is elevated.

Transcortin, also called corticosteroid-binding globulin, is a plasma glycoprotein that binds cortisol, progesterone, deoxycorticosterone, corticosterone, and some of the other minor corticoid compounds. Normally, about 75% of circulating cortisol is bound to transcortin, 15% is loosely bound to albumin, and 10% is unbound or free. Progesterone circulates in the following percentages: less than 2% unbound, 80% bound to albumin, 18% bound to transcortin, and less than 1% bound to SHBG. Binding in the circulation follows the law of mass action: the amount of the free, unbound hormone is in equilibrium with the bound hormone. Thus, the total binding capacity of a binding globulin will influence the amount that is free and unbound.

The biologic effects of the major sex steroids are largely determined by the unbound portion, known as the free hormone. In other words, the active hormone is unbound and free, whereas the bound hormone is relatively inactive. This concept is not without controversy. The hormone-protein complex may be involved in an active uptake process at the target cell plasma membrane.<sup>36,37,38</sup> The albumin-bound fraction of steroids may also be available for cellular action because this binding has low affinity. Because the concentration of albumin in plasma is much greater than that of SHBG, the contribution of the albumin-bound fraction can be significant. Routine assays determine the total hormone concentration, bound plus free, and special steps are required to measure the active free level of testosterone, estradiol, and cortisol.

# THE IMPORTANCE OF LOCAL SEX HORMONE PRODUCTION

---

While blood transport of the sex steroids is a key mediator of their biologic effects, it is important to note that the circulating levels of sex hormones do not always reflect concentrations in target cells. In premenopausal women, target tissues synthesize and metabolize most of the testosterone produced. Thus, in women, testosterone functions as a paracrine and intracrine hormone. In men, abundant secretion of testosterone creates circulating levels that are sufficient to allow testosterone to function as a classic hormone. In women, the same description applies to estradiol. Estradiol functions as a classical circulating hormone until menopause, after which both estradiol and testosterone activities are due to local target tissue synthesis, using precursors derived from the circulation. Clinical interventions after menopause, therefore, are directed to local hormone production, for example, the use of aromatase inhibitors to treat breast cancer.

# EXCRETION OF STEROIDS

Active steroids and metabolites are excreted as sulfo- and glucuroconjugates. Conjugation of a steroid converts a hydrophobic compound into a hydrophilic one and generally reduces or eliminates the activity of a steroid. This is not completely true, however, because hydrolysis of the ester linkage can occur in target tissues and restore the active form. Furthermore, estrogen conjugates can have biologic activity, and it is known that sulfated conjugates are actively secreted and may serve as precursors, present in the circulation in relatively high concentrations because of binding to serum proteins. Ordinarily, however, conjugation by the liver and intestinal mucosa is a step in deactivation preliminary to, and essential for, excretion into urine and bile ([Figure 1.12](#)).

**FIGURE 1.12**

For example, the metabolic fate of progesterone, as expressed by its many excretion products, is relatively complex. About 10–20% of progesterone is excreted as pregnanediol. Pregnanediol glucuronide is present in the urine in concentrations less than 1 mg/day until ovulation. Postovulation pregnanediol excretion reaches a peak of 3–6 mg/day, which is maintained until 2 days prior to menses. The assay of

pregnanediol in the urine now has little clinical use. Pregnanetriol is the chief urinary metabolite of  $17\alpha$ -hydroxyprogesterone and has clinical significance in congenital adrenal hyperplasia, in which an enzymatic defect (most frequently 21-hydroxylase) results in accumulation of  $17\alpha$ -hydroxyprogesterone and increased excretion of pregnanetriol (**Figure 1.10**). However, the plasma or serum assay of  $17\alpha$ -hydroxyprogesterone is a more sensitive and accurate index of this enzyme deficiency than measurement of pregnanetriol.

# MECHANISM OF ACTION FOR STEROID HORMONES

The specificity of the reaction of tissues to sex steroid hormones is due to the presence of intracellular receptor proteins. Different types of tissues, such as liver, kidney, and uterus, respond in a similar manner. The mechanism includes (1) steroid hormone diffusion across the cell membrane, (2) steroid hormone binding to a receptor protein, (3) interaction of a hormone-receptor complex with nuclear DNA, (4) synthesis of messenger RNA (mRNA), (5) transport of the mRNA to the ribosomes, and, finally, (6) protein synthesis in the cytoplasm that results in specific cellular activity (**Figure 1.13**). The steroid hormone receptors primarily affect gene transcription, but also regulate posttranscriptional events and nongenomic events. Steroid receptors regulate gene transcription through multiple mechanisms, not all of which require direct interactions with DNA.

**FIGURE 1.13**

Each of the major classes of the sex steroid hormones, including estrogens, progestins, and androgens, acts according to this general mechanism. Glucocorticoid and mineralocorticoid receptors, when in the unbound state, reside in the cytoplasm and move into the nucleus after hormone-receptor binding. Estrogens, progestins, and androgens are transferred across the nuclear membrane and bind to their receptors within the nucleus.

Steroid hormones are rapidly transported across the cell membrane by simple diffusion. The factors responsible for this transfer are unknown, but the concentration of free (unbound) hormone in the bloodstream seems to be an important and influential determinant of cellular function. Once in the cell, the sex steroid hormones bind to their individual receptors. During this process, **transformation or activation** of the receptor occurs. Transformation refers to a conformational change of the hormone-receptor complex revealing or producing a binding site that is necessary in order for the complex to bind to the chromatin. In the unbound state, the receptor is associated with heat shock proteins that stabilize and protect the receptor and maintain a conformational shape that keeps the DNA-binding region in an inactive state. Activation of the receptor is driven by hormone binding that causes a dissociation of the receptor-heat shock protein complex.

The hormone-receptor complex binds to specific DNA sites (**hormone-responsive elements**) that are located upstream of the gene. The specific binding of the hormone-receptor complex with DNA results in RNA polymerase initiation of transcription. Transcription is followed by translation and mRNA-mediated protein synthesis on the ribosomes. The principal action of steroid hormones is the regulation of intracellular protein synthesis by means of the receptor mechanism.

Biologic activity is maintained only while the nuclear site is occupied with the hormone-receptor complex. The dissociation rate of the hormone and its receptor and the half-life of the nuclear chromatin-bound complex are factors in the biologic response because the hormone response elements are abundant and, under normal conditions, are occupied only to a small extent.<sup>39</sup> Thus, an important clinical principle is the following: **duration of exposure to a hormone is as important as dose**. One reason only small amounts of estrogen need be present in the circulation is the long half-life of the estrogen hormone-receptor complex. Indeed, a major factor in the potency differences among the various estrogens (estradiol, estrone, estriol) is the length of time the estrogen-receptor complex occupies the nucleus. The higher rate of dissociation with the weak estrogen (estriol) can be compensated for by continuous application to allow prolonged nuclear binding and activity. Cortisol and progesterone must circulate in large concentrations because their receptor complexes have short half-lives in the nucleus.

An important action of estrogen is the modification of its own and other steroid hormones' activities by affecting receptor concentrations. Estrogen increases target tissue responsiveness to itself and to progestins and androgens by increasing the concentration of its own receptor and that of the intracellular progestin and androgen receptors. Progesterone and clomiphene, on the other hand, limit tissue response to estrogen by blocking this mechanism, thus decreasing over time the concentration of estrogen receptors. Small amounts of receptor depletion and small amounts of steroid in the blood activate the mechanism.

The synthesis of the sex steroid receptors obviously takes place in the cytoplasm, but for estrogen and progestin receptors, synthesis must be quickly followed by transportation into the nucleus. There is an amazingly extensive nuclear traffic.<sup>40</sup> The nuclear membrane contains 3,000–4,000 pores. A cell synthesizing DNA imports about one million histone molecules from the cytoplasm every 3 minutes. If the cell is growing rapidly, about three newly assembled ribosomes will be transported every minute in the other direction. The typical cell can synthesize 10,000–20,000 different proteins. How do they know where to go? The answer is that these proteins have localization signals. In the case of steroid hormone receptor proteins, the signal sequences are in the hinge region.

Estrogen and progestin receptors exit continuously from the nucleus to the cytoplasm and are actively transported back to the nucleus. This is a constant shuttle; diffusion into the cytoplasm is balanced by the active transport into the nucleus. This raises the possibility that some diseases are due to poor traffic control. This can be true of some acquired diseases as well (e.g., Reye syndrome, an acquired disorder of mitochondrial enzyme function).

The fate of the hormone-receptor complex after gene activation is referred to as hormone-receptor **processing** (**Figure 1.14**). In the case of estrogen receptors, processing involves the rapid degradation of receptors unbound with estrogen and a much slower degradation of bound receptors after gene transcription. The rapid turnover of estrogen receptors has clinical significance. The continuous presence of estrogen is an important factor for continuing response.

**FIGURE 1.14**

The best example of the importance of these factors is the difference between estradiol and estriol. Estriol has only 20–30% affinity for the estrogen receptor compared with estradiol; therefore, it is rapidly cleared from a cell. But if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.<sup>41</sup> In pregnancy, where the concentration of estriol is very high, it can be an important hormone, not just a metabolite.

The depletion of estrogen receptors in the endometrium by progestational agents is the fundamental reason for adding progestins to estrogen treatment programs. The progestins accelerate the turnover of preexisting receptors, and this is followed by inhibition of estrogen-induced receptor synthesis. Using monoclonal antibody immunocytochemistry, this action has been pinpointed to the interruption of transcription in estrogen-regulated genes. The mechanism is different for androgen antiestrogen effects. Androgens also decrease estrogen receptors within target tissues, especially in the uterus.<sup>42,43</sup>

# The Nuclear Receptor Superfamily

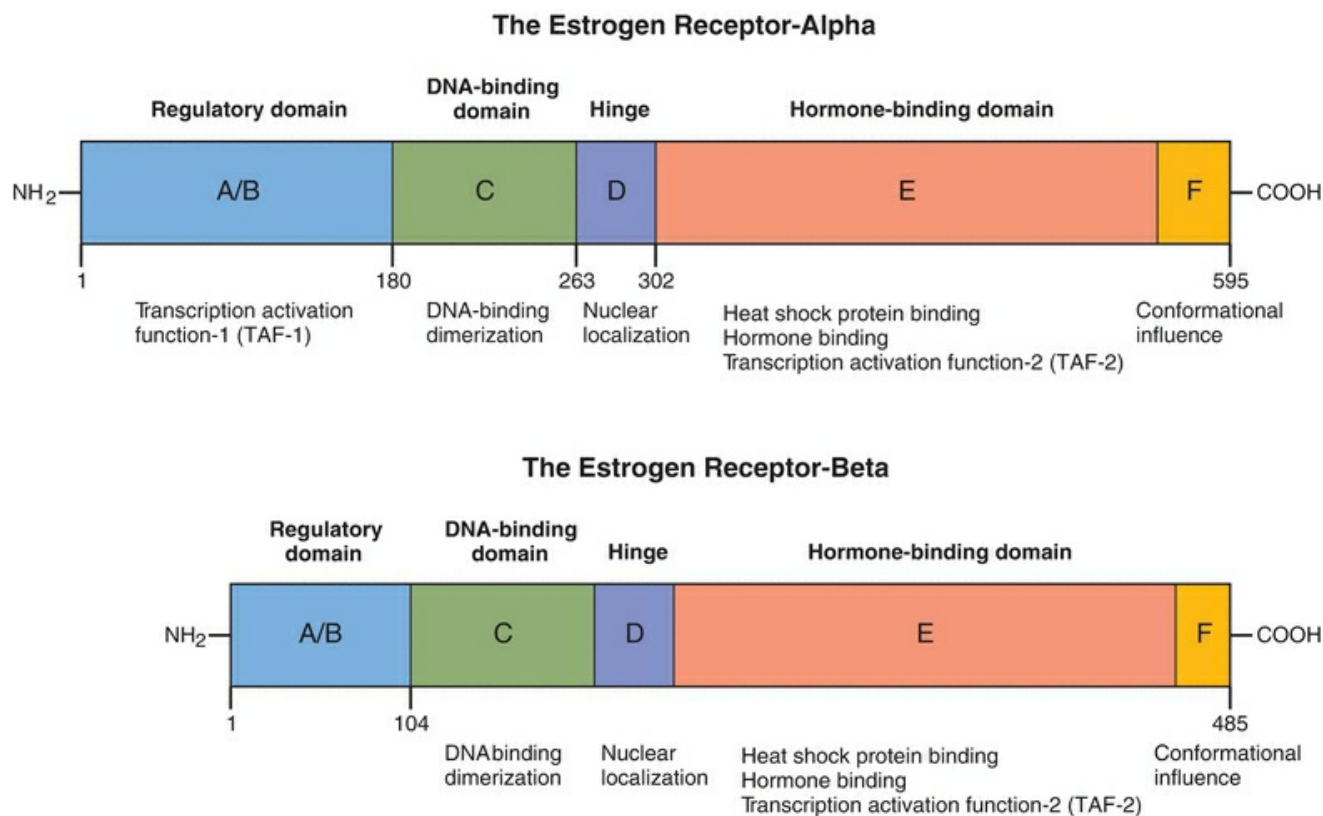

Recombinant DNA techniques have permitted the study of the gene sequences that code for the synthesis of nuclear receptors. Steroid hormone receptors share a common structure with the receptors for thyroid hormone, 1,25-dihydroxyvitamin D<sub>3</sub>, and retinoic acid; thus, these receptors are called a superfamily (**Figure 1.15**).<sup>44,45</sup> Each receptor contains characteristic domains that are similar and interchangeable. Therefore, it is not surprising that the specific hormones can interact with more than one receptor in this family. Analysis of these receptors suggests a complex evolutionary history during which gene duplication and swapping between domains of different origins occurred. This family now includes hundreds of proteins, present in practically all species, from worms to insects to humans. Some are called **orphan receptors** because specific ligands for these proteins have not been identified, but the number of orphan receptors is gradually diminishing (“deorphanization”). It has been convincingly argued that the six steroid receptors originated in a common ancestral receptor gene.<sup>46</sup> The identification of steroid receptors in the sea lamprey dates the origin to over 450 million years ago, and the characterization of a receptor that functions like an estrogen receptor in the mollusk suggests that the ancient and initial sex steroid receptor was an estrogen receptor.<sup>47</sup> Knowledge of the complete human genome has confirmed that there are 48 nuclear receptors in this superfamily.<sup>45</sup>

**FIGURE 1.15**

# The Estrogen Receptors

Two estrogen receptors have been identified, designated as estrogen receptor-alpha (ER- $\alpha$ ) and estrogen receptor-beta (ER- $\beta$ ) (Figure 1.16).<sup>48,49</sup> The estrogen receptor- $\alpha$  was discovered about 1960, and the amino acid sequence was reported in 1986.<sup>50,51,52</sup> The estrogen receptor- $\alpha$  is translated from a 6.8-kilobase mRNA derived from a gene that contains eight exons on the long arm of chromosome 6.<sup>53</sup> It has a molecular weight of approximately 66 kDa with 595 amino acids. The receptor- $\alpha$  half-life is approximately 4–7 hours; thus the estrogen receptor- $\alpha$  is a protein with a rapid turnover. The more recently discovered estrogen receptor- $\beta$ , a protein with 530 amino acids, is encoded by a gene localized to chromosome 14q23.2, in close proximity to genes related to Alzheimer disease.<sup>54,55</sup> Multiple isoforms exist of ER- $\beta$ , including five full-length forms.

**FIGURE 1.16**

Orphan receptors have been identified that are related to the estrogen receptors. They have been designated as estrogen-related receptor (ERR $\alpha$ , ERR $\beta$ , and ERR $\gamma$ ). ERR $\alpha$  may be regulated by coactivator proteins and interacts with typical steroid signaling pathways.<sup>56,57</sup> These orphan receptors are expressed in most tissues and may be

involved in typical estrogen activities, such as the proliferation and differentiation of target cells in the bone and in the breast. Nevertheless, they do not bind estrogens, and no endogenous ligand has been yet identified.

The story is further complicated with the recognition that members of the nuclear receptor superfamily are each associated with multiple isoforms.<sup>58</sup> This increases the number of possible signaling pathways in physiology and disease. In this discussion, we will mention only the most biologically important isoforms.

The estrogen receptors are divided into six regions in five domains, labeled A to F. The ER- $\beta$  is 96% homologous in amino acid sequence with the alpha estrogen receptor in the DNA-binding domain and 60% homologous in the hormone-binding domain. The full comparison is shown in [Table 1.2](#).<sup>54,59,60</sup>

## **TABLE 1.2 Hormone-Binding Domain**

## ER- $\alpha$ and ER- $\beta$ Homology (%)

The regulatory domain	18
The DNA-binding domain	96
The hinge	30
The hormone-binding domain	55
The F region	18

The hormone-binding characteristics of the ER- $\alpha$  and the ER- $\beta$  are similar, indicating that they respond in a comparable manner to the same hormones.<sup>61</sup> Thus, both receptors bind to the estrogen response element with a similar affinity, and the affinity of estradiol for each receptor is similar. There are differences, however; for example, phytoestrogens have a greater affinity for ER- $\beta$  than for ER- $\alpha$ . In other words, estrogenic agents demonstrate preferential binding for one or the other receptor. Different genetic messages can result not only because of differences in binding affinity but also through variations in the mechanisms to be discussed, notably differences in conformational shape and cellular contexts. In addition, because the regulatory domains differ in the two receptors, the ability of ER- $\beta$  to activate gene transcription by means of AF-1 is impaired (discussed below).

### A/B Region, the Regulatory Domain

The amino acid terminal is the most variable in the superfamily of nuclear receptors, ranging in size from 20 amino acids (in the vitamin D receptor) to 600 amino acids (in the mineralocorticoid receptor). In the ER- $\alpha$ , it contains several phosphorylation sites and the **transcription activation function called AF-1**. AF-1 can stimulate transcription in the absence of hormone binding. The regulatory domain is considerably different in the two estrogen receptors; in ER- $\beta$ , AF-1 is either significantly modified or absent.

### C Region, the DNA-Binding Domain

The middle domain binds to DNA and consists of 100 amino acids with nine cysteines in fixed positions, the two **zinc fingers** (Figure 1.17). This domain is essential for activation of transcription. Hormone binding induces a conformational change in the three helices that allows binding to the hormone-responsive elements in the target gene. This domain is very similar for each member of the steroid and thyroid receptor superfamily; however, the genetic message is specific for the hormone that binds to the hormone-binding domain. The DNA-binding domain controls which gene will be regulated by the receptor and is responsible for target gene specificity and high-affinity DNA binding. The specificity of receptor binding to its hormone-responsive element is determined by the zinc finger region, especially the first finger. The specific message can be changed by changing the amino acids in the base of the fingers. Substitutions of amino acids in the fingertips lead to loss of function. Functional specificity is localized to the second zinc finger in an area designated the d (distal) box. Different responses are due to the different genetic expression of each target cell (i.e., the unique activity of each cell's genetic constitution allows individual behavior).

**FIGURE 1.17**

## D Region, the Hinge

The region between the DNA-binding domain and the hormone-binding domain contains a signal area that is important for the movement of the receptor to the nucleus following

synthesis in the cytoplasm. This nuclear localization signal must be present for the estrogen receptor to remain within the nucleus in the absence of hormone. This region is also a site of rotation (hence the hinge designation) in achieving conformational change.

## **E Region, the Hormone-Binding Domain**

The carboxyl end of the estrogen receptor- $\alpha$  is the hormone-binding domain (for both estrogens and antiestrogens), consisting of 251 amino acids (residues 302–553). It contains 12 helices with a folding pattern that forms a pocket where the hormones bind. The pocket is about 20% smaller in ER- $\beta$ . In addition to hormone binding, this region contains the sites for cofactor binding, is responsible for **dimerization**, and harbors the **transcription activation function called AF-2**. This is also the site for binding by heat shock proteins (specifically hsp 90); when bound, the heat shock proteins prevent dimerization and DNA binding. In contrast to AF-1 activity, AF-2 depends on hormone binding for full activity.

## **F Region**

The F region of ER- $\alpha$  is a 42-amino acid C-terminal segment. This region modulates gene transcription by estrogen and antiestrogens, having a role that influences antiestrogen efficacy in suppressing estrogen-stimulated transcription.<sup>62</sup> The conformation of the receptor-ligand complex is different with estrogen and antiestrogens, and this conformation is different with and without the F region. The F region is not required for transcriptional response to estrogen; however, it affects the magnitude of ligand-bound receptor activity. It is speculated that this region affects conformation in such a way that protein interactions are influenced. Thus, it is appropriate that the effects of the F domain vary according to cell type and protein context. The F region affects the activities of both AF-1 and AF-2, which is what one would expect if the effect is on conformation.<sup>63</sup>

# Estrogen Receptor Mechanism of Action

## Ligand-Dependent Nuclear Activity

The steroid family receptors are predominantly in the nucleus even when not bound to a ligand, except for mineralocorticoid and glucocorticoid receptors (for which nuclear uptake depends on hormone binding). However, the estrogen receptor does undergo what is called **nucleocytoplasmic shuttling** (Figure 1.18). The estrogen receptor can diffuse out of the nucleus and be rapidly transported back in or undergo metabolism. When this shuttling is impaired, receptors are more rapidly degraded. Agents that inhibit dimerization (e.g., the pure estrogen antagonists) prevent nuclear translocation and thus increase cytoplasmic degradation.

**FIGURE 1.18**

In the absence of estrogen (the ligand), the receptor can become associated with the estrogen response element on a gene, a signal for a process that leads to its proteasome degradation via the ubiquitin pathway.<sup>64</sup> The receptor bound to its ligand, estrogen, undergoes the same process, but at a pace much slower than unliganded receptor, allowing time for gene transcription. This cyclic turnover allows the target cell to be very sensitive to the concentration of the ligand (estrogen) within the cell.

Prior to binding, the estrogen receptor is an inactive complex that includes a variety of chaperone proteins, including the heat shock proteins. Heat shock protein 90 appears

to be a critical protein, and many of the others are associated with it. This heat shock protein is important not only for maintaining an inactive state but also for causing proper folding for transport across membranes. “Activation” or “transformation” occurs with the dissociation of heat shock protein 90<sup>65</sup> (Figure 1.19).

**FIGURE 1.19**

One can imagine the unoccupied steroid receptor as a loosely packed, mobile protein complexed with heat shock proteins. The steroid family of receptors exists in this complex and cannot bind to DNA until union with a steroid hormone liberates the heat shock proteins and allows dimerization. The conformational change induced by hormone binding involves a dissociating process to form a tighter packing of the receptor. The hormone-binding domain contains helices that form a pocket.<sup>66</sup> After binding with a hormone (or with drugs engineered for this purpose), this pocket undergoes a conformational change that creates new surfaces with the potential to interact with coactivator and corepressor proteins. **Conformational shape is an important factor in determining the exact message transmitted to the gene.** Conformational shape is slightly but significantly different with each ligand; estradiol, tamoxifen, and raloxifene each induce a distinct conformation that contributes to the ultimate message of agonism or antagonism.<sup>67,68</sup> Tamoxifen and raloxifene, both AF-2 antagonists, cause a steric repositioning, about a 90-degree rotation, of a helix (the AF-2 helix) that then occupies the binding site of a coactivator in those tissues where such a

coactivator is a requisite for AF-2 activity. The weak estrogen activity of estriol is because of its altered conformational shape when combined with the estrogen receptor in comparison with estradiol.<sup>69</sup>

The hormone-binding domain of the estrogen receptors contains a cavity (the pocket) surrounded by a wedge-shaped structure, and it is the fit into this cavity that is so influential in the final genetic message. The size of this cavity on the estrogen receptor is relatively large, larger than the volume of an estradiol molecule, explaining the acceptance of a large variety of ligands. Thus, estradiol, tamoxifen, and raloxifene each bind in the same cavity within the hormone-binding domain, but the conformational shape with each is not identical.

Conformational shape is a major factor in determining the ability of a ligand and its receptor to interact with coactivators and corepressors. Conformational shapes are not simply either “on” or “off,” but intermediate conformations are possible providing a spectrum of agonist/antagonistic activity. The specific conformational shape of a receptor allows or prevents the recruitment of coactivators and corepressors that ultimately yield various biologic responses.

Members of the thyroid and retinoic acid receptor subfamily do not exist in inactive complexes with heat shock proteins. They can form dimers and bind to response elements in DNA without ligand; in this context, they act as repressors of transcription.

Estrogen receptor mutants can be created that are unable to bind estradiol. These mutants can form dimers with natural estrogen receptor (wild type) and then bind to the estrogen response element, but they cannot activate transcription.<sup>70</sup> This indicates that transcription is dependent on the result after estradiol binding to the estrogen receptor, an estrogen-dependent structural change. Dimerization by itself is not sufficient to lead to transcription; neither is binding of the dimer to DNA sufficient.

Molecular modeling and physical energy calculations indicate that binding of estrogen with its receptor is not a simple key and lock mechanism. It involves conversion of the estrogen-receptor complex to a preferred geometry dictated to a major degree by the specific binding site of the receptor. The estrogenic response depends on the final bound conformation and the electronic properties of functional groups that contribute energy. The final transactivation function is dependent on these variables.

**Estrogen, progesterone, androgen, and glucocorticoid receptors bind to their response elements as dimers, one molecule of hormone to each of the two units in the dimer.** The estrogen receptor- $\alpha$  can form dimers with other  $\alpha$ -receptors (homodimers) or with an estrogen receptor- $\beta$  (heterodimer). Similarly, the estrogen receptor- $\beta$  can form homodimers or heterodimers with the  $\alpha$ -receptor. This creates the potential for many pathways for estrogen signaling, alternatives that are further

increased by the possibility of utilizing various response elements in target genes. Cells that express only one of the estrogen receptors would respond to the homodimers; cells that express both could respond to a homodimer and a heterodimer.

The similar amino acid sequence of the DNA-binding domains in this family of receptors indicates evolutionary conservation of homologous segments. An important part of the conformational pattern consists of multiple cysteine-repeating units found in two structures, each held in a finger-like shape by a zinc ion, the so-called zinc fingers.<sup>71</sup> The zinc fingers on the various hormone receptors are not identical. These fingers of amino acids interact with similar complementary patterns in the DNA. Directed changes (experimental mutations) indicate that conservation of the cysteine residues is necessary for binding activity, as is the utilization of zinc.

The DNA-binding domain is specific for an enhancer site (the hormone-responsive element) in the gene promoter, located in the 5'-flanking region. The activity of the hormone-responsive element requires the presence of the hormone-receptor complex. Thus, this region is the part of the gene to which the DNA-binding domain of the receptor binds. There are at least four different hormone-responsive elements, one for glucocorticoids/progesterone/androgen, one for estrogen, one for vitamin D<sub>3</sub>, and one for thyroid/retinoic acid.<sup>72</sup> These sites significantly differ only in the number of intervening nucleotides.

Binding of the hormone-receptor complex to its hormone-responsive element leads to many changes, only one of which is a conformational alteration in the DNA. Although the hormone-responsive elements for glucocorticoids, progesterone, and androgens mediate all of these hormonal responses, there are subtle differences in the binding sites, and there are additional sequences outside of the DNA-binding sites that influence activation by the three different hormones. The cloning of complementary DNAs for steroid receptors has revealed a large number of similar structures of unknown function. It is believed that the protein products of these sequences are involved in the regulation of transcription initiation that occurs at the TATA box.

There are three different RNA polymerases (designated I, II, and III), each dedicated to the transcription of a different set of genes with specific promoters (the site of polymerase initiation of transcription). **Transcription factors are polypeptides, complexed with the polymerase enzyme, that modulate transcription either at the promoter site or at a sequence further upstream on the DNA.**<sup>73</sup> The steroid hormone receptors, therefore, are transcription factors. The polymerase transcription factor complex can be developed in sequential fashion with recruitment of individual polypeptides, or transcription can result from interaction with a preformed complete complex. The effect can be either positive or negative, activation or repression.

In most cases, therefore, the steroid hormone receptor activates transcription in

partnership with several groups of polypeptides<sup>73</sup>:

1. **Other transcription factors—peptides that interact with the polymerase enzyme and DNA.**
2. **Coactivators and corepressors—peptides that interact with the AF areas of the receptor, also called adaptor proteins or coregulators. Previously considered nuclear proteins, these regulators may also have functions within the cytoplasm.**
3. **Chromatin factors—structural organizational changes that allow an architecture appropriate for transcription response.**

The steroid-receptor complex regulates the amount of mRNA transcripts emanating from target genes. The estrogen-occupied receptor binds to estrogen response elements in the 5'-flanking regions of estrogen-regulated genes, allowing efficient induction of RNA transcription. This can occur by direct binding to DNA and interaction with the estrogen response element or by protein interactions with **coactivators** between the estrogen receptor and DNA sites. **Coactivators and corepressors are intracellular proteins, recruited by hormone receptors, that activate or suppress the AF areas by acting enzymatically either on the receptors or on DNA.**<sup>74,75,76,77,78,79</sup> Most of the genes regulated by estrogens respond within 1–2 hours after estrogen administration. Only a few respond within minutes. This time requirement may reflect the necessity to synthesize regulating proteins.<sup>80</sup> A large number (over 300—a current list is available at [www.nursa.org](http://www.nursa.org)) of coactivator and corepressor proteins have been identified, suggesting that there is a process involved with these proteins, causing selection, activation, queuing, and coordination.<sup>81</sup> In general, corepressor proteins bind to hormone receptors in the absence of a ligand and suppress any basal transcription activity. Active investigation of this step will undoubtedly yield understanding of pathologic responses and new pharmacologic developments because it is already recognized that these proteins influence the phenotypes of human diseases.<sup>82</sup>

Just as coregulators can lead to different responses to the same hormones in different tissues, there is evidence that posttranslational modifications of the coregulators can diversify the regulatory effects.<sup>79,81</sup> The activity of a coregulator protein can be altered by modifications such as phosphorylation or methylation. The response to a specific hormone, therefore, can be complex, differing in various tissues as directed by the coregulators present in that tissue and how the coregulators are modified. The diversity from tissue to tissue is thus very complex, but even within a single cell, impressive diversity is the norm. Because genomic differences among various species are amazingly small (1% or less), evolutionary differences in the way in which genes act, including the complex coregulatory story, make a major contribution

to the phenotypic and behavioral differences in life forms, especially humans. In addition, coregulators provide another evolutionary reservoir that can yield adaptation to new environmental challenges and stresses.

The concentration of coactivators/corepressors can affect the cellular response, and this is another explanation for strong responses from small amounts of hormone. With a small amount of receptor but a large amount of coactivator/corepressor, the cell can be very responsive to a weak signal.

One of the aspects of activation of the estrogen receptor, for example, is an increase in affinity for estrogen. This is an action of estrogen, and it is greatest with estradiol and least with estriol. This action of estradiol, the ability of binding at one site to affect another site, is called **cooperativity**. An increase in affinity is called positive cooperativity. The biologic advantage of positive cooperativity is that this increases the receptor's ability to respond to small changes in the concentration of the hormone. One of the antiestrogen actions of clomiphene is its property of negative cooperativity, the inhibition of the transition from a low-affinity to a high-affinity state. The relatively long duration of action exhibited by estradiol is due to the high-affinity state achieved by the receptor.

AF (activation function) is the part of the receptor that activates gene transcription after binding to DNA. Ligand binding produces a conformational change that allows AFs to accomplish their tasks. AF-1 can stimulate transcription in the absence of hormone when it is fused to DNA; however, it also promotes DNA binding in the intact receptor. AF-2 is affected by the bound ligand, and the estrogen receptor depends on estrogen binding for full activity. AF-2 consists of a number of dispersed elements that are brought together after estrogen binding. The activities of AF-1 and AF-2 vary according to the promoters in target cells. These areas can act independently or with one another. Indeed, the classic estrogen compounds (e.g., estradiol) produce a conformational shape that allows AF-1 and AF-2 to react in a synergistic fashion.

**Thus, the differential activities of the AFs account for different activities in different cells. In addition to the binding of the dimerized steroid receptor to the DNA response element, steroid hormone activity is modulated by other pathways (other protein transcription factors and coactivators/corepressors) that influence transcription activation.<sup>83,84</sup> This concept of cellular context is an important one. The same hormone can produce different responses in different cells according to the cellular context of protein regulators, and responses can be altered by posttranslational modifications of the coregulator proteins.**

## **Ligand-Independent Nuclear Activity**

Phosphorylation of specific receptor sites is an important method of regulation, as well as phosphorylation of other peptides that influence gene transcription. Phosphorylation can be regulated by cell membrane receptors and ligand binding, thus establishing a method for cell membrane-bound ligands to communicate with steroid receptor genes.

Cyclic AMP and protein kinase A pathways increase transcriptional activity of the estrogen receptor by phosphorylation. In some cases, phosphorylation modulates the activity of the receptor; in other cases, the phosphorylation regulates the activity of a specific peptide or coactivator/corepressor that, in turn, modulates the receptor. Phosphorylation follows steroid binding and occurs in both the cytoplasm and nucleus. Thus, phosphorylation enhances activity of the steroid receptor complex (**Figure 1.20**).

**FIGURE 1.20**

Phosphorylation of the receptor increases the potency of the molecule to regulate transcription. Growth factors can stimulate protein kinase phosphorylation that can produce synergistic activation of genes or even ligand-independent activity. Epidermal growth factor (EGF), IGF-I, and transforming growth factor-alpha (TGF- $\alpha$ ) can activate the estrogen receptor in the absence of estrogen, through the AF-1 domain. This response to growth factors can be blocked by pure antiestrogens (suggesting that a strong antagonist locks the receptor in a conformation that resists ligand-independent

pathways). The exact mechanism of growth factor activation is not known, but it is known that a steroid receptor can be activated by means of a chemical signal (a phosphorylation cascade) originating at the plasma membrane. **The recruitment of kinase activity is specific for specific ligands; thus, not all ligands stimulate phosphorylation.**

Another explanation for strong responses from small amounts of steroids is a positive feedback relationship. Estrogen activates its receptor, gene expression stimulates growth factors (EFG, IGF-I, TGF- $\alpha$ , fibroblast growth factor [FGF]), and the growth factors in an autocrine fashion further activate the estrogen receptor.<sup>85</sup> Ligand-independent activation of the estrogen receptor may be an important mechanism where estrogen levels are low, such as in the male.<sup>86</sup>

## Key Points: Steps in the Steroid Hormone Receptor Signaling Mechanism

- Binding of the hormone to the hormone-binding domain that has been kept in an inactive state by various heat shock proteins
- Activation of the hormone-receptor complex, by conformational change, follows the dissociation of the heat shock proteins
- Dimerization of the complex
- Binding of the dimer to the hormone-responsive element on DNA at the zinc finger area of the DNA-binding domain.
- Stimulation of transcription, mediated by activation functions (AFs) and influenced by the protein (other transcription factors and coactivators/corepressors) context of the cell and by phosphorylation

## Key Points: Factors That Determine Biologic Activity

- Affinity of the hormone for the hormone-binding domain of the receptor
- Target tissue differential expression of the receptor subtypes (e.g., ER- $\alpha$  and ER- $\beta$ )
- The concept of conformational shape: the structure of the ligand-receptor complex, with effects on two important activities: dimerization and the recruitment of regulating proteins

- The concept of cellular context: the differential expression of target tissue regulating proteins, coactivators and corepressors and phosphorylation, yielding various biologic responses

## Different Roles for ER- $\alpha$ and ER- $\beta$

Male and female mice have been developed that are homozygous for disruption of the estrogen receptor genes, “estrogen receptor knockout mice.”<sup>59,87,88</sup> Estrogen receptor- $\alpha$ -deficient mice are known as  $\alpha$ ERKO or ERKO mice and ER- $\beta$ -deficient mice as  $\beta$ ERKO or BERKO mice (Table 1.3).<sup>89</sup>

### TABLE 1.3 Characteristics of ERKO and BERKO Mice

**ERKO Mice****BERKO Mice**

Normal life span

Normal life span

normal adult responseIncrease in visceral adiposity  
and insulin resistanceNormal body fat distribution and  
insulin secretion

Infertile males and females

Fertile males, subfertile females  
with reduced follicular growth

Spermatogenesis in the  $\alpha$ ERKO male is reduced and the testes undergo progressive atrophy, a result of a testicular role for estrogen, because gonadotropin levels and testicular steroidogenesis remain normal. Sexual mounting behavior is not altered, but intromission, ejaculation, and aggressive behaviors are reduced. Female mice with the alpha estrogen receptor gene disrupted do not ovulate, and the ovaries do not respond to gonadotropin stimulation. These female animals have high levels of estradiol, testosterone, and LH. FSH  $\beta$ -subunit synthesis is increased, but FSH secretion is at normal levels, indicating different sites of action for estrogen and inhibin. Uterine development is normal (due to a lack of testosterone in early life), but growth is impaired. Mammary gland ductal and alveolar development is absent. Female mice with absent alpha estrogen receptor activity do not display sexual receptive behaviors. This genetically engineered line of mice demonstrates essential activities for the alpha estrogen receptor. Relatively normal fetal and early development suggests that the beta estrogen receptor plays a primary role in these functions. For example, the fetal adrenal gland expresses high levels of ER- $\beta$  and low levels of ER- $\alpha$ .<sup>90</sup> However, nongenomic

actions of estrogen are also possible and can explain some of the estrogenic responses in a knockout model. The results from estrogen receptor knockout mice as well as mice with disruption of the aromatase enzyme indicate that estrogen is essential for fertility, but not for the development of the reproductive tract or for survival.<sup>91</sup>

These genetic mice experiments also highlight the importance of estrogen in preventing the development of the metabolic syndrome. Knockout models for the estrogen receptors as well as the knockout model for the aromatase enzyme yield mice with hyperinsulinemia and increased visceral adiposity, with a reversal achieved by estrogen treatment.<sup>19</sup>

Differential expression of the  $\alpha$ - and  $\beta$ -receptors is present in various tissues (e.g., ER- $\beta$  is the prevalent estrogen receptor in certain areas of the brain and the cardiovascular system) resulting in different and selective responses to specific estrogens.<sup>88,92,93</sup> Human granulosa cells from the ovarian follicle contain only ER- $\beta$  mRNA; the human breast expresses both ER- $\alpha$  and ER- $\beta$ , but ER- $\alpha$  is primarily involved in mammary development and function. Some parts of the rat brain contain only ER- $\beta$ , others only ER- $\alpha$ , and some areas contain both receptors.<sup>94</sup> Target tissues that have been classically regarded as estrogen-sensitive (such as the uterus and the breast) express mainly ER- $\alpha$ . But, the knockout models have oversimplified the roles of ER- $\alpha$  and ER- $\beta$ , at least in breast tissue; their roles are dynamic and changing, not a simple expression of always one or the other.

Two commonly used estrogens, 17 $\beta$ -estradiol and ethinyl estradiol (the estrogen component of steroid contraceptives), bind equally well to the alpha and beta estrogen receptors. However, ER- $\beta$  plays a lesser role in those target tissues affected by these two estrogens, specifically the uterus, breast, bone, hypothalamus, and pituitary.

ER- $\beta$  may have a regulatory role. In some tissues, ER- $\beta$  reduces ER- $\alpha$ -regulated gene transcription, even though in the absence of ER- $\alpha$ , ER- $\beta$  can function as an estrogen receptor.<sup>95</sup> ER- $\beta$  acts as a natural suppressor of estrogen (ER- $\alpha$ ) activity in breast tissue, and decreased concentrations of ER- $\beta$  are associated with more aggressive tumors and reduced sensitivity to tamoxifen.<sup>96,97</sup> The colon contains only ER- $\beta$ , and the reduction in the risk of colonic cancer associated with postmenopausal estrogen therapy may reflect an antiproliferative activity of the  $\beta$ -receptor. Decreases in ER- $\beta$  expression have been observed in cancers occurring in the endometrium, ovary, colon, and prostate.<sup>98</sup>

The estrogen story is further complicated by the fact that the same estrogen binding to the  $\alpha$ - and  $\beta$ -receptors can produce opposite effects. For example, estradiol can stimulate gene transcription with ER- $\alpha$  at a given site of the estrogen response element, whereas estradiol inhibits gene transcription with ER- $\beta$  in this same system.<sup>99</sup> In other

tissues, the opposite scenario can occur with estradiol increasing ER- $\beta$  expression. Different and unique messages, therefore, can be determined by the specific combination of (1) a particular estrogen, (2) the  $\alpha$ - or  $\beta$ -receptor, and (3) the targeted response element. **To some degree, differences with ER- $\alpha$  and ER- $\beta$  are influenced by activation of AF-1 and AF-2; agents that are capable of mixed estrogen agonism and antagonism produce agonistic messages via AF-1 with ER- $\alpha$ , but because ER- $\beta$  lacks a similar AF-1, such agents can be pure antagonists in cells that respond only to ER- $\beta$ .**<sup>97</sup> ER- $\alpha$  and ER- $\beta$  affect the peptide context of a cell, especially coactivators and corepressors, differently. At least one component of this differing behavior is the fact that the two receptors do not bind to DNA in the same exact site, and the locations have different properties that could account for some of the differences in effects produced by each receptor; specifically, the two receptors can each activate regions of a gene, but some regions selectively respond to one or the other.<sup>100</sup>

# Ligand-Cell Membrane Extranuclear Receptor Activity

Not all actions of estrogen, and presumably all steroid hormones, are genomic, requiring gene transcription. Rapid cellular responses after estrogen stimulation are initiated by estrogen binding at the level of the cell membrane. These responses are traditionally associated with growth factors and G-protein-coupled receptors. However, it is not appropriate to designate this activity as “nongenomic” because the cell membrane estrogen-induced signaling leads to both gene transcription and to events independent of transcription. This extranuclear pathway activates various protein kinases that can cause ion fluxes of calcium and potassium, modification of second messenger systems, and indirect effects on growth factors, transcription factors, and genetic promoters.<sup>101</sup> A good example of membrane-associated estrogen activity is the stimulation of endothelial nitric oxide synthase.<sup>102</sup> Putative membrane receptors have been reported to be both related to ER- $\alpha$  and different from the estrogen receptor. The expression of a truncated isoform of ER- $\alpha$  involved in acute activation of nitric oxide has been described in the caveoli of human vascular endothelial cells.<sup>103</sup> A G-protein-coupled receptor localized to the endoplasmic reticulum has been identified that binds estrogen and affects intracellular functions.<sup>104</sup>

# Ligand-Dependent, ERE-Independent Activity

We have described three pathways that mediate estrogen activity:

- 1. Ligand-dependent nuclear activity: the classical mechanism involving the estrogen receptors with binding to DNA estrogen response elements**
- 2. Ligand-independent nuclear activity: activation of the estrogen receptor pathway through second messengers, involving phosphorylation of estrogen receptors and coregulator proteins**
- 3. Ligand-cell membrane extranuclear receptor activity: rapid responses mediated by estrogen receptors in cell membranes**

There is at least one more pathway, evident from studies with mutant mice: the ligand-dependent, ERE-independent nuclear pathway.<sup>105</sup> In these animals, mutant forms of the estrogen receptor cannot bind to ERE, the estrogen response element in DNA, and yet some physiologic actions of estrogen can be demonstrated, such as negative feedback inhibition of LH secretion, indicating hormonal mediation of a cellular response, but not through the classical pathway.

# The Progesterone Receptor

The progesterone receptor is induced by estrogens at the transcriptional level and decreased by progestins at both the transcriptional and translational levels (probably through receptor phosphorylation).<sup>106,107</sup> The progesterone receptor (in a fashion similar to the estrogen receptor) has three major forms, designated the A, B, and C receptors, of which A and B are most relevant to progesterone signaling. The C receptor is the smallest and lacks the ability to initiate transcription, and may even function in some tissues as an inhibitor of the B receptor (**Figure 1.21**).<sup>108</sup> The three isoforms are expressed by a single gene on chromosome 11 at q22–23; the three forms are a consequence of transcription from distinctly different promoters, in a complex system of transcription regulation.<sup>109</sup> Each form is associated with additional proteins, which are important for folding of the polypeptide into a structure that allows hormone binding and receptor activity.<sup>110</sup> The molecular weight of PR-A is 94 kDa, while PR-B's molecular weight is 114 kDa, containing 933 amino acids (164 more than PR-A). The B receptor has a unique upstream segment (128–165 amino acids, depending on the species) referred to as the B-upstream segment (BUS).

**FIGURE 1.21**

On the progesterone receptor, AF-1 is located in a 91-amino acid segment just upstream of the DNA-binding domain. AF-2 is located in the hormone-binding domain. A fragment missing the hormone-binding domain activates transcription to levels comparable to full-length hormone-activated B receptors, and higher than that with the A receptor, thus beyond that of AF-1 alone. In appropriate cells, therefore, BUS contains a third activation domain, AF-3, and can autonomously activate transcription, or it can synergize with the other AFs.<sup>111</sup> In the absence of hormone binding, the C-terminal region of the progesterone receptor exerts an inhibitory effect on transcription.<sup>112</sup> Progesterone agonists induce a conformational change that overcomes the inherent inhibitory function within the carboxy tail of the receptor. Binding with a progesterone antagonist produces a structural change that allows the inhibitory actions to be maintained.

Progestational agents can elicit a variety of responses determined by target tissue production and activity of the two receptor forms with dimerization as AA and BB (homodimers) or AB (heterodimer). The progesterone receptors function in the mechanism shared by this superfamily of receptors: an unbound complex with heat shock proteins, hormone binding, dimerization, DNA binding to a progesterone response element, and modulation of transcription by phosphorylation and various proteins.<sup>68,113</sup>

PR-A and PR-B are expressed in varying amounts in breast cancer and endometrial cancer cell lines. Studies indicate that the two receptors can be regulated independently; for example, the relative levels differ in the endometrium during the menstrual cycle.<sup>114</sup> Tissue specificity with the progesterone receptor is influenced by which receptor and which dimer is active; in addition, the transcriptional activities of PR-A and PR-B depend on target cell differences, especially in promoter context. **However, in most cells, PR-B is the positive regulator of progesterone-responsive genes, and PR-A inhibits PR-B activity.** Mutations within the carboxy terminus of PR-B affect its transcriptional activity. But mutations in PR-A have no effect on its transcriptional inhibitory activity. This indicates two separate pathways for transcription activation and repression by the progesterone receptor. Thus, repression of human estrogen receptor transcriptional activity (as well as glucocorticoid, mineralocorticoid, and androgen transcription) is dependent on the expression of PR-A.<sup>115,116</sup> The A and B progesterone receptors have different molecular functions, affecting different genes, and, therefore, target tissue response to progesterone will be influenced by the differential expression of each receptor and the ratio of their concentrations, as well as the target tissue context of adaptor proteins.<sup>117,118</sup>

The broad activity of PR-A in regard to all steroids suggests that it regulates inhibition of steroid hormone action wherever it is expressed. PR-A does not form a heterodimer with the estrogen receptor, nor does it prevent the estrogen receptor from

binding with DNA. PR-A does not change the structure of the estrogen receptor. Therefore, either PR-A competes with the estrogen receptor for a critical protein (in this case, PR-A would inhibit the estrogen receptor only in cells that contain the critical factor), or the target is a critical protein, again an essential transcription activator.<sup>110,114</sup>

Progesterone shares with estrogen (and probably all steroid hormones) the ability to exert activity at the cell membrane, independently of the progesterone receptor.<sup>119</sup> For example, progesterone or a progesterone metabolite can prevent uterine contractions by binding to the oxytocin G protein receptor in the cell membrane and inhibiting its function.<sup>120</sup>

PRKO mice (lacking both progesterone receptors A and B) are unable to ovulate due to a failure to expel a mature oocyte in a fully developed follicle, specifically a failure in the LH-induced rupture of a follicle.<sup>121</sup> When only PR-A is deficient, ovulation is severely impaired, but not totally reduced, indicating that both receptors contribute to ovulation, but PR-A is essential for normal function.

Like estrogen, G-protein-coupled receptors for progesterone have been identified, providing a pathway for progesterone activation of various signaling cascades involved in cellular functions, including gene expression.<sup>122</sup> A role for a membrane receptor has been proposed for progesterone's antiapoptotic actions in ovarian granulosa cells.<sup>123</sup>

# The Androgen Receptor

The cellular mechanism is more complex for androgens (**Figure 1.22**). Androgens can work in any one of three ways:

**FIGURE 1.22**

1. By intracellular conversion of testosterone to dihydrotestosterone (DHT), intracrine activity
2. By testosterone itself, endocrine activity
3. By intracellular conversion of testosterone to estradiol (aromatization), intracrine activity

Tissues that exclusively operate via the testosterone pathway are the derivatives of the Wolffian duct, whereas hair follicles and derivatives of the urogenital sinus and urogenital tubercle require the conversion of testosterone to DHT. The hypothalamus actively converts androgens to estrogens; hence, aromatization may be necessary for certain androgen feedback messages in the brain.

In those cells that respond only to DHT, only DHT will be found within the nucleus activating messenger RNA production. Because testosterone and DHT bind to the same high-affinity androgen receptor, why is it necessary to have the DHT mechanism? One explanation is that this is a mechanism for amplifying androgen action, because the androgen receptor preferentially will bind DHT (greater affinity). The antiandrogens, including cyproterone acetate and spironolactone, bind to the androgen receptor with about 20% of the affinity of testosterone.<sup>124</sup> This weak affinity is characteristic of binding without activation of the biologic response.

The androgen receptor, like the progesterone receptor, exists as the full-length B form and a shorter A form (**Figure 1.23**).<sup>125</sup> It is likely that the A and B forms of the androgen receptor have functional differences. The amino acid sequence of the androgen receptor in the DNA-binding domain resembles that of the receptors for progesterone, mineralocorticoids, and glucocorticoids but most closely that of the progesterone receptor.<sup>126</sup> Androgens and progestins can cross-react for their receptors but do so only when present in pharmacologic concentrations. Progestins compete not only for androgen receptors but also for the metabolic utilization of the 5 $\alpha$ -reductase enzyme. The dihydroprogesterone that is produced, in turn, also competes with testosterone and DHT for the androgen receptor. A progestin, therefore, can act both as an antiandrogen and as an antiestrogen. Androgen-responsive gene expression can also be modified by estrogen; it has been known for years that androgens and estrogens can counteract each other's biologic responses. These responses of target tissues are determined by gene interactions with the hormone-receptor complexes, androgen with its receptor, and estrogen with its receptor. The ultimate biologic response reflects the balance of actions of the different hormones with their respective receptors, modified by various transcription regulators.

## FIGURE 1.23

The syndrome of androgen insensitivity represents a congenital abnormality in the androgen intracellular receptor (with several hundred identified unique mutations)<sup>127,128</sup> The androgen receptor gene is localized on the human X chromosome at Xq12, the only steroid hormone receptor to be located on the X chromosome.<sup>129</sup> Thus, androgen insensitivity is an X-linked disorder. The genotype-phenotype correlation can be conceptualized as a progressive increase in androgen receptor action. At one end, there is a complete absence of androgen binding—complete androgen insensitivity. In the middle is a spectrum of clinical presentations representing varying degrees of abnormal receptors and binding. At the other end, about 25% of infertile men with normal genitalia and normal family histories have azoospermia due to an androgen receptor disorder.<sup>130,131</sup> The androgen receptor also plays a role in motor neuron physiology, because a specific mutation in the androgen receptor is responsible for Kennedy disease (X-linked spinobulbar muscular atrophy), a condition associated with motor neuron degeneration.<sup>132</sup>

# STEROID HORMONE RECEPTOR ANTAGONISTS

---

While agonists are substances that stimulate a response when bound to a receptor, antagonists inhibit the actions of an agonist. Antagonistic activity is characterized by blockage of the receptor message or nontransmission of the message. Most compounds used in this fashion that bind to hormone nuclear receptors have a mix of agonist and antagonist responses, depending on the tissue and hormonal milieu. Examples of antagonists include tamoxifen, mifepristone (RU-486), and androgen receptor antagonists.

## **Short-Acting Antagonists**

Short-acting antagonists, such as estriol, are actually a mixed combination of agonism and antagonism depending on time. Short-term estrogen responses can be elicited because estriol binds to the nuclear receptor, but long-term responses do not occur because this binding is short-lived. Antagonism results when estriol competes with estradiol for receptors. However, if a constant presence of the weak hormone, estriol, can be maintained, then long-term occupation is possible, and a potent estrogen response can be produced.

# **Long-Acting Antagonists**

Clomiphene and tamoxifen are mixed estrogen agonists and antagonists. The endometrium is very sensitive to the agonistic response, whereas the breast is more sensitive to the antagonistic behavior. The antagonistic action is the result of nuclear receptor binding with an alteration in normal receptor-DNA processing and eventual depletion of hormone receptors.

# Physiologic Antagonists

Strictly speaking, a progestin is not an estrogen antagonist. It modifies estrogen action by causing a depletion of estrogen receptors. There is also evidence that a progestin can inhibit transcription activation by the estrogen receptor.<sup>133</sup> In addition, progestins induce enzyme activity that converts the potent estradiol to the impotent estrone sulfate, which is then secreted from the cell.<sup>134</sup> Androgens block the actions of estrogen, also by depleting target tissues of estrogen receptors.

# Antiestrogens

Currently, there are two groups of antiestrogens: pure antiestrogens and compounds with both agonistic and antagonistic activities ([Figure 1.24](#)). The mixed agonist-antagonist compounds include both the triphenylethylene derivatives (the nonsteroidal estrogen relatives such as clomiphene and tamoxifen) and the nonsteroidal sulfur-containing agents (the benzothiophenes, such as raloxifene). The pure antiestrogens have a bulky side chain that, with only a little imagination, can be pictured as an obstruction to appropriate conformational changes. **An ideal antiestrogen would have the following properties:**

Triphenylethylene derivatives

Clomiphene

Tamoxifen

Droloxifene

Toremifene

Benzothiphene derivative

Raloxifene

Pure antiestrogens

ICI 164,384

Fulvestrant  
(ICI 182,780)

## FIGURE 1.24

1. A compound that would be a pure antagonist on proliferating breast carcinoma cells.
2. Development of resistance would be rare or require long exposure.
3. High affinity for the estrogen receptor so that therapeutic doses could be easily achieved.
4. No interference with the beneficial actions of estrogens.
5. No toxic or carcinogenic effects.

### The Antiestrogen Tamoxifen

Tamoxifen is very similar to clomiphene (in structure and actions), both being nonsteroidal compounds structurally related to diethylstilbestrol. Tamoxifen, in binding to the estrogen receptor, competitively inhibits estrogen binding. In vitro, the estrogen-binding affinity for its receptor is 100–1,000 times greater than that of tamoxifen. Thus, tamoxifen must be present in a concentration 100–1,000 times greater than estrogen to maintain inhibition of breast cancer cells. In vitro studies demonstrated that this action was not cytotoxic, but, rather, cytostatic (and thus, its use must be long term). The tamoxifen-estrogen receptor complex binds to DNA, but whether an agonistic, estrogenic message or an antagonistic, antiestrogenic message predominates is determined by what promoter elements (coactivators) are present in specific cell types. If the mechanism is cytostatic, why does a treatment period of 5 years provide protection against recurrent disease for at least 10 years? It has been suggested that exposure to tamoxifen sensitizes cells to the apoptotic effects of a woman's own estrogen levels.<sup>135,136</sup>

There have been many clinical trials with adjuvant treatment of breast cancer with tamoxifen, and many are still ongoing.<sup>137,138,139</sup> Overall, the impact of tamoxifen treatment on breast cancer can be summarized as follows: disease-free survival is prolonged. There is an increased survival after 5 years of treatment and 10 years of follow-up of approximately 26%, most evident in women over age 50. Response rates in advanced breast cancer are 30–35%, most marked in patients with tumors that are positive for estrogen receptors, reaching 75% in tumors highly positive for estrogen receptors.

Serum protein changes reflect the estrogenic (agonistic) action of tamoxifen. This includes decreases in antithrombin III, cholesterol, and LDL cholesterol, while SHBG levels increase (as do other binding globulins). The estrogenic activity of tamoxifen (when taken as 20 mg daily) is nearly as potent as 2 mg estradiol in lowering FSH

levels in postmenopausal women, 26% versus 34% with estradiol.<sup>140</sup> The estrogenic actions of tamoxifen include the stimulation of progesterone receptor synthesis, an estrogen-like maintenance of bone, and estrogenic effects on the vaginal mucosa and the endometrium. Tamoxifen causes a decrease in antithrombin III, and there has been a small increase in the incidence of venous thromboembolism observed in tamoxifen-treated patients compared with controls.<sup>141,142,143</sup>

All too often, the antagonistic, antiestrogenic action of tamoxifen is featured, and the estrogenic, agonistic action is ignored. There is about a fourfold increase in endometrial cancer occurring in women receiving tamoxifen treatment.<sup>143,144,145</sup> In addition, tamoxifen has been associated with major flare-ups in endometriosis. Tamoxifen, therefore, has a variety of side effects that indicate both estrogenic activity and antiestrogenic activity. How can tamoxifen be both an estrogen agonist and an estrogen antagonist?

## **Tamoxifen Mechanism of Action**

AF-1 and AF-2 areas can both activate transcription, but AF-2 activates transcription only when it is bound by estrogen. The individual transactivating abilities of AF-1 and AF-2 depend on the promoter and cell context. Tamoxifen's agonistic ability is due to activation of AF-1; its antagonistic activity is due to competitive inhibition of the estrogen-dependent activation of AF-2 (**Figure 1.25**).

**FIGURE 1.25**

An estrogen-associated protein, a coactivator, binds to the right-hand side of AF-2. Estrogen binding induces binding of this protein, which then activates transcription. This protein recognizes only an activated conformation of the estrogen receptor, the result of estrogen binding. Tamoxifen binding to the AF-2 area does not activate this domain because, in at least one explanation, the conformational change does not allow binding of the estrogen-associated protein, the activating factor.<sup>74,146</sup> Antagonism of AF-2 activity is further enhanced by the recruitment of corepressors after tamoxifen binds to the hormone-binding domain.<sup>84</sup>

The activity of AF-2 is negligible in the presence of tamoxifen. In cells where AF-1 and AF-2 function independently of each other, tamoxifen would be chiefly an antagonist in cells where AF-2 predominates and an agonist where AF-1 predominates, and in some cells, a mixed activity is possible.<sup>147</sup>

The contact sites of estrogens and antiestrogens with the estrogen receptor are not identical.<sup>148</sup> When an antiestrogen binds to the estrogen receptor, the conformational changes that are induced alter the ability of the estrogen receptor-antiestrogen complex

to modulate transcriptional activity. The relative agonist-antagonist activity is determined by the specific conformation achieved by the specific antiestrogen.

Even though tamoxifen can block estrogen-stimulated transcription of many genes, its degree of antagonistic activity varies among different animals, different cell types, and different promoters within single cells. These differences are due to differences in the relative activities of the AFs. Thus, the extent to which an antiestrogen inhibits an estrogen-mediated response depends on the degree to which that response is mediated by AF-2 activity as opposed to AF-1 activity, or mixed activity.<sup>149</sup> In some cell lines, AF-1 is dominant; in others, both are necessary. No cells have yet been identified where AF-2 is dominant.

In most cell types, AF-1 is too weak to activate transcription by itself, but, of course, there are well-known exceptions: endometrium, bone, and liver. In these tissues, the promoter context is right. Tamoxifen is a significant activator of estrogen receptor-mediated induction of promoters that are regulated by the AF-1 site.

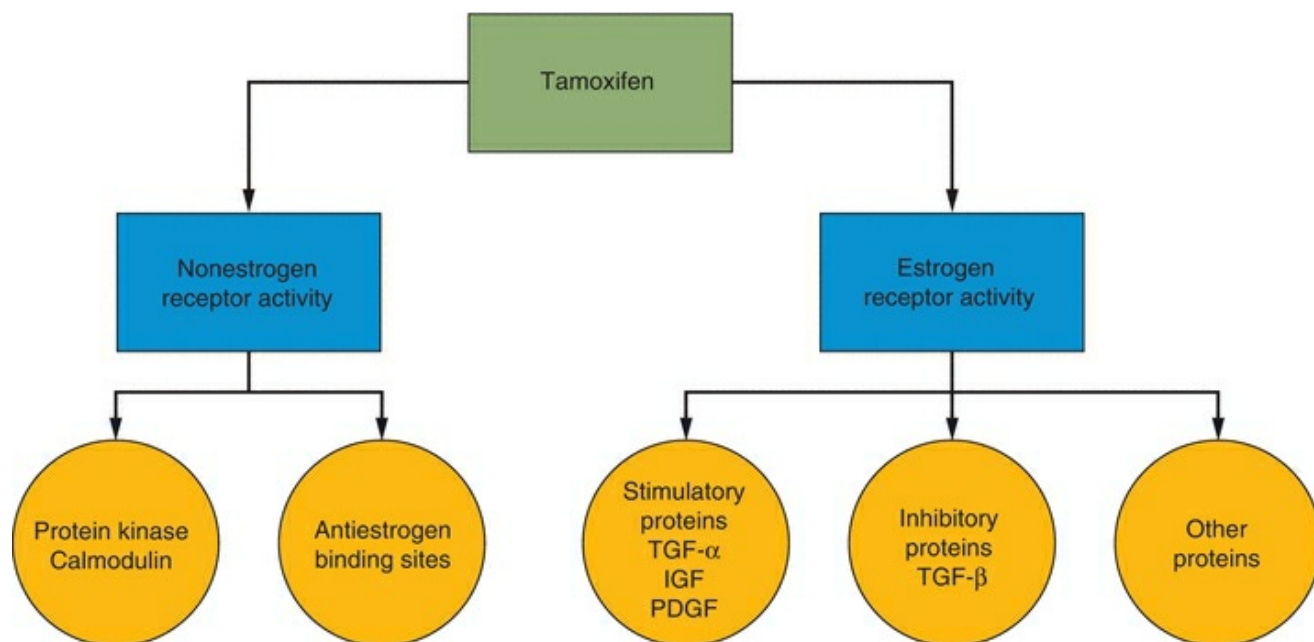

## Key Points

The response of cells to estrogens and antiestrogens depends on:

- **The nature of the estrogen receptor**
- **The estrogen response elements and nearby promoters**
- **The cell context of protein coactivators and corepressors**
- **The properties of the ligand**
- **Modulation by growth factors and agents that affect protein kinases and phosphorylation**

## Tamoxifen Treatment of Breast Cancer

Tamoxifen treatment achieves its greatest effect (50% reduction in recurrent disease) in estrogen receptor-positive tumors, but it is also effective in estrogen receptor-negative tumors. Most importantly, it is now recognized that acquired resistance eventually develops. Therefore, there are two important questions. Why is tamoxifen treatment effective with estrogen receptor-negative tumors? How does tamoxifen resistance develop (**Figure 1.26**)?

**FIGURE 1.26**

## Efficacy of Tamoxifen with Estrogen Receptor–Negative Tumors

Besides binding to the estrogen receptor and providing competitive inhibition, tamoxifen has the following actions:

1. Tamoxifen and clomiphene inhibit protein kinase C activity (phosphorylation).
2. Tamoxifen inhibits calmodulin-dependent cyclic AMP phosphodiesterase, by binding to calmodulin.
3. Tamoxifen and estrogen have opposing effects on growth factors.<sup>150,151</sup> Tamoxifen stimulates secretion of transforming growth factor- $\beta$  (TGF- $\beta$ ) in breast cancer cells as well as in fibroblasts and stromal cells, and TGF- $\beta$  inhibits growth of breast cancer cells, whereas estrogen and insulin decrease the secretion of TGF- $\beta$  in cancer cells. Tamoxifen decreases and estrogen increases IGF-I and insulin-like growth factor II (IGF-II) production in stromal fibroblasts.

Some of these actions (especially inhibition of protein kinase activity and stimulation of TGF- $\beta$  production) occur independently of tamoxifen binding to the estrogen receptor, and, thus, estrogen receptor–negative tumors can be affected by these actions; however, the overall impact of tamoxifen on recurrence or death in women with estrogen receptor–poor tumors is negligible.<sup>138</sup>

## Mechanisms for Tamoxifen Resistance

The results of randomized clinical trials have indicated that there is little reason to

extend tamoxifen treatment of breast cancer patients beyond 5 years.<sup>142,152,153</sup> Indeed, the data suggested that survival and recurrence rates worsened with longer therapy, probably due to the emergence of tamoxifen-resistant tumors. There are several possible explanations for resistance, and whichever of these are operative, it is believed that a subpopulation resistant to tamoxifen is present from the beginning and over time grows to be clinically apparent.<sup>154</sup>

## Loss of Estrogen Receptors

Generally, it is believed that estrogen receptor expression is not a permanent phenotype of breast cancer cells; thus, tumors can change from receptor-positive to receptor-negative. But more than 50% of resistant tumors retain estrogen receptors.<sup>155</sup> The conventional wisdom has been that progression is associated with loss of cellular control and loss of estrogen receptor expression. However, the correlation between metastatic disease and estrogen receptor-negative state is not strong. Indeed, metastatic disease with estrogen receptor-positive cells despite an estrogen receptor-negative primary lesion has been reported. In addition, the rate of estrogen receptor expression is about the same in in situ disease and invasive disease. Most normal breast cells are estrogen receptor negative, and in vitro cell lines maintain their receptor status. Thus, there is little reason to believe that tamoxifen-resistant tumors lose receptor expression. The importance of this is that resistance is not a wild, potentially uncontrollable dedifferentiation.<sup>156</sup>

## Variant and Mutant Estrogen Receptors

Mutations in resistant breast tumors are uncommon and are not a frequent cause of resistance.<sup>157</sup> Studies of breast tumors from tamoxifen-resistant patients indicate that most express wild-type normal estrogen receptor. However, approximately 20% of metastatic ER+ breast tumors may harbor mutations in the estrogen-binding domain of the estrogen receptor; these mutations have been shown to confer partial resistance to tamoxifen.<sup>158</sup>

## Changes in Coactivators

If a breast cancer cell were to begin expressing these factors in a fashion similar to the endometrium or bone, then agonistic actions would occur.

## Cross Talk Between Signaling Pathways

Because of the synergism between the estrogen receptor and protein kinase pathways, stimulation of protein kinase pathways can change an antagonist message to agonism.<sup>159</sup>

This mechanism operates through the phosphorylation of the estrogen receptor or proteins involved in estrogen receptor-mediated transcription. Stimulation of this protein kinase phosphorylation activates the agonist activity of tamoxifen-like antiestrogens. Furthermore, the lack of response of pure antiestrogens to this phosphorylation may be part of the reason for the response of resistant tumors to pure antiestrogens.

## Binding to Other Proteins

A remote possibility is the prevention of action by binding to other proteins, such as anti-estrogen-binding sites, microsomal proteins that bind to tamoxifen with high affinity but do not bind estrogen.<sup>160</sup>

## Differential Cellular Transport

Overexpression of the transmembrane efflux pump that excretes compounds from cells could diminish the intracellular amount of tamoxifen present.

## Differential Metabolism

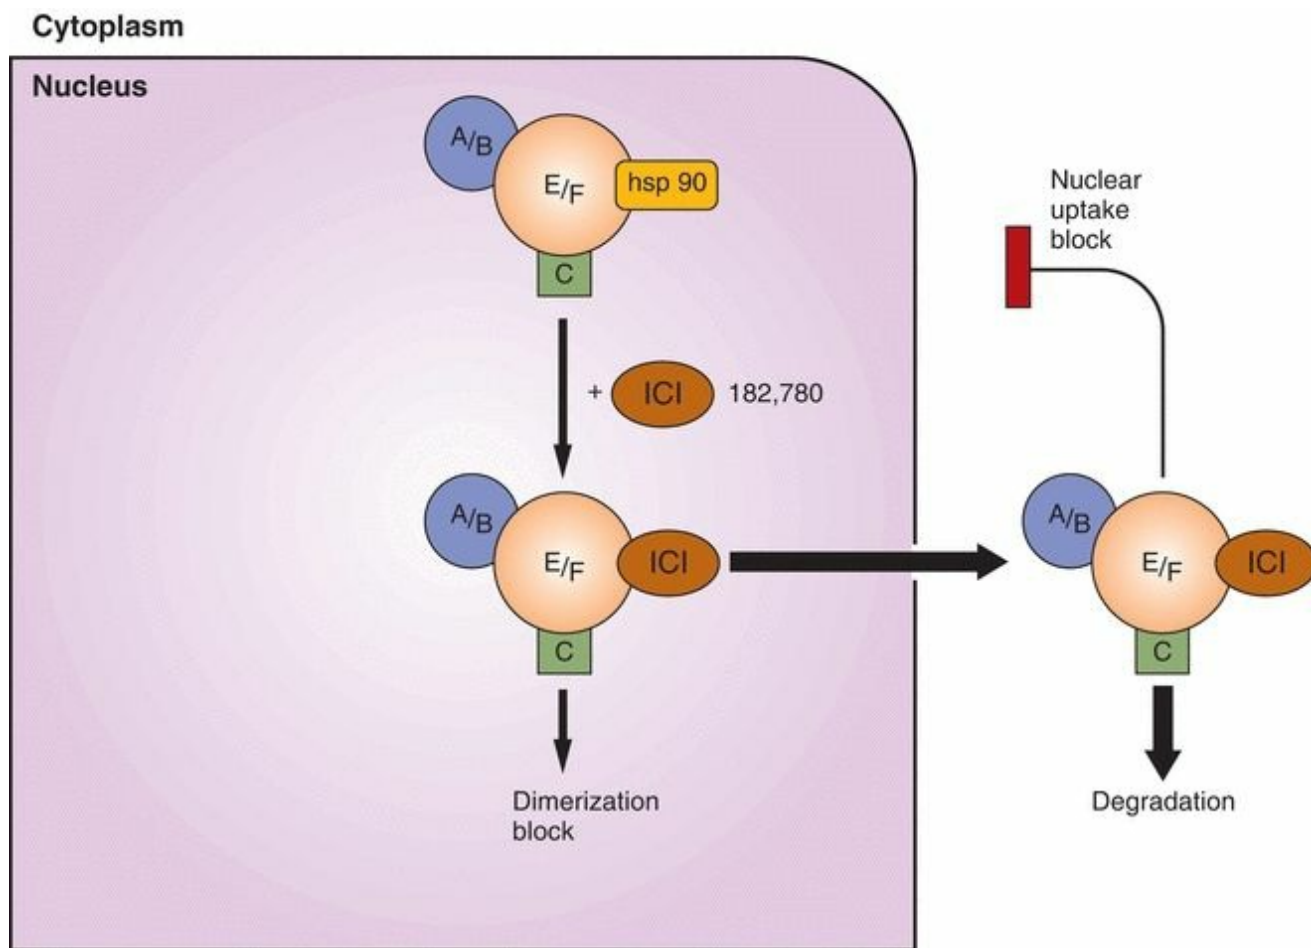

Changes in pharmacology and metabolism of tamoxifen might occur so that cells acquire the ability to metabolize the antagonist to greater agonist activity. Some breast cancer patients develop tumors that regress when tamoxifen is withdrawn. However, estrogenic metabolites of tamoxifen have not been identified.

Tamoxifen resistance occurs because essentially, the estrogen receptor is not the dominant mechanism involved in the growth of these cells. Evidence supports growth factor stimulation and kinase phosphorylation as the predominant systems in tamoxifen-resistant cells. These cells are hypersensitive to estrogen and respond to tamoxifen as an agonist.<sup>161</sup>

Randomized trials have demonstrated the superiority of aromatase inhibitors compared with tamoxifen for the treatment of hormone-sensitive early breast cancer. This includes better disease-free survival, a reduction in new contralateral primary tumors, and an increased time to recurrence. Because of this superiority, the standard has shifted from tamoxifen to aromatase inhibitors for postmenopausal women with ER+ breast cancer (as discussed in [Chapter 16](#)). Nevertheless, tamoxifen made a major contribution to the molecular understanding of hormonal action.

# The Pure Antiestrogens

The pure antiestrogens are derivatives of estradiol with long hydrophobic side chains at the 7 position (Figure 1.24). Binding with the pure antiestrogens prevents DNA binding. Because the site responsible for dimerization overlaps with the hormone-binding site, it is believed that pure antiestrogens sterically interfere with dimerization and thus inhibit DNA binding. In addition, these compounds increase the cellular turnover of estrogen receptor, and this action contributes to its antiestrogen effectiveness. One such antiestrogen, fulvestrant (ICI 182, 780), is used to treat metastatic breast cancer that has failed to respond to the usual endocrine therapy.<sup>162</sup> The estrogen receptor combined with fulvestrant is immobilized in the cell and rapidly undergoes degradation.<sup>163,164</sup> The half-life of the estrogen receptor when occupied with estradiol is about 5 hours; when occupied with a pure antiestrogen, it is less than 1 hour (Figure 1.27).

**FIGURE 1.27**

# **Estrogen Agonists/Antagonists (Also Known as Selective Estrogen Receptor Modulators, SERMs)**

This class of synthetic compounds is characterized by a fundamental principle: the conformational shape produced after binding to the receptor results in modified action, influenced by the cellular context of adapter (regulating) proteins and which of these proteins are selected. Tamoxifen rightfully belongs to this family, and its use stimulated the pursuit of a related drug that would not stimulate the endometrium. Agents such as raloxifene and lasofoxifene have antiestrogenic activity in the uterus as well as in the breast and at the same time exert agonistic effects in certain target tissues.<sup>136</sup> Raloxifene inhibits bone resorption and improves lipids (although there is no effect on HDL cholesterol). By virtue of variations in conformational changes in the drug-receptor complex and the cellular context of specific tissues, drugs such as these can be developed to produce beneficial effects in certain target systems (such as bone) and to avoid unwanted actions (such as endometrial stimulation). The unique conformational shape raloxifene produces when it binds to the estrogen receptor prevents the involvement of a required coactivator protein at the AF-2 site. In target tissues that respond principally to AF-2 gene transcription, these agents will lack estrogenic activity; however, in tissues with the appropriate cellular context of proteins, estrogenic gene transcription can occur through the AF-1 mechanism. In tissues that respond principally to the estrogen receptor- $\beta$  that lacks AF-1 activity or when target tissues lack coactivating proteins that interact with AF-1, these agents will be pure estrogen antagonists.

# Antiprogestins

Both progesterone and the antiprogestins, such as mifepristone (RU-486) and onapristone, form hormone-responsive element-receptor complexes that are similar, but the antiprogestin complex has a slightly different conformational change (in the hormone-binding domain) that prevents full gene activation.<sup>165</sup> RU-486 has some agonistic activity due to its ability to activate certain, but not all, of the transcription activation functions on the progesterone receptor; the final biologic response is modulated by the target tissue context of coactivators and corepressors.<sup>166</sup> While mifepristone is best known for its abortifacient activity, the combination of its agonistic and antagonistic actions can be exploited for many uses, including contraception, medical treatment of endometriosis, induction of labor, treatment of Cushing syndrome, and, potentially, treatment of various cancers.

The search for inhibitors of progesterone binding began many years ago, in the late 1960s, but it wasn't until the early 1980s that mifepristone, the first successful antiprogestin, was produced by scientists at Roussel Uclaf, a pharmaceutical company in Paris. Mifepristone is a 19-nortestosterone derivative. The dimethyl (dimethylaminophenyl) side chain at carbon 11 is the principal factor in its antiprogestone action. Three major characteristics of its action are important: a long half-life, high affinity for the progesterone receptor, and active metabolites.

The affinity of mifepristone for the progesterone receptor is five times greater than that of the natural hormone. In the absence of progesterone, it can produce an agonistic (progesterone) effect. It does not bind to the estrogen receptor, but it can act as a weak antiandrogen because of its low-affinity binding to the androgen receptor. Mifepristone also binds to the glucocorticoid receptor, but higher doses are required to produce effects. The binding affinity of mifepristone and its metabolites for the glucocorticoid receptor is very, very high. The reason why it takes such a high dose to produce an effect via this receptor is because the circulating level of cortisol is so high, 1,000-fold higher than progesterone. These receptor-binding properties allow titration of clinical effects by adjustments of dose.

Both progesterone and mifepristone induce conformational changes with the progesterone receptor, especially in the hormone-binding domain.<sup>167,168</sup> Thus, the antiprogestin not only competes with progesterone for the progesterone receptor, but after binding to the hormone-binding domain, the receptor structure is altered in such a way that the transcription activity of the B progesterone receptor is inhibited. In cells where the A progesterone receptor is expressed, antiprogestin binding stimulates A receptor-induced inhibition of transcription activity for all steroid hormone receptors (this would explain the antiestrogen activity of mifepristone).

Another clinically useful progesterone receptor modulator is ulipristal acetate. Through its primarily antiprogestogenic action, it is useful as an emergency contraceptive agent (by delaying ovulation and, likely, by altering endometrial receptivity) and for the management of symptomatic leiomyomata. Like mifepristone, ulipristal acetate binds to glucocorticoid and androgen receptors at high dose concentrations.

# Androgen Antagonists

The two most commonly used androgen antagonists are cyproterone acetate and spironolactone. Cyproterone and spironolactone bind to the androgen receptor and exert mixed agonism-antagonism. In the presence of significant levels of androgens, the antagonism predominates, and these agents are effective for the treatment of hirsutism. Flutamide is a nonsteroidal pure antiandrogen, effectively blocking androgenic action at target sites by competitive inhibition.

# OTHER MECHANISMS OF HORMONE ACTION

---

Central to the regulation of steroid hormone synthesis and release are the actions of the tropic hormones. Tropic hormones include the releasing hormones originating in the hypothalamus and a variety of peptides and glycoproteins secreted by the anterior pituitary gland and placenta. To understand their mechanisms of action, it is important to first consider the general ways in which nonsteroid hormones can activate receptors.

The many different types of receptors can be organized into the following basic categories.

# **G Protein Receptors**

These receptors are composed of a single polypeptide chain that spans the cell membrane. Binding to a specific hormone leads to interaction with G proteins that, in turn, activate second messengers. Examples include receptors for tropic hormones, prostaglandins, light, and odors. The second messengers include the adenylate cyclase enzyme and the phospholipase system.

# **Ion Gate Channels**

These cell surface receptors are composed of multiple units that, after binding, open ion channels. The influx of ions changes the electrical activity of the cells. One example of this type is the nicotinic acetylcholine receptor.

# **Receptors with Intrinsic Enzyme Activity**

These transmembrane receptors have an intracellular component with tyrosine or serine kinase activity. Binding leads to receptor autophosphorylation and activity. Examples include the receptors for insulin and growth factors (tyrosine kinase) and the receptors for activin and inhibin (serine kinase).

# **The System of Internalization**

Receptors that do not fit the above categories include the receptors for LDL, prolactin, growth hormone, and some of the growth factors. These receptors allow entry of their ligands into cells by the process of endocytosis (discussed later in this chapter).

# MECHANISM OF ACTION FOR TROPIC HORMONES

---

The specificity of tropic hormones depends on the presence of a receptor in the cell membrane of the target tissue. Tropic hormones do not enter the cell to stimulate physiologic events but unite with a receptor on the surface of the cell.

The receptor protein in the cell membrane can act as the active agent and, after binding, operate as an ion channel or function as an enzyme, as described in the general mechanisms above. Alternatively, the receptor protein is coupled to an active agent, an intracellular messenger. The major intracellular messenger molecules are cyclic AMP, inositol 1,4,5-triphosphate (IP<sub>3</sub>), 1,2-diacylglycerol (1,2-DG), calcium ion, and cyclic guanosine 3',5'-monophosphate (cyclic GMP). Because G protein receptors play a large role, it is worth taking a closer look at their general structure and function.

# The G Protein System

The 1994 Nobel Prize in Medicine and Physiology was awarded to Alfred G. Gilman and Martin Rodbell for the discovery and description of G proteins. Adenylate cyclase is composed of three protein units: the receptor, a guanyl nucleotide regulatory unit, and a catalytic unit.<sup>169</sup> The regulatory unit is a coupling protein, regulated by guanine nucleotides (specifically guanosine 5'-triphosphate, GTP), and therefore it is called GTP-binding protein or G protein for short.<sup>170,171</sup> The catalytic unit is the enzyme itself that converts ATP to cyclic AMP. The receptor and the nucleotide regulatory unit are structurally linked, but inactive until the hormone binds to the receptor. Upon binding, the complex of hormone, receptor, and nucleotide regulatory unit is activated leading to an uptake of GTP by the regulatory unit. The activation and uptake of GTP result in an active enzyme that can convert ATP to cyclic AMP. This result can be viewed as the outcome of the regulatory unit **coupling** with the catalytic unit, forming an intact complete enzyme. Enzyme activity is then terminated by hydrolysis of the GTP to guanosine 5'-diphosphate (GDP) returning the enzyme to its inactive state. Quick action and acute control of adenylate cyclase are assured because the G protein is a GTPase that self-activates upon binding of GTP.

The G protein has been purified. From the amino acid sequence, complementary DNA clones have been produced. These studies have indicated that a family of G proteins exists that couples receptors to active ligands, playing roles in signal transduction, intracellular transport, and exocytosis. The ability of the hormone-receptor complex to work through a common messenger (cyclic AMP) and produce contrasting actions (stimulation and inhibition) is thought to be due to the presence of both stimulatory nucleotide regulatory G proteins and inhibitory nucleotide regulatory G proteins (**Figures 1.28** and **1.29**).<sup>172,173</sup> However, the G protein system is not limited to the cyclic AMP signal, but can activate other messenger-generating enzymes, as well as ion channels.

**FIGURE 1.28**

## FIGURE 1.29

The G proteins are composed of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -subunits, each the product of many distinct genes.<sup>174</sup> The  $\beta$ - and  $\gamma$ -subunits are not all alike, and they exhibit selectivity for specific ligands. Indeed, there are several hundred G protein receptors, with a common structure but sufficiently dissimilar to be activated by different ligands. Each G protein has a unique  $\alpha$ -subunit, and there are 16 mammalian  $\alpha$ -subunit genes. Based on amino acid similarities, they are grouped into four subfamilies:  $G_s\alpha$ ,  $G_q\alpha$ ,  $G_i\alpha$ , and  $G_{12}$ .  $G_s$  and  $G_q$  proteins mediate stimulatory events such as hormone secretion, whereas  $G_i$  proteins exert inhibition. The role of the  $G_{12}$  group is not yet certain. These multiple subunits allow great variability in function to be expressed by many different combinations that produce conformational changes linked to message transmission.

In the inactive state, GDP is bound to the  $\alpha$ -subunit. Hormone-receptor interaction and binding change the  $\alpha$ -subunit conformation. GTP replaces GDP on the  $\alpha$ -subunit, freeing the  $\beta$ - and  $\gamma$ -subunits, which allows the GTP  $\alpha$ -subunit to bind to the catalytic unit of adenylate cyclase, forming the active enzyme. The GTP  $\alpha$ -subunit can also activate other messengers, such as ion channels. Intrinsic GTPase activity quickly hydrolyzes the GTP- $\alpha$  to GDP- $\alpha$ , which leads to reassociation with the  $\beta$ - and  $\gamma$ -subunits, reforming the G protein complex for further activation. The functional specificity is due to the  $\alpha$ -subunit, which differs for each G protein, and therefore there are many different  $\alpha$ -subunits encoded by different genes.

# The G Protein Receptors

The more than 200 receptors linked to G proteins are derived from a supergene family; the 800 genes presumably originated from a common ancestral gene.<sup>175</sup> The gonadotropin receptor contains a transmembrane region that has the structural features of a receptor that couples with G protein and a large extracellular domain.<sup>176</sup> Receptors that utilize the G proteins are inserted in membranes and consist of a long polypeptide chain that folds into seven helices; the amino acid loops that connect the helices extend either into the cytoplasm or into the extracellular space. The amino end extends outside the cell, and the carboxyl end extends into the cell. The large extracellular segment is the site for specific gonadotropin recognition and binding. Binding changes the conformation (which is associated with phosphorylation), leading to interaction with the G proteins, which in turn activate second messengers, either enzymes or ion channels. These are ancient proteins; for example, they are used by yeast to detect mating pheromones (perhaps, this is why this protein is the basic structure for sight and smell in higher organisms; rhodopsin is a G protein located in the light-sensitive rod of the retina). Thus, the G receptors can be activated by hormones, neurotransmitters, growth factors, odorants, and photons of light.

LH and hCG bind to a common receptor, encoded by genes on chromosome 2p21. The LH/hCG receptor is highly conserved in mammals; the human receptor is very similar to that of rat and bovine receptors.<sup>177</sup> It is likely that expression of the LH/hCG receptor is regulated by many factors, including endocrine, paracrine, and autocrine mechanisms, but the primary requirement is FSH. In addition to the G protein pathway, activation of the LH/hCG receptor stimulates the calcium messenger system.

The receptor for FSH is very similar to the LH/hCG receptor, but it is structurally distinct.<sup>178,179</sup> Appropriately (for specificity), the extracellular segment contains the major sequence divergence. The FSH receptor gene is located on chromosome 2p21–16, near the LH/hCG receptor gene. The FSH receptor is also regulated by its hormone environment, especially by FSH and estradiol. Other members of this family include receptors for thyroid-stimulating hormone (TSH), catecholamines, vasopressin, angiotensin II, and dopamine.

# Mutations in the G Protein System

Rare mutations that alter the structure and activity of G proteins can result in disease.<sup>171,174,180,181,182,183</sup> Loss of function mutations of a G protein or a given receptor will result in hormone deficiency syndromes, for example, the TSH receptor and hypothyroidism, the LH receptor and male pseudohermaphroditism, and pseudohypoparathyroidism due to a  $G_s\alpha$  mutation. Activation of gonadotropin-releasing hormone (GnRH) at puberty is mediated by kisspeptin 1, a ligand that binds to its G protein receptor on GnRH neurons; an inactivating mutation in this receptor causes hypogonadism and delayed or absent puberty. Mutations in the G protein receptor for GnRH have been identified that are responsible for familial hypogonadism. The McCune-Albright syndrome (sexual precocity, polyostotic fibrous dysplasia, café au lait skin pigmentation, and autonomous functioning of various endocrine glands) is due to unregulated activity (gain in function) of the adenylate cyclase system because of a mutation in the  $G_s\alpha$  gene.  $G_s\alpha$  protein mutations have also been found in adrenal and ovarian tumors, growth hormone–secreting pituitary adenomas, and thyroid adenomas. It is possible that alterations in the G protein system may ultimately explain abnormalities in endocrine-metabolic functions, as well as oncogenic mutations.<sup>172,173,184</sup>

Besides mutations, altered G protein receptor function can be due to polymorphisms, slight genetic changes that can be associated with altered physiology or disease. Single nucleotide polymorphisms (SNPs) associated with these receptors are being identified, and correlations are being made with risks and outcomes for diseases.<sup>185</sup> This is an avenue of genetic research that is bound to reveal explanations for some instances of infertility or problems of sexual differentiation (Table 1.4).

## TABLE 1.4 Some Genetic Diseases Due to Specific G-Protein System Mutations

<b>Mutation</b>	<b>Disorder</b>
Activating LH receptor	Precocious puberty in boys
Inactivating LH receptor	Male pseudohermaphroditism
Activating FSH receptor	Ovarian hyperstimulation
Inactivating FSH receptor	Premature ovarian failure
Inactivating TRH receptor	Hypothyroidism
G <sub>s</sub> a (stimulatory)	McCune-Albright syndrome
G <sub>i</sub> a (inhibitory)	Hypothyroidism
Rhodopsin	Retinitis pigmentosa
Activating vasopressin receptor	Diabetes insipidus

# The Cyclic AMP Mechanism

Cyclic AMP is the intracellular messenger for FSH, LH, human chorionic gonadotropin (hCG), TSH, and ACTH. Union of a tropic hormone with its cell membrane G protein receptor activates the adenylate cyclase enzyme within the cell membrane leading to the conversion of adenosine 5'-triphosphate (ATP) within the cell to cyclic AMP. Specificity of action and/or intensity of stimulation can be altered by changes in the structure or concentration of the receptor at the cell membrane-binding site. In addition to changes in biologic activity due to target cell alterations, changes in the molecular structure of the tropic hormone can interfere with cellular binding and physiologic activity.

The cell's mechanism for sensing the low concentrations of circulating tropic hormone is to have an extremely large number of receptors but to require only a very small percentage (as little as 1%) to be occupied by the tropic hormone. The cyclic AMP released is specifically bound to a cytoplasm receptor protein, and this cyclic AMP-receptor protein complex activates a protein kinase. The protein kinase is present in an inactive form as a tetramer containing two regulatory subunits and two catalytic subunits. Binding of cyclic AMP to the regulatory subunits releases the catalytic subunits, with the regulatory subunits remaining as a dimer. The catalytic subunits catalyze the phosphorylation of serine and threonine residues of cellular proteins such as enzymes and mitochondrial, microsomal, and chromatin proteins. The physiologic event follows this cyclic AMP-mediated energy-producing event. Cyclic AMP is then degraded by the enzyme phosphodiesterase into the inactive compound, 5'-AMP.

Most noteworthy, the genome contains responsive elements that bind proteins phosphorylated by the catalytic units, thus leading to activation of gene transcription. The **cyclic AMP-responsive element (CRE)** functions as an enhancer element upstream from a gene's transcription start site.<sup>186</sup> A large family of transcription factors interact with the CRE, creating an important regulatory unit for gene transcription. Cyclic AMP activates a specific transcription factor, cyclic AMP regulatory element-binding protein (CREB); the binding of CREB to CRE activates many genes. This system can also involve DNA sequences upstream from the CRE site.

The cyclic AMP system can be regarded as an example of evolutionary conservation. Rather than developing new regulatory systems, certain critical regulators have been preserved from bacteria to mammals. How is it that a single intracellular mediator can regulate different events? This is accomplished by turning on different biochemical processes governed by the different gene expression in individual cells. In addition, the adenylate cyclase enzyme exists in several isoforms, which respond either with stimulation or inhibition to various systems and agents.<sup>187</sup>

The cyclic AMP system provides a method for amplification of the faint hormonal signal swimming in the sea of the bloodstream. Each cyclase molecule produces a lot of cyclic AMP; the protein kinases activate a large number of molecules that in turn lead to an even greater number of products. This is an important part of the sensitivity of the endocrine system, a major reason why only a small percentage of the cell membrane receptors need be occupied in order to generate a response.

Prostaglandins stimulate adenylate cyclase activity and cyclic AMP accumulation. Despite the effect on adenylate cyclase, prostaglandins appear to be synthesized after the action of cyclic AMP. This implies that tropic hormone stimulation of cyclic AMP occurs first; cyclic AMP then activates prostaglandin synthesis, and, finally, intracellular prostaglandin moves to the cell membrane to facilitate the response to the tropic hormone. In addition to actions mediated by cyclic AMP, prostaglandins can also operate through changes in intracellular concentrations of calcium.

Prostaglandins and cyclic GMP can participate in an intracellular negative feedback mechanism governing the degree of, or direction of, cellular activity (e.g., the extent of steroidogenesis or shutting off of steroidogenesis after a peak of activity is reached). In other words, the level of cellular function can be determined by the interaction among prostaglandins, cyclic AMP, and cyclic GMP.

There are differences among the tropic hormones. Oxytocin, insulin, growth hormone, prolactin, and human placental lactogen (hPL) do not utilize the adenylate cyclase mechanism. Receptors for prolactin, growth hormone, and a number of cytokines (including erythropoietin and interleukins) belong to a single transmembrane domain receptor family.<sup>188</sup> Studies of this receptor family indicate that prolactin operates through various signal transduction mechanisms, including ion channels and nuclear kinase activation.

# The Calcium Messenger System

The intracellular calcium concentration is a regulator of both cyclic AMP and cyclic GMP levels.<sup>189</sup> Activation of the surface receptor either opens a channel in the cell membrane that lets calcium ions into the cell, or calcium is released from internal stores (the latter is especially the case in muscle). This calcium flux is an important intracellular mediator of response to hormones, functioning itself as a second messenger in the nervous system and in muscle.

The calcium messenger system is linked to hormone-receptor function by means of a specific enzyme, phospholipase C, which catalyzes the hydrolysis of polyphosphatidylinositols, specific phospholipids in the cell membrane. Activation of this enzyme by hormone binding to its receptor leads to the generation of two intracellular messengers, inositol triphosphate ( $IP_3$ ) and diacylglycerol (DAG), which initiate the function of the two parts of the calcium system. The first part is a calcium-activated protein kinase, responsible for sustained cellular responses, and the second part involves a regulator called calmodulin, responsible for acute responses. These responses are secondary to alterations in enzyme activity, especially protein kinases and transcription factors.

Calmodulin has been identified in all animal and plant cells that have been examined. Therefore, it is a very ancient protein. It is a single polypeptide chain of 148 amino acid residues whose sequence and structural and functional properties are similar to those of troponin C, the substance that binds calcium during muscle contractions, facilitating the interaction between actin and myosin. The calmodulin molecule has four calcium-binding sites, and binding with calcium gives a helical conformation, which is necessary for biologic activity (**Figure 1.30**). A typical animal cell contains more than 10 million molecules of calmodulin, constituting about 1% of the total cell protein. As a calcium regulatory protein, it serves as an intracellular calcium receptor and modifies calcium transport, enzyme activity, the calcium regulation of cyclic nucleotide and glycogen metabolism, and such processes as secretion and cell motility. Thus, calmodulin serves a role analogous to that of troponin C while mediating calcium's actions in noncontractile tissues, and cyclic AMP works together with calcium and calmodulin in the regulation of intracellular metabolic activity.

**FIGURE 1.30**

GnRH is one example of a receptor that is calcium dependent in its mechanism of action, utilizing IP<sub>3</sub> and 1,2-DG as second messengers to stimulate protein kinase activity.<sup>190</sup> These responses require a G protein and are associated with cyclical release of calcium ions from intracellular stores and the opening of cell membrane channels to allow entry of extracellular calcium.

# Kinase Receptors

The cell membrane receptors of insulin, insulin-like growth factor, EGF, platelet-derived growth factor, and FGF are tyrosine kinases. All tyrosine kinase receptors have a similar structure: an extracellular domain for ligand binding, a single transmembrane domain, and a cytoplasmic domain (**Figure 1.31**). The unique amino acid sequences determine a three-dimensional conformation that provides ligand specificity. The transmembrane domains are not highly conserved (thus differing in makeup). The cytoplasmic domains respond to ligand binding by undergoing conformational changes and autophosphorylation. The structure of the receptors for insulin and insulin-like growth factor is more complicated, with two  $\alpha$ - and two  $\beta$ -subunits, forming two transmembrane domains connected extracellularly by disulfide bridges. The receptors for the important autocrine and paracrine factors, activin and inhibin, function as serine-specific protein kinases.

### Insulin and Type I IGF Receptors Have a Similar Structure

**FIGURE 1.31**

Kinase activation requires distinctive sequences; thus, there is considerable homology among the kinase receptors in the cytoplasmic domain. Many of the substrates for these kinases are the enzymes and proteins in other messenger systems, for example, the calcium messenger system. Thus, the kinase receptors can cross-talk with other receptor-regulated systems that involve the G proteins.

# **REGULATION OF TROPIC HORMONE ACTION**

---

Modulation of the peptide hormone mechanism is an important biologic system for enhancing or reducing target tissue response. **The regulation of tropic hormone action can be divided into four major components:**

- 1. Autocrine and paracrine regulation factors**
- 2. Heterogeneity of tropic hormones**
- 3. Up- and down-regulation of receptors**
- 4. Regulation of adenylate cyclase**

# Autocrine and Paracrine Regulation Factors

Growth factors are polypeptides that modulate activity either in the cells in which they are produced or in nearby cells; hence, they are autocrine and paracrine regulators. Regulation factors of this type (yet another biologic family) are produced by local gene expression and protein translation, and they operate by binding to cell membrane receptors. The receptors usually contain an intracellular component with tyrosine kinase activity that is energized by a binding-induced conformational change that induces autophosphorylation. However, some factors work through other second messenger systems, such as cyclic AMP or IP<sub>3</sub>. Growth factors are involved in a variety of tissue functions, including mitogenesis, tissue and cellular differentiation, chemotactic actions, and angiogenesis. The growth factors involved in reproductive physiology include activin, inhibin, antimüllerian hormone (AMH), IGF-I, IGF-II, TGF- $\beta$ , FGF, and EGF.

In addition to the growth factors, various immune factors, especially cytokines, modulate ovarian steroidogenesis. These factors, including interleukin-1, tumor necrosis factor, and interferon, are found in human follicular fluid and, in general, inhibit gonadotropin stimulation of steroidogenesis.

For mitogenesis to occur, cells may require exposure to a sequence of growth factors, with important limitations in duration and concentrations. Growth factors are important for the direction of embryonic and fetal growth and development. In cellular differentiation, growth factors can operate in a cooperative, competitive, or synergistic fashion with other hormones. For example, IGF-I plus FSH, but not IGF-I alone, increases the number of LH receptors, progesterone synthesis, and aromatase activity in granulosa cells.<sup>191</sup>

Activin and inhibin are disulfide-linked dimers composed of peptide subunits (one  $\alpha$ -subunit and two  $\beta$ -subunits) as shown in [Table 1.5](#).<sup>192</sup>

## TABLE 1.5 Peptide Subunits

Each of the subunits is encoded by separate genes that produce precursor proteins that are cleaved to form the subunits. In addition, the free subunits and related monomeric products can be secreted. Despite the structural similarity between activin and inhibin, they function as antagonists in some systems (e.g., activin stimulates and inhibin inhibits FSH secretion). Activins, inhibins, and TGF- $\beta$  come from the same gene family, which also includes AMH. The activity of activin is regulated by protein binding, specifically to follistatin. Follistatin is a single-chain glycosylated peptide, structurally unrelated to inhibin and activin, that regulates the activin-inhibin system. Signaling by this family of peptides is accomplished by several receptor isoforms that are transmembrane serine kinases.

TGF- $\beta$  can either stimulate or inhibit growth and differentiation, depending on the target cell and the presence or absence of other growth factors. In the ovary, TGF- $\beta$  promotes granulosa cell differentiation by enhancing the actions of FSH (especially in expression of FSH and LH receptors) and antagonizing the down-regulation of FSH receptors. TGF- $\beta$  and the insulin-like growth factors are required for the maintenance of normal bone mass. EGF is a structural analog of TGF- $\alpha$  and is involved in mitogenesis. In the ovary, EGF, secreted by theca cells, is important for granulosa cell proliferation, an action opposed by TGF- $\beta$  (which is also secreted by the theca cells). The most potent mitogens are the two forms of FGF. Additional roles for FGF, secreted by the granulosa, include modulation of enzyme activity involved in the physical act of ovulation and angiogenic function during the development of the corpus luteum.

## The Insulin-Like Growth Factors

The insulin-like growth factors (called somatomedins in the past) are single-chain polypeptides that resemble insulin in structure and function.<sup>191</sup> These factors are widespread and are involved in growth and differentiation in response to growth

hormone and as local regulators of cell metabolism. IGF-II is more prominent during embryogenesis, whereas IGF-I is more active postnatally. Only the liver produces more IGF-I than the ovary. According to animal studies, both IGF-I and IGF-II are secreted by granulosa cells. IGF-I amplifies the action of gonadotropins and coordinates the functions of theca and granulosa cells. IGF-I receptors on the granulosa are increased by FSH and LH and augmented by estrogen. In the theca, IGF-I increases steroidogenesis. In the granulosa, IGF-I is important for the formation and increase in numbers of FSH and LH receptors, steroidogenesis, the secretion of inhibin, and oocyte maturation. It should be noted that the endogenous insulin-like growth factor in the human ovarian follicle is IGF-II in both the granulosa and the theca cells.<sup>193</sup> Studies indicating activity of IGF-I with human ovarian tissue can be explained by the fact that both IGF-I and IGF-II activities can be mediated by the type I IGF receptor that is structurally similar to the insulin receptor.

Granulosa cells also contain receptors for insulin, and insulin can bind to the IGF-I receptor. The IGF-I receptor is a heterotetramer with two  $\alpha$ - and two  $\beta$ -subunits in a structure similar to that of the insulin receptor. Insulin can bind to the  $\alpha$ -subunit ligand-binding domain and activate the  $\beta$ -subunit, which is a protein kinase. Thus, insulin can modulate ovarian cellular functions either through its own receptor or through the IGF-I receptor.

The biologic potency and availability of the insulin-like growth factors are further modulated by a collection of IGF-binding proteins that bind circulating insulin-like growth factors and also alter cellular responsiveness. Six insulin-like growth factor-binding proteins (IGFBP-1 through IGFBP-6) have been detected in serum and various tissues.<sup>194</sup> IGF-I and IGF-II circulate in the blood in a concentration 1,000 times greater than insulin; however, largely all of the circulating IGFs are bound to IGFBPs. The multiple IGFBPs and their proteases provide a mechanism for tissue-specific activities of IGFs. The various IGFBPs differ in their actions and individual expression, depending on the specific cell type and tissue. The principal IGFBP that regulates IGF biologic availability can vary according to metabolic changes. There are many possible permutations because the IGFBPs are not simply transport proteins; there are inhibitory and stimulatory IGFBPs that inhibit or potentiate IGF actions. Tissue-specific regulation of IGFBP protease activity can change the bioavailability of IGFs at specific sites. In addition, the IGFBPs have been demonstrated to have direct effects of their own, independent of IGF. Therefore, this is a complex regulatory system that provides both endocrine signals and autocrine and paracrine functions.

# Receptors Involved in Steroidogenesis

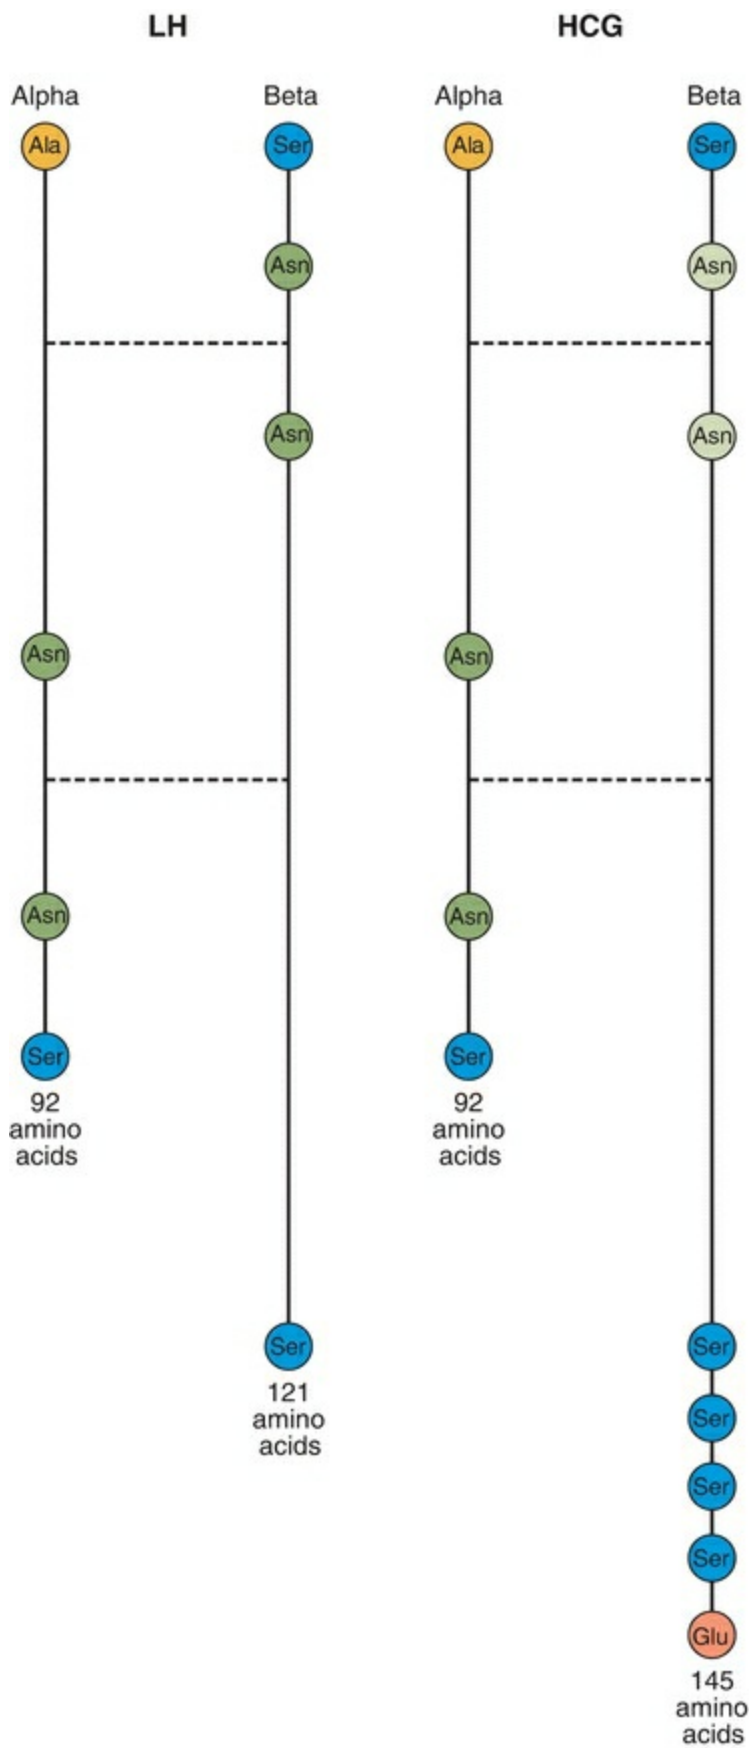

Steroidogenic factor-1 (SF-1) and DAX-1 (a name that represents Dosage-sensitive sex reversal-Adrenal hypoplasia congenita critical region on the X chromosome) are nuclear receptors for which specific ligands have not been identified (“orphan receptors”). SF-1 influences the expression of genes that encode steroidogenic enzymes, and when genetic expression of SF-1 is disrupted in mice, gonads and adrenal glands fail to develop.<sup>195,196</sup> In addition, SF-1 regulates transcription of the StAR gene.<sup>197</sup> Partial loss of SF-1 causes reduced ovarian activity and infertility.<sup>198</sup> Inactivating mutations in the DAX1 gene result in X-linked adrenal hypoplasia, which is also associated with hypogonadotropic hypogonadism.<sup>199</sup> DAX-1 is believed to work with SF-1 in regulating development and function of steroid-producing tissues as well as the regulation of gonadotropins.<sup>200</sup> SF-1 regulates genes that encode the gonadotropin subunits, as well as the GnRH receptor.<sup>196</sup> Thus, SF-1 and DAX-1 are involved at all levels: the hypothalamus, the pituitary, and the steroid-producing organs. These proteins function as transcription factors (as are the traditional nuclear hormone receptors such as the estrogen receptor) in the complex mechanisms being unraveled by molecular biologists.

# Heterogeneity of Tropic Hormones

The glycoproteins, such as FSH and LH, are not single proteins but should be viewed as a family of heterogeneous forms of varying immunologic and biologic activity.<sup>201</sup> The various forms (isoforms) arise in various ways, including different DNA promoter actions, alterations in RNA splicing, point mutations, and posttranslational carbohydrate changes.<sup>202</sup> The impact of the variations is to alter structure and metabolic clearance, thus affecting binding and activity. The isoforms have different molecular weights, circulating half-lives, and biologic activities. Throughout the menstrual cycle, the amazing number of at least 20–30 isoforms of both FSH and LH are present in the bloodstream.<sup>203</sup> **The overall activity of a glycoprotein, therefore, is due to the effects of the mixture of forms that reach and bind to the target tissue.**

The nonglycosylated subunit precursors of glycoprotein hormones are synthesized in the endoplasmic reticulum, followed by glycosylation. The glycosylated subunits combine and then are transported to the Golgi apparatus for further processing of the carbohydrate component. The units combine to form a compact heterodimer. The protein moiety binds to specific target tissue receptors, whereas the carbohydrate moiety plays a critical role in coupling the hormone-receptor complex to adenylate cyclase (perhaps by determining the necessary conformational structure).

The preciseness of the chemical makeup of the tropic hormones is an essential element in determining the ability of the hormone to mate with its receptor. The glycopeptides (FSH, LH, TSH, and hCG) are dimers composed of two glycosylated polypeptide subunits, the  $\alpha$ - and  $\beta$ -subunits. The  $\alpha$ - and  $\beta$ -subunits are tightly bound in a noncovalent association. The three-dimensional structure and the active conformation of the subunits are maintained by internal disulfide bonds.<sup>204</sup> All of the glycopeptides of the human species (FSH, LH, TSH, and hCG) share a common  $\alpha$ -chain, an identical structure containing 92 amino acids. The  $\beta$ -chains (or the  $\beta$ -subunits) differ in both amino acid and carbohydrate content, conferring the specificity inherent in the relationship between hormones and their receptors (**Figure 1.32**). Therefore, the specific biologic activity of a glycopeptide hormone is determined by the  $\beta$ -subunit; hypogonadism has been reported due to single amino acid substitution in the LH  $\beta$ -subunit.<sup>205</sup>

**FIGURE 1.32**

$\beta$ -hCG is the largest  $\beta$ -subunit, containing a larger carbohydrate moiety and 145 amino acid residues, including a unique carboxyl-terminal tail piece of 29 amino acid groups. It is this unique part of the hCG structure that allows the production of highly specific antibodies and the utilization of very specific immunologic assays. The extended sequence in the carboxyl-terminal region of  $\beta$ -hCG contains four sites for glycosylation (**Figure 1.32**); thus, hCG is glycosylated to a greater extent than LH, a difference that is responsible for the longer circulating half-life for hCG.

These differences in structure are associated with a different promoter and transcriptional site that is located upstream in the hCG  $\beta$ -subunit gene compared with the site in the LH  $\beta$ -subunit gene. The hCG  $\beta$ -subunit gene transcription site does not contain a hormone response element, allowing hCG secretion to escape feedback regulation by the sex steroids, in contrast to FSH and LH.

The rate-limiting step in the synthesis of gonadotropins and TSH is the availability of  $\beta$ -subunits, because excess  $\alpha$ -subunits can be found in blood and in tissue. Furthermore, the three-dimensional structure of the  $\beta$ -subunit, accomplished by folding the subunit by the formation of the disulfide bonds, is an important conformational step that is essential for assembly with the  $\alpha$ -subunit.<sup>206</sup> This conformational change is not completed until the subunits are fully united to produce the final whole hormone.

The half-life of  $\alpha$ -hCG is 6–8 minutes and that of whole hCG from the placenta about 24 hours. All human tissues appear to make hCG as a whole molecule, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving its biologic activity through a long half-life. The carbohydrate components of the glycoproteins are composed of fructose, galactose, mannose, galactosamine, glucosamine, and sialic acid. Although the other sugars are necessary for hormonal function, sialic acid is the critical determinant of biologic half-life. Removal of sialic acid residues in hCG, FSH, and LH leads to very rapid elimination from the circulation.

FSH consists of the  $\alpha$ -subunit of 92 amino acids and a  $\beta$ -subunit of 118 amino acids. It has four carbohydrate side chains, two on each subunit. The  $\beta$ -subunit of LH consists of 121 amino acids. LH has three carbohydrate side chains with a single glycosylation site (with less than half of the sialic acid in FSH). The initial half-life of LH is approximately 20 minutes, compared with the initial half-life of FSH of 3–4 hours.

Genes for tropic hormones contain promoter and enhancer or inhibitor regions located in the 5'-flanking regions upstream from the transcription site. These sites respond to second messengers (cyclic AMP) as well as steroids and other yet unknown regulators. The protein cores of the two glycoprotein subunits are the products of distinct genes.<sup>207</sup> Using recombinant DNA technology, it has been demonstrated that there is a single human gene for the expression of the  $\alpha$ -subunit. The gene for the  $\alpha$ -

subunit shared by FSH, LH, hCG, and TSH is located on chromosome 6q12.21. A single promoter site subject to multiple signals and hormones regulates transcription of the  $\alpha$  gene in both the placenta and pituitary. The  $\alpha$ -subunit gene is expressed in several different cell types, but the  $\beta$ -subunit genes are restricted in cell type. The TSH  $\beta$ -gene is expressed only in thyrotropes regulated by thyroid hormone; the FSH  $\beta$ -gene is expressed in gonadotropes regulated by GnRH, activin, inhibin, and gonadal steroids; the LH  $\beta$ -gene, also expressed in gonadotropes, is regulated by GnRH and unaffected by activin and inhibin<sup>208</sup>.

The  $\alpha$ -subunit gene requires the activation of distinct regulatory elements in thyrotrope and gonadotrope cells, as well as in the placenta. It is the activation of these cell-specific elements that produces tissue specificity for a gene expression. In gonadotropes, the GnRH signaling pathway for a gene transcription utilizes phosphorylase stimulation of diacylglycerol (DAG) and inositol triphosphate (IP<sub>3</sub>) that leads to a release of intracellular calcium stores. GnRH also stimulates the influx of calcium at the cell membrane. DAG, IP<sub>3</sub>, and calcium work together to stimulate protein kinase C activity. Protein kinase regulation of the  $\alpha$ -promoter is a principal part of the overall mechanism. This pituitary process is influenced by multiple factors, including growth factors and gonadal steroids. In the placenta, the mechanism also utilizes specific regulatory elements, but the primary signal is mediated by the cyclic AMP-protein kinase A pathway.

The gene for the FSH  $\beta$ -subunit is on chromosome 11p13. In the pituitary, its expression is markedly influenced by activin.<sup>209,210</sup> Although FSH and LH both require GnRH stimulation, the FSH  $\beta$ -gene is unique in that response to GnRH is dependent on activin.<sup>211</sup> With increasing GnRH stimulation, the role of activin is increasingly repressed by its binding protein, follistatin, the secretion of which is also stimulated by GnRH and activin. Activin is further antagonized by inhibin, the first of these factors recognized to suppress FSH secretion.<sup>212</sup>

The genes that encode for the  $\beta$ -subunits of LH, hCG, and TSH are located in a cluster on chromosome 19q13.32. There are six genes for the  $\beta$ -subunit of hCG, and only one for  $\beta$ -LH.<sup>213</sup> Transcription for the six hCG genes, each with different promoter activity, varies, and it is not certain why hCG requires multigenic expression (perhaps, this is necessary to reach the extremely high level of production in early pregnancy). It is thought that  $\beta$ -hCG evolved relatively recently from  $\beta$ -LH, and the unique amino acid terminal extension of  $\beta$ -hCG arose by a read-through mutation of the translation stop codon in the  $\beta$ -LH gene; the DNA sequences of the  $\beta$ -hCG genes and the  $\beta$ -LH gene are 96% identical.<sup>213</sup> Only primates and the equine species (horse, donkey, and zebra) have been demonstrated to have genes for the  $\beta$ -subunit of chorionic gonadotropin. In contrast to human chorionic gonadotropin, equine chorionic gonadotropin exerts both LH and

FSH activities in many mammalian species because it contains peptide sequences in its  $\beta$ -subunit that are homologous to those in the pituitary gonadotropins of other species. The equine  $\beta$ -chorionic gonadotropin gene is identical to the equine  $\beta$ -LH gene, and although the primate  $\beta$ -hCG gene evolved from the same ancestral  $\beta$ -LH gene, the horse chorionic gonadotropin gene evolved in a different way about 50 million years ago.<sup>214</sup> The  $\beta$ -LH gene is not expressed in the placenta.

A specific immunologic LH variant is relatively common. This variant is due to two point mutations in the LH  $\beta$ -subunit gene and is more common in people of northern European descent, reaching a carrier frequency of 41.9% in Lapps of northern Finland.<sup>215</sup> The clinical significance of this mutation is not known; however, routine immunoassays can provide falsely low readings because this variant is not detected. Inherited disorders because of disruptions in the coding sequences of both LH and FSH are in fact quite rare.<sup>216</sup>

The placenta-specific expression of  $\beta$ -hCG is due to several differences in DNA sequences between the  $\beta$ -hCG and  $\beta$ -LH genes.<sup>208</sup> The cyclic AMP-mediated enhancement of the  $\beta$ -hCG promoter is influenced by several regulatory proteins. The study of the  $\beta$ -subunit genes has been hampered by difficulties in maintaining glycoprotein-producing cell lines. The availability of choriocarcinoma cell lines, however, has allowed greater investigation of the  $\beta$ -hCG genes.

Although the  $\beta$ -subunit specifies the biologic activity of an individual glycoprotein, the combination of the  $\alpha$ - and  $\beta$ -subunits is necessary for full hormonal expression. Furthermore, the  $\alpha$ -subunit also plays an important role in accomplishing normal receptor binding and activation.<sup>217,218</sup> Neither subunit alone can effectively bind to the receptor with high affinity or exert biologic effect. In other words, binding and activation occur only when the hormone is in the combined  $\alpha$ - $\beta$  form. In addition, the  $\alpha$ -subunit influences the overall bioactivity of the glycoprotein hormones.<sup>219</sup> Thus, structural alterations in either the  $\alpha$ -subunit or the  $\beta$ -subunit could alter target tissue responses.

## Variations in Carbohydrate

The glycopeptide hormones can be found in the pituitary existing in a variety of forms, differing in their carbohydrate (oligosaccharides) makeup. The isoform mixture of gonadotropins is influenced both quantitatively and qualitatively by GnRH and the feedback of the steroid hormones, producing posttranslational carbohydrate modifications.<sup>220,221</sup> This heterogeneity in structure (which is also associated with heterogeneity in charge) represents a mechanism under endocrine control that modulates half-lives and bioactivity.

Certain clinical conditions can be associated with alterations in the usual chemical structure of the glycopeptides, resulting in interference with the ability to bind to receptors and stimulate biologic activity. In addition to deglycosylation and the formation of antihormones, gonadotropins can be produced with an increased carbohydrate content. A low-estrogen environment in the pituitary gland, for example, favors the production of the so-called big gonadotropins, gonadotropins with an increased carbohydrate component and, as a result, decreased biologic activity.<sup>222</sup> Immunoassay in these situations may not reveal the biologic situation; an immunoassay sees only a certain set of molecules but not all.

Bioactive levels of FSH and LH are very low in women receiving oral contraceptives and during the luteal and late follicular phases. The highest values are during the midcycle surge and in postmenopausal women (including women with premature ovarian failure).<sup>223</sup> The levels of bioactive FSH parallel those of immunoactive FSH with a constant ratio throughout the cycle. The greater bioactivity of FSH at midcycle is associated with less sialylated, shorter-lived isoforms. These changes are effects of both GnRH and estrogen.

The carbohydrate component, therefore, affects target tissue response in two ways: (1) metabolic clearance and half-life and (2) biologic activity. The circulating half-life of a gonadotropin is mainly proportional to the amount of sialic acid present.<sup>224</sup> The higher content of sialic acid in FSH compared with LH accounts for the more rapid clearance of LH from the circulation (the FSH half-life is several hours; the LH half-life is about 50 minutes). hCG is highly sialylated and, accordingly, has a half-life of 5–6 hours. However, clearance of gonadotropins as measured by half-lives is not explained totally by carbohydrate differences. Differences in amino acid sequences also contribute, and most importantly, the stability of the complete hormone (resisting dissociation into the rapidly cleared subunits) is a major factor.

Biologic activity is determined by both the binding and the activation of the hormone-receptor complex. Experimental data indicate that the carbohydrate chains have no role in the binding of gonadotropins to their receptors.<sup>225</sup> Nevertheless, removal of the carbohydrate moiety of either subunit diminishes gonadotropic activity. Therefore, the carbohydrate component affects the biologic activity of the hormone-receptor complex after binding. Specific studies indicate that the carbohydrate component plays a critical role in activation (coupling) of the adenylate cyclase system.<sup>226</sup>

## **Heterogeneity of Prolactin**

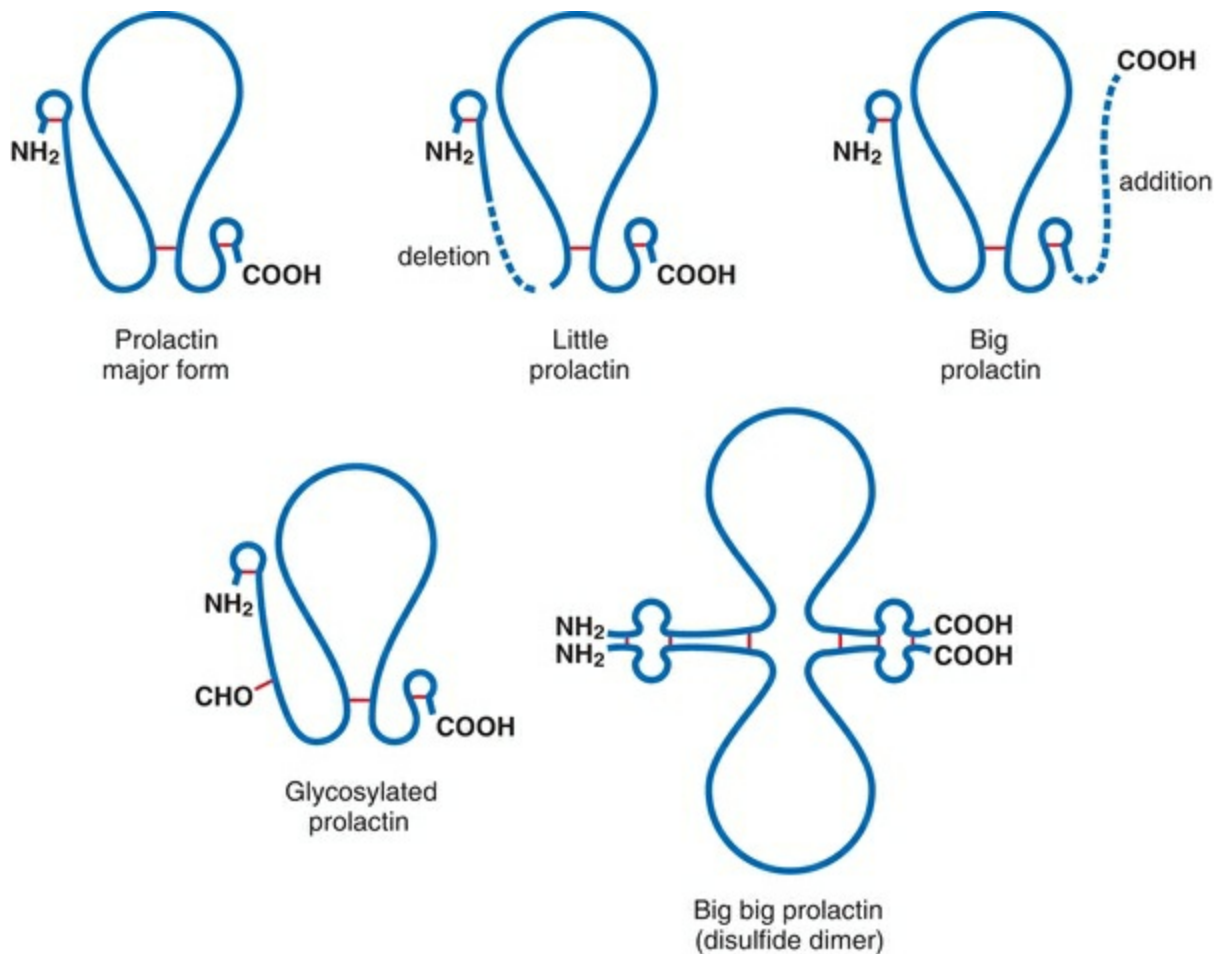

In most mammalian species, prolactin is a single-chain polypeptide of 199 amino acids,

40% similar in structure to growth hormone and placental lactogen.<sup>227</sup> All three hormones are believed to have originated in a common ancestral protein about 400 million years ago. Many hormones, growth factors, and neurotransmitters affect the prolactin gene.

Simultaneous measurements of prolactin by both bioassay and immunoassay reveal discrepancies. At first, differences in prolactin were observed based on size, leading to the use of terms such as little, big, and, the wonderfully sophisticated term, big big prolactin. Further chemical studies have revealed structural modifications that include glycosylation, phosphorylation, and variations in binding and charge. This heterogeneity is the result of many influences at many levels: transcription, translation, and peripheral metabolism.<sup>228,229</sup>

Prolactin is encoded by a single gene on chromosome 6, producing a molecule that in its major form is maintained in three loops by disulfide bonds.<sup>227</sup> Most, if not all, variants of prolactin are the result of posttranslational modifications (**Figure 1.33**). The predominant form, little prolactin, results from the proteolytic deletion of amino acids. Big prolactin has little biologic activity and does not cross-react with antibodies to the predominant form of prolactin. The so-called big big variants of prolactin are due to separate molecules of prolactin binding to each other, either noncovalently or by interchain disulfide bonding. Some of the apparently larger forms of prolactin are prolactin molecules complexed to binding proteins. High levels of relatively inactive prolactin in the absence of a tumor can be due to the creation of macromolecules of prolactin by antiprolactin autoantibodies.<sup>230,231</sup> Overall, the presence of big prolactins accounts for somewhere between 10% and 25% of the hyperprolactinemia reported by commercial assays<sup>232</sup>.

**FIGURE 1.33**

Other variations of prolactin exist. Enzymatic cleavage of the prolactin molecule yields fragments that may be capable of biologic activity. Prolactin that has been glycosylated continues to exert activity; differences in the carbohydrate moieties can produce differences in biologic activity and immunoreactivity. However, the nonglycosylated form of prolactin is the predominant form of prolactin secreted into the circulation.<sup>233</sup> Modification of prolactin also includes phosphorylation, deamidation, and sulfation.

The prolactin receptor is encoded by a gene on chromosome 5 that is near the gene for the growth hormone receptor. However, there is evidence for more than one receptor, depending on the site of action (e.g., decidua and placenta).<sup>234</sup> The prolactin receptor belongs to the receptor family that includes many cytokines and some growth factors, supporting a dual role for prolactin as a classic hormone and as a cytokine. The prolactin signal is mediated through a cytoplasmic tyrosine kinase pathway.

**At any one point of time, the bioactivity (e.g., galactorrhea) and the immunoreactivity (circulating level by immunoassay) of prolactin represent the cumulative effect of the family of structural variants. Remember, immunoassays do**

**not always reflect the biologic situation (e.g., a normal prolactin level in a woman with galactorrhea).**

# Up- and Down-Regulation of Receptors

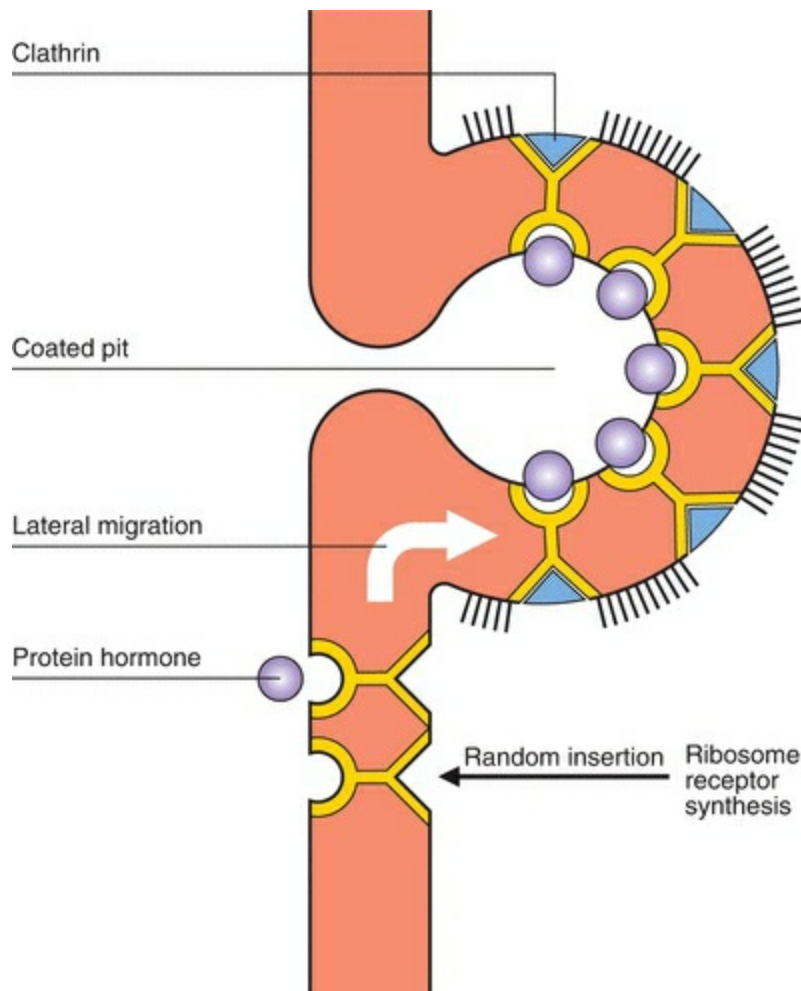

Positive or negative modulation of receptors by homologous hormones is known as up- and down-regulation. Little is known regarding the mechanism of up-regulation; however, hormones such as prolactin and GnRH can increase the cell membrane concentrations of their own receptors.

Theoretically, deactivation of the hormone-receptor complex could be accomplished by dissociation of the complex or loss of receptors from the cell, either by shedding (externally) or by internalization of the receptors into the cell. It is the process of **internalization** that is the major biologic mechanism by which polypeptide hormones down-regulate their own receptors and thus limit hormonal activity. As a general rule, an excess concentration of a tropic hormone, such as LH or GnRH, will stimulate the process of internalization, leading to a loss of receptors in the cell membrane and a decrease in biologic response. We now understand that the principal reason for the episodic (pulsatile) secretion of hormones is to avoid down-regulation and to maintain, if not up-regulate, its receptors. The pulse frequency is a key factor, therefore, in regulating receptor number. This concept underlies the pharmacology of GnRH agonist action. Chemical alteration of the GnRH molecule has produced both pharmacologic agonists and antagonists. GnRH is a decapeptide; antagonists have substitutions at multiple positions, while agonists have substitutions at the 6 or 10 positions. The GnRH agonist molecules first stimulate the pituitary gland to secrete gonadotropins; then, because of the constant stimulation, down-regulation and desensitization of the cell membrane receptors occur, and gonadotropin secretion is literally turned off. The GnRH antagonist molecules bind to the cell membrane receptor and fail to transmit a message and thus are competitive inhibitors. Various GnRH agonists and antagonists are used to treat endometriosis, uterine leiomyomas, and precocious puberty and also are key components of most controlled ovarian hyperstimulation protocols used for in vitro fertilization (see [Chapter 28](#) for more details).

It is believed that receptors are randomly inserted into the cell membrane after intracellular synthesis. The receptor may be viewed as having three important segments: an external binding site that is specific for a polypeptide hormone, the transmembrane region, and an internal site that plays a role in the process of internalization. When the receptor is bound to a polypeptide hormone and when high concentrations of the hormone are present in the circulation, the hormone-receptor complex moves through the cell membrane in a process called lateral migration. Lateral migration carries the complex to a specialized region of the cell membrane, **the coated pit**. Each cell in target tissues contains from 500 to 1,500 coated pits. Lateral migration, thus, concentrates hormone-receptor complexes in the coated pit (**clustering**), allowing

increased internalization of the complex via the special mechanism of **receptor-mediated endocytosis**.<sup>235</sup> The time course for this process (minutes rather than seconds) is too slow to explain the immediate hormone-induced responses, but other cellular events may be mediated by this mechanism that circumvents the intracellular messenger, cyclic AMP.

The coated pit is a lipid vesicle hanging on a basket of specific proteins, called **clathrins** (from the Latin “clathra” meaning “lattice”). The unit is a network of hexagons and pentagons, thus looking like a soccer ball (**Figure 1.34**). The internal margin of the pit has a brush border, hence the name coated pit. The clathrin protein network serves to localize the hormone-receptor complexes by binding to the internal binding site on the receptor.

**FIGURE 1.34**

When fully occupied, the coated pit invaginates, pinches off, and enters the cell as a coated vesicle also called a **receptosome** (**Figure 1.35**). The coated vesicle is

delivered to the lysosomes in which the structure then undergoes degradation, releasing the substance (e.g., a polypeptide hormone) and the receptor. The receptor may be recycled; that is, it may be reinserted into the cell membrane and used again. On the other hand, the receptor and the hormone may be metabolized, thus decreasing that hormone's biologic activity. The internalized hormones may also mediate biologic response by influencing cellular organelles such as the Golgi apparatus, the endoplasmic reticulum, and even the nucleus. For example, nuclear membranes from human ovaries bind hCG and LH, and there follows an enzyme response that is involved in the transfer of mRNA from nucleus to the cytoplasm.<sup>236</sup>

**FIGURE 1.35**

A similar process, called **potocytosis**, utilizes cholesterol-rich membrane invaginations called **caveolae** (far fewer in number and smaller in structure than the clathrin-coated pits) for the internalization of small molecules and ions.<sup>237</sup> This is another method of intracellular signaling in response to hormones, and many proteins involved in cell signaling have been detected in caveolae, for example, G proteins, kinases, and growth factor receptors. Caveolin is the major protein structural component of caveolae. Nitric oxide, the important mediator of vascular events, resides in caveolae and is regulated

by tyrosine phosphorylation and interaction with caveolin.<sup>238,239</sup> Caveolae also facilitate endocytosis and exocytosis of substances, by the recycling of caveolin between the cell surface and the Golgi network.<sup>240</sup>

Besides down-regulation of polypeptide hormone receptors, the process of internalization can be utilized for other cellular metabolic events, including the transfer into the cell of vital substances such as iron or vitamins. Indeed, this is the basic mechanism for transporting large molecules across the cell membrane into the interior.

Cell membrane receptors can be randomly distributed in the cell membrane and transmit information to modify cell behavior.<sup>241</sup> For these receptors, internalization is a method for down-regulation by degradation in lysosomes. Because of this degradation, recycling is usually not a feature of this class of receptors. Hormones that utilize this category of receptors include FSH, LH, hCG, GnRH, TSH, TRH, and insulin. For these hormones, the coated pit can be viewed as a trap to immobilize hormone-receptor complexes. The fate of the hormone, however, can vary from tissue to tissue. In some target tissues, hCG is internalized and the hCG-receptor complex is transferred intact from the coated vesicle into the lysosomes for dissociation and degradation. In other tissues, especially the placenta, it is thought that the hCG-receptor complex is recycled back to the cell surface as a means of transporting hCG across the placenta into both maternal and fetal circulations.<sup>242</sup>

Cell membrane receptors, located in the coated pits, when bound to ligands lead to internalization, thus providing the cell with required factors, the removal of noxious agents from the biologic fluid bathing the cell, or the transfer of substances through the cell (transendocytosis). These receptors are spared from degradation and can be recycled. Examples of this category include LDLs, which supply cholesterol to steroid-producing cells; cobalamin and transferrin, which supply vitamin B12 and iron, respectively; and the transfer of immunoglobulins across the placenta to provide fetal immunity.

A closer look at LDL and its receptor is informative because it is the prototype for this system. The LDL particle is a sphere. It contains in its center about 1,500 molecules of cholesterol that are attached as esters to fatty acids. This core is contained by a bilayer lipid membrane. Protein-binding proteins (the apoproteins) project on the surface of this membrane, and it is these proteins that the receptor must recognize.

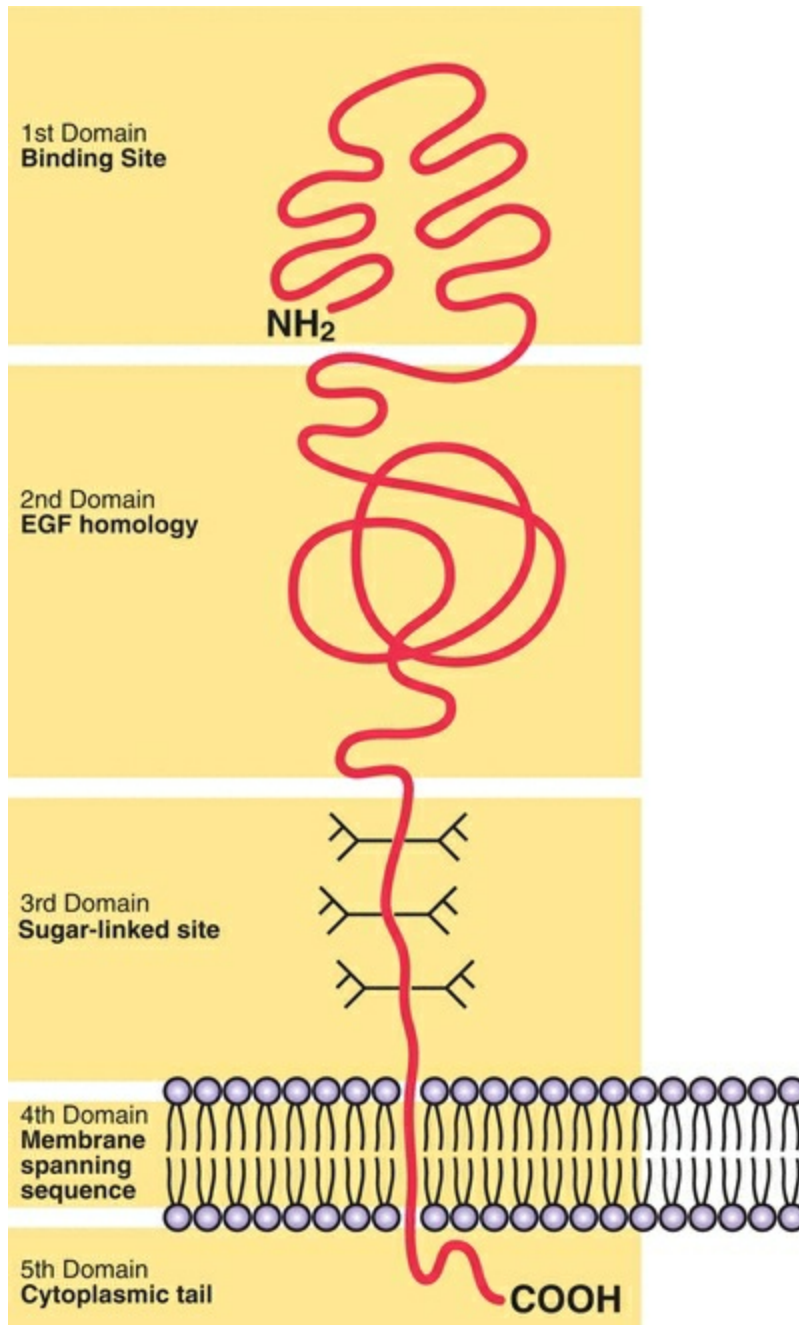

Remember, this is an important story, because all cells that produce steroids must use cholesterol as the basic building block. Such cells cannot synthesize enough cholesterol and therefore must bring cholesterol into the cell from the bloodstream. LDL is the principal messenger delivering the cholesterol. Experimental evidence, however, indicates that HDL cholesterol as well as LDL can provide cholesterol to steroid-producing cells.<sup>243</sup> Indeed, human ovarian granulosa cells use HDL cholesterol in a

system that differs from the LDL cholesterol pathway: the lipoproteins are not internalized, but, rather, the cholesteryl esters are extracted from the lipoproteins at the cell surface and then transferred into the cell.<sup>244</sup>

Different cell surface receptors and proteins contain similar structural parts.<sup>245</sup> For example, the receptor for LDL contains a region that is homologous to the precursor of EGF and another region that is homologous to a component of complement. The LDL receptor is a “mosaic protein.” There are regions of proteins derived from the exons of different gene families. This is an example of a protein that evolved as a new combination of preexisting functional units of other proteins.

The LDL receptor is synthesized as a precursor of 860 amino acids. The precursor includes 21 amino acids that constitute a hydrophobic signal sequence that is cleaved prior to its insertion into the cell surface. This signal sequence presumably directs the protein where to go in the cell. **This leaves an 839-amino acid protein that has five recognizable domains:**

- 1. NH<sub>2</sub> terminal of 292 amino acids, composed of a sequence of 40 amino acids repeated with some variation seven times. This domain is the binding site for LDL and is located on the external surface of the cell membrane.**
- 2. Approximately 400 amino acids 35% homologous to EGF precursor.**
- 3. The sugar-linked site.**
- 4. 22 hydrophobic amino acids that cross the cell membrane. Deletion of the transmembrane signal sequence (found in a naturally occurring mutation) results in an LDL receptor that is secreted from the cell instead of being inserted into the membrane.**
- 5. Cytoplasmic tail of 50 amino acids that is located internally and serves to cluster LDL receptors in coated pits (Figure 1.36).**

**FIGURE 1.36**

When the coated pit is fully occupied with LDL, a coated vesicle is delivered into the cell in the process called endocytosis. The vesicle moves to the Golgi system and then is routed by an unknown mechanism (although a similar coated pit system in the Golgi appears to be involved) to the lysosomes in which the structure undergoes degradation, releasing cholesterol esters and the receptor. The receptor can be recycled or degraded. The intracellular level of free cholesterol influences the following important activities: the rate-limiting enzyme for cholesterol synthesis, the reesterification of excess cholesterol for storage as lipid droplets, and the synthesis of LDL receptors. The

cholesterol derived from the LDL transport process can have any one of the following fates: utilization in the mitochondria for steroidogenesis, reesterification for storage, use in membrane structures, or excretion.<sup>246</sup> Excretion (release of free cholesterol into the circulation by means of the HDL mechanism) involves the cell surface caveolae.<sup>237,240</sup> Thus, entry is via coated pits (endocytosis) and efflux from endoplasmic reticulum to the cell membrane is via caveolae (exocytosis).

Synthesis and insertion of new LDL receptors are a function of LH in the gonads and ACTH in the adrenal. This process is relatively fast. It has been calculated that the coated pit system turns over an amount of cell surface equivalent to the total amount of plasma membrane every 30–90 minutes.<sup>246</sup> The LDL receptor makes one round trip every 10 minutes during its 20-hour life span for a total of several hundred trips.<sup>247</sup> Genetic defects in receptors for LDL lead to a failure in internalization and hyperlipidemia

## Key Points: Down-Regulation

Down-regulation is a decrease in response in the presence of continuous stimulation. It can involve any of the following mechanisms:

- Desensitization by autophosphorylation of the cytoplasmic segment of the receptor
- Loss of receptors by internalization, a relatively slow mechanism
- Uncoupling of the regulatory and catalytic subunits of the adenylate cyclase enzyme
- Alterations in key intracellular regulatory proteins

# Regulation of Tropic Hormone Action

One way in which tropic hormone action is regulated is via stimulating and inhibiting actions at the adenylate cyclase level through coupling. LH stimulates steroidogenesis in the corpus luteum and works through the coupling of stimulatory regulatory units to the catalytic units of adenylate cyclase. Prostaglandin  $F_{2a}$  is directly luteolytic, inhibiting luteal steroidogenesis through a mechanism that follows binding to specific receptors. This luteolytic action may be exerted via an inhibitory regulatory unit that leads to uncoupling with the catalytic unit, thus interfering with gonadotropin action.

Increasing concentrations of tropic hormones, such as gonadotropins, are directly associated with desensitization of adenylate cyclase independent of the internalization of receptors. Desensitization is a rapid, acute change without loss of receptors in contrast to the slower process of internalization and true receptor loss. The desensitization process after prolonged agonist exposure involves receptor phosphorylation (which uncouples the receptor from the G protein). The LH/hCG receptor, a member of the G protein family, undergoes desensitization/uncoupling in response to LH or hCG in a process that involves phosphorylation of the C-terminal cytoplasmic tail of the receptor.<sup>248,249</sup> Decreased gonadotropin secretion in the presence of prolonged continuous GnRH stimulation is a desensitization response that can occur followed by recovery within the time frame of a normal endogenous GnRH secretory pulse.<sup>250</sup>

Desensitization can also follow enzymatic alterations that affect the key intracellular proteins that regulate steroidogenesis. Activation of the mitogen-activated protein kinase (MAPK) system increases levels of SF-1, which in turn attenuates StAR expression, which is essential for the transport of cholesterol in gonadal cells producing steroids.<sup>251</sup>

## The Ovary—Embryology and Development

The great names of early Western medicine were Hippocrates, Soranus, and Galen. Although Aristotle (384–322 B.C.) referred to castration as a common agricultural practice, it was Soranus who provided the first anatomic description of the ovaries. Soranus of Ephesus (a city founded by Greeks on the coast of what is now Turkey) lived from 98 to 138 A.D. and has often been referred to as the greatest gynecologist of antiquity.<sup>1</sup> He studied in Alexandria and practiced in Rome. His great text was lost for centuries and was not published until 1838.

Galen was born in 130 A.D. in Pergamum, a Greek city in eastern Turkey; studied in Alexandria; and became a famous practitioner and teacher of medicine also in Rome. He lived 70 years and wrote about 400 treatises, 83 of which are still in existence. Galen preserved in his own writings (in Greek) Aristotle's descriptions of reproduction. He was a true scholar and was regarded as the ultimate authority on anatomy and physiology until the 16th century.<sup>2</sup> It was Galen who established bleeding as the appropriate treatment for almost every disorder. Although in retrospect Galen's conclusions and teachings contained many errors, how many other individuals have been able to satisfy the needs of scholars and physicians for hundreds of years?

After Galen, no further thoughts or advances were recorded for well over 1,000 years as the dark weight of the medieval ages descended on Western civilization. During the medieval years, it was safe to copy Galen's works but literally dangerous to contribute anything original. Medieval scholars believed it was impossible to progress in knowledge beyond Galen. The doctrine according to Galen was not challenged until the introduction of printing made Galen's works available to scholars.

Although Leonardo da Vinci (1452–1519) drew accurately the anatomy of the uterus and the ovaries, the major advances in anatomic knowledge can be traced to the University of Padua, the famed Italian university where a succession of anatomists made important contributions.<sup>3</sup> It was Andreas Vesalius (1514–1564), who while still in his 20s, because of his own human dissections, realized that Galen described only animals. Appointed Professor of Surgery and Anatomy at the University of Padua at the age of 23, he published *De Humani Corporis Fabrica*, his authoritative, illustrated book on human anatomy, in 1543, at the age of 29. Vesalius was harshly attacked by the medical establishment, and 1 year after the publication of his book, he left Padua to become the court physician in Spain.

Vesalius was the first to describe ovarian follicles and probably the corpus luteum. Fallopius (1523–1562), remembered for his description of the fallopian tubes, was a pupil of Vesalius and then a successful and popular teacher of anatomy at Padua. Fabricius (Girolamo Fabrici d'Acquapendente, 1533–1619), a pupil of Fallopius, succeeded Fallopius as chair of anatomy at Padua and made major contributions to embryology. Studying an organ in birds and observing that it contained eggs, Fabricius called it the “ovary.” During this period of time, the ovaries came to be recognized as structures, but their function remained a mystery.

William Harvey published the first original English book on reproductive anatomy and physiology in 1651, at the age of 69, 35 years after his discovery of the circulation of blood. He obtained his medical education at the University of Padua, where he learned to describe accurately his own observations, a practice he was to continue and that culminated in his writings. Credited with the well-known “ex ovo omnia” (everything comes from the egg) statement, Harvey actually promoted and maintained the Aristotelian belief that the egg was a product of conception, a result of an interaction between semen and menstrual blood. This view was corrected by Bishop Niels Stensen of Denmark in 1667, and in 1672, at the age of 31, the Dutch physician Regnier de Graaf published his great work on the female reproductive organs, *De Mulierum Organis Generationi Inservientibus Tractatus Novus* (A New Treatise on the Female Reproductive Organs), that established the ovary as the source of the ovum.

Ovarian follicles had been described by Vesalius and Fallopius, but the impact of his publication earned de Graaf eternal recognition as the mature ovarian follicle became known as the graafian follicle, even though de Graaf believed that the whole follicle was the egg. de Graaf was the first to accurately describe the corpus luteum, although Marcello Malpighi, whose works were published posthumously in 1697, invented the name “corpus luteum.”

With the discovery of mammalian spermatozoa by van Leeuwenhoek in 1677, it became possible to speculate that fertilization resulted from the combination of a spermatozoon and the graafian follicle. It would be another 150 years before it was appreciated that the oocyte resides within the follicle (described in 1827 by Carl Ernst von Baer) and that there is a relationship between the ovaries and menstruation. The process of fertilization was described by Newport in 1853–1854, and Oscar Hertwig, studying sea urchins, reported in 1876 the penetration of a spermatozoon into an egg and chromosome reduction during meiosis, bringing to a close the era of descriptive anatomy of the ovary and marking the beginning of scientific explorations into physiology and endocrinology.

# THE HUMAN OVARY

---

The physiologic responsibilities of the ovary are the periodic release of gametes (eggs, oocytes) and the production of the steroid hormones estradiol and progesterone. Both activities are integrated in the continuous repetitive process of follicle maturation, ovulation, and corpus luteum formation and regression. The ovary, therefore, cannot be viewed as a relatively static endocrine organ whose size and function expand and contract, depending on the vigor of stimulating tropic hormones. Rather, the female gonad is a heterogeneous ever-changing tissue whose cyclicity is measured in weeks, rather than hours.

The ovary consists of three major portions: the outer cortex, the central medulla, and the rete ovarii (the hilum). The hilum is the point of attachment of the ovary to the mesovarium. It contains nerves, blood vessels, and hilus cells, which have the potential to become active in steroidogenesis or to form tumors. These cells are very similar to the testosterone-producing Leydig cells of the testes. The outermost portion of the cortex is called the tunica albuginea, topped on its surface by a single layer of cuboidal epithelium, referred to as the ovarian surface epithelium or the ovarian mesothelium (epithelial ovarian carcinomas account for 90% of human ovarian cancers). The oocytes, enclosed in complexes called follicles, are in the inner part of the cortex, embedded in stromal tissue. The stromal tissue is composed of connective tissue and interstitial cells, which are derived from mesenchymal cells, and have the ability to respond to luteinizing hormone (LH) or human chorionic gonadotropin (hCG) with androgen production. The central medullary area of the ovary is derived largely from mesonephric cells.

# THE FETAL OVARY

---

During fetal life, the development of the human ovary can be traced through four stages<sup>4,5</sup>: (1) the indifferent gonad stage, (2) the stage of differentiation, (3) the period of oogonial multiplication and oocyte formation, and finally, (4) the stage of follicle formation.

# The Indifferent Gonad Stage

At approximately 5 weeks of gestation, the paired gonads are structurally consolidated coelomic prominences overlying the mesonephros, forming the gonadal ridges. At this point, the gonad is morphologically indistinguishable as a primordial testis or ovary. The gonad is composed of primitive germ cells intermingled with coelomic surface epithelial cells and an inner core of medullary mesenchymal tissue. Just below this ridge lies the mesonephric duct. This indifferent stage lasts about 7–10 days. Together, the mesonephros and the genital ridge are called the urogenital ridge, indicating the close association of the urinary and reproductive systems.

The origin of the gonadal somatic cells is still not certain. The earliest recognizable gonad contains, besides the germ cells, somatic cells derived from at least three different tissues: coelomic epithelium, mesenchyme, and mesonephric tissue. In one early model, the gonad was believed to be formed by the invasion of the “germinal epithelium” into the underlying mesenchyme. The germinal epithelium is simply that part of the coelomic epithelium that gives rise to gonadal tissue. The invading cells were thought to form the primary sex cords that contain the germ cells surrounded by somatic cells (the cells destined to form the tissue that holds the germ cells). In a newer model, well-supported by experimental data, the somatic cells of the gonad are believed to arise from the mesonephros and not the coelomic epithelium.<sup>6,7,8</sup> Ultrastructural studies have even suggested that both coelomic epithelial and underlying mesonephric cells provide the somatic cells that are destined to become follicular cells.<sup>9</sup>

The contribution of mesonephric cells requires migration into the gonad. This movement is regulated by fibroblast growth factor 9 in the male, and it may be repressed by a gene encoding a protein known as SPRY2.<sup>10</sup> Thus, the Y chromosome directs sexual development by influencing gene expression via specific regulating and signaling proteins.

The primordial germ cells originate within the primitive ectoderm, but the specific cells of origin cannot be distinguished.<sup>11</sup> The germ cells are first identified at the end of the 3rd week after fertilization in the primitive endoderm at the caudal end in the dorsal wall of the adjacent yolk sac, and, soon, they also appear in the splanchnic mesoderm of the hindgut.<sup>12,13</sup> The gonadal ridge is the one and only site where the germ cells can survive. By displacement because of growth of the embryo and also by active amoeboid movement along the dorsal mesentery of the hindgut toward the genital ridges, the germ cells “migrate” from the yolk sac around the hindgut to their gonadal sites between weeks 4 and 6 of gestation.<sup>11,14</sup>

The factors that initiate and guide the migration of the germ cells are not known, although chemotactic and adhesive peptides, such as fibronectin and laminin, are

involved. In rodents, germ cell proliferation and migration involve stem cell factor (kit ligand) and the expression of its receptor (c-KIT), a transmembrane tyrosine kinase receptor encoded by the C-KIT oncogene.<sup>15</sup> In gonads obtained from individuals with intersex disorders that have a high risk of testicular tumors, the expression of KIT protein was detected at a later gestational age than in normal controls, consistent with both later germ cell migration and a change in the oncogene expression.<sup>16</sup> The KIT gene is located on chromosome 4, and mutations in this gene have not been discovered in women with premature ovarian failure.<sup>17</sup>

The germ cells begin their proliferation during their migration.<sup>9</sup> The germ cells are the direct precursors of sperm and ova, and by the 6th gestational week, on completion of the indifferent state, these primordial germ cells have multiplied by mitosis to a total of 10,000. By the 6th week of gestation, the indifferent gonads contain the germ cells and supporting cells derived from the coelomic epithelium and the mesenchyme of the gonadal ridge.

Male or female differentiation of the gonad is directed by the sex chromosomes. But the decision to be male or female must be communicated to the cells of the indifferent gonad.<sup>18</sup> This communication, too, is genetic in origin, involving signaling proteins and their receptors, programmed by the fundamental impact that depends on whether a Y chromosome is present. A genetic program involving hundreds of genes is initiated in the indifferent gonad at the urogenital ridge that leads to differentiation into a testis or an ovary.<sup>19</sup>

# The Stage of Differentiation

If the indifferent gonad is destined to become a testis, differentiation along this line will take place at 6–9 gestational weeks. The absence of testicular evolution (formation of medullary primary sex cords, primitive tubules, and incorporation of germ cells) gives implicit evidence of the existence of a primitive, albeit momentarily quiescent, ovary. In contrast to the male, female internal and external genitalia differentiation precedes gonadal maturation. These events are related to the genetic constitution and the territorial receptivity of the mesenchyme. If either factor is deficient or defective, improper development occurs. As has been noted, primitive germ cells are unable to survive in locations other than the gonadal ridge. If partial or imperfect gonadal tissue is formed, the resulting abnormal nonsteroidal and steroidal events have wide ranging morphologic, reproductive, and behavioral effects.

## The Testes

The factor that determines whether the indifferent gonad will become a testis is called, appropriately, the testes-determining factor (TDF), a product of a single gene located on the Y chromosome.<sup>20,21</sup> The testicular-determining factor gene is located within a region named SRY, the sex-determining region on the Y chromosome.<sup>22</sup> The protein product of the SRY gene contains a DNA-binding domain to activate gene transcription that diverts the development of gonadal somatic cells from the pathway of follicle cells to Sertoli cells.<sup>23</sup> Rare cases have been reported of phenotypic, infertile males with a 46, XX karyotype, where the male differentiation is due to a translocation of a Y chromosome fragment containing SRY to an autosome or an X chromosome.

Normal testis development requires not only the presence of the SRY gene but its interaction with autosomal genes.<sup>24,25</sup> Genes similar to SRY have been named SOX genes (the similarity is with the SRY box region that contains the DNA-binding sequence).<sup>23</sup> SRY expression precedes SOX expression; indeed, SRY, acting cooperatively with steroidogenic factor 1, SF1, and FGF9, a member of the fibroblast growth factor family, up-regulates SOX9 gene expression.<sup>21</sup> Thus, SRY along with partner proteins targets male-specific genes that are essential for testicular development. This process is discussed in detail in [Chapter 8](#). In mice, the developmental consequences of activating and inactivating mutations in Sox9 resemble those of similar mutations in SRY, implying not only that Sox9 is required for testis differentiation but also that SRY activation of Sox9 may be all that is necessary to activate other genes important to testis development, such as Fgf9 (fibroblast growth factor 9), and to repress genes that induce ovary development, such as Wnt4 (a member of the wingless family of genes), Rspo1 (R-spondin 1), Dax1 (dosage-sensitive sex

reversal, adrenal hypoplasia critical region, on chromosome X, gene 1), and Foxl2 (forkhead box L2).<sup>26</sup>

Both testis and ovary differentiation require dominantly acting genes, with SRY inducing testis development via up-regulation of SOX9, and with other genes, primarily WNT4 and RSPO1, teaming to promote ovary development via repression of SOX9. This concept views the fate of the bipotential gonad as balanced between opposing forces and SRY as the key factor. In XY gonads, SRY induces SOX9 and tips differentiation toward testis development, and in XX gonads lacking SRY, other genes combine to repress SOX9 and promote ovary development.<sup>27</sup>

The expression of the SRY gene is confined to the genital ridge during fetal life, but the gene is also active in the germ cells of the adult, perhaps playing a role in spermatogenesis.<sup>20</sup> The traditional view assigns **active** gene control and expression for testicular differentiation and a **passive**, “default” mode of development for the ovary. However, recent evidence has challenged that concept, revealing that ovarian development requires the actions of genes such as WNT4, RSPO1, and DAX1, which team to repress the expression of genes in the testis pathway (e.g., SOX9), and other genes that promote ovarian development.<sup>26,28</sup> “Passive” is not an accurate description because even before the gonad differentiates into an ovary, robust gene activity associated with the female genotype occurs in the urogenital ridge.<sup>19</sup>

When the Y chromosome containing SRY is present, the gonads develop into testes. The male phenotype is dependent on the products (antimüllerian hormone and testosterone) of the fetal testes, whereas the female phenotype is the result of an absence of these fetal gonadal products.<sup>29</sup> Anti-müllerian hormone (AMH), which inhibits the formation of the müllerian ducts, is secreted at the time of Sertoli cell differentiation, beginning at 7 weeks. AMH expression is altered only by mutations in the AMH gene, located on chromosome 19p13.3.<sup>30</sup> Regression of the müllerian ducts is dependent on the presence of an adequate number of Sertoli cells, and the regulation of AMH receptor.<sup>31</sup> Mutations in the AMH receptor gene result in the presence of the uterus, fallopian tubes, and the upper vagina in 46,XY men with normal external virilization.

After involution of the müllerian system, AMH continues to be secreted, but there is no known function. However, evidence in the mouse suggests a role in early germ cell transformation during spermatogenesis.<sup>32</sup> In the ovary, very small amounts of AMH mRNA are present early in life, and although there may be no role in female development, its production later in life by the granulosa cells leads to autocrine and paracrine actions in oocyte maturation and follicular development.<sup>33</sup> Serum AMH levels in adult women correlate with the number of ovarian follicles present and predict the response to stimulation with ovulation-inducing therapy.<sup>34</sup>

The testis begins its differentiation in week 6–7 of gestation by the appearance of Sertoli cells that aggregate to form the testicular cords. The primordial germ cells are embedded in the testicular cords that will form the Sertoli cells and spermatogonia. The mature Sertoli cells are the site of production of ABP (androgen-binding protein, important in maintaining the high local androgen environment necessary for spermatogenesis) and inhibin.

The Leydig cells differentiate (beginning week 8) from mesenchymal cells of the interstitial component surrounding the testicular cords. Thus, secretion of AMH precedes steroidogenesis in Leydig cells. Shortly after the appearance of the Leydig cells, secretion of testosterone begins. Androgen secretion increases in conjunction with increasing Leydig cell numbers until a peak is reached at 15–18 weeks. At this time, Leydig cell regression begins, and at birth, only a few Leydig cells are present.

The cycle of fetal Leydig cells follows the rise and decline of fetal hCG levels during pregnancy. This relationship and the presence of hCG receptors in the fetal testes indicate a regulatory role for hCG.<sup>4</sup> The pattern of hCG in the fetus parallels that of the mother, peaking at about 10 weeks and declining to a nadir at 20 weeks of gestation, but the concentrations are only 5% of maternal concentrations. hCG stimulation produces Leydig cell hypertrophy, and peak fetal testosterone levels are seen at 15–18 weeks.<sup>35</sup> However, normal masculine differentiation occurs in mouse models lacking LH receptors, and molecular evidence indicates that fetal Leydig cells (but not adult cells) respond to adrenocorticotrophic hormone (ACTH) as well as hCG.<sup>36,37</sup>

Testosterone synthesis in human fetal testes begins at the 8th week of gestation, reaches a peak between 15 and 18 weeks, and then declines. Testicular function in the fetus can be correlated with the fetal hormonal patterns. Although the initial testosterone production and sexual differentiation are in response to the fetal levels of ACTH and hCG, further testosterone production and masculine differentiation are maintained by the fetal pituitary gonadotropins. Decreased testosterone levels in late gestation probably reflect the decrease in gonadotropin levels. The fetal Leydig cells, by an unknown mechanism, avoid down-regulation and respond to high levels of hCG and LH by increased steroidogenesis and cell multiplication. This generation of cells is replaced by the adult generation of Leydig cells that becomes functional at puberty and responds to high levels of hCG and LH with down-regulation and decreased steroidogenesis. Leydig cells, therefore, are composed of two distinct populations, one active during fetal life and one active during adult life.

The fetal spermatogonia, derived from the primordial germ cells, are in the testicular cords, surrounded by the Sertoli cells. In contrast to the female, male germ cells do not start meiotic division before puberty (**Figure 2.1**).

**FIGURE 2.1**

The differentiation of the wolffian system begins with the increase in testicular testosterone production. The classic experiments by Jost indicate that this effect of testosterone is due to local action, explaining why male internal genitalia in true hermaphrodites are only on the side of the testis.<sup>29</sup> Not all androgen-sensitive tissues require the prior conversion of testosterone to dihydrotestosterone (DHT). In the process of masculine differentiation, the development of the wolffian duct structures (epididymis, the vas deferens, and the seminal vesicle) is dependent on testosterone as the intracellular mediator, whereas development of the urogenital sinus and urogenital

tubercle into the male external genitalia, urethra, and prostate requires the conversion of testosterone to DHT.<sup>38</sup> In the female, the loss of the wolffian system is due to the lack of locally produced testosterone.

# The Stage of Oogonial Multiplication and Oocyte Formation in the Ovary

Just as testicular development requires SRY and SOX9 expression, specific molecular signaling pathways are necessary for ovarian differentiation and oocyte survival. In the developing ovary, the most important genes are WNT4 and RSPO1. Both activate the beta-catenin signaling pathway in somatic cells, which results in the loss of cell-cell adhesion between female germ cells that is required for their entry into meiosis.<sup>39</sup> WNT4 and RSPO1 also cooperate to suppress somatic cell SOX9 expression. Thus, ovarian differentiation is dependent on essential genetic molecular signaling that is active in the absence of SRY. Evidence suggests that RSPO1 also may act directly to suppress male differentiation, even in the absence of SRY.<sup>40</sup> The ultimate fate of the gonad depends on which molecular signaling pathway dominates.<sup>41</sup>

At 6–8 weeks, the first signs of ovarian differentiation are reflected in the rapid mitotic multiplication of germ cells, reaching 6–7 million oogonia by 16–20 weeks.<sup>12,42</sup> This represents the maximal oogonial content of the gonad. From this point in time, germ cell content will irretrievably decrease until, some 50 years later, the store of oocytes will be finally exhausted.

By mitosis, primordial germ cells give rise during week 9 to the oogonia. The oogonia are transformed to oocytes as they enter the first meiotic division and arrest in prophase. This process begins at 11–12 weeks, perhaps in response to a factor or factors produced by the rete ovarii,<sup>43</sup> that may act directly on the germ cells or indirectly via actions on the somatic cells. Studies in mice suggest that retinoic acid derived from the mesonephros may act as a functional meiosis-inducing factor in the female germ cells.<sup>44</sup> Progression of meiosis to the diplotene stage is accomplished throughout the rest of pregnancy and completed by birth. Arrest of meiosis at the diplotene stage of the first meiotic prophase is probably maintained by inhibiting substances produced by granulosa cells. A single ovum is formed from the two meiotic divisions of the oocyte, one just before ovulation and the second (forming the haploid ovum) at the time of sperm penetration. The excess genetic material is extruded as one polar body at each meiotic division. Gonadotropins and various growth factors (but not sex steroids) can induce resumption of meiosis *in vitro*, but only in oocytes enclosed by cumulus-granulosa cells. Follicle-stimulating hormone (FSH) prepares the oocyte for the resumption of meiosis, a process that requires the presence of the gap junction network that allows communication between the cumulus cells and the oocyte. A family of sterols is present in follicular fluid, presumably secreted by the granulosa and cumulus cells in response to gonadotropins, that activates oocyte meiotic resumption and maturation<sup>45,46</sup> (**Figures 2.2 and 2.3**).

**FIGURE 2.2**

**1st trimester**

**2nd trimester**

**Adult life**

Meiosis I

Meiosis II

## FIGURE 2.3

The massive loss of oocytes during the second half of pregnancy is the consequence of several mechanisms. Besides follicular growth and atresia, substantial numbers of oocytes regress during meiosis, and those oogonia that fail to be enveloped by granulosa cells undergo degeneration. This process is influenced by genes that actively repress germ cell death.<sup>47</sup> In addition, germ cells (in the cortical area) migrate to the surface of the gonad and become incorporated into the surface epithelium or are eliminated into the peritoneal cavity.<sup>48,49</sup> In contrast, once all oocytes are encased in follicles (shortly after birth), the loss of oocytes will be only through the process of follicular growth and atresia.

Chromosomal anomalies can accelerate germ cell loss. Individuals with Turner syndrome (45,X) experience normal migration and mitosis of germ cells, but the oogonia do not undergo meiosis, and rapid loss of oocytes leaves the gonad without follicles early in life, and it appears as a fibrous streak. The rate of loss varies, and 10–20% experience spontaneous menstruation; rare pregnancies have been reported in those who have had spontaneous menstruation.<sup>50,51</sup> However, the presence of menstrual function and reproduction in a patient with Turner phenotype may be due to an undetected mosaic complement, such as a 46,XX line in addition to 45,X.

# The Stage of Follicle Formation

At 18–20 weeks, the highly cellular cortex is gradually perforated by vascular channels originating in the deeper medullary areas, and this marks the beginning of follicle formation.<sup>52</sup> As the finger-like vascular projections enter the cortex, it takes on the appearance of secondary sex cords. As blood vessels invade and penetrate, they divide the previously solid cortical cell mass into smaller and smaller segments. Drawn in with the blood vessels are perivascular cells that originate in the mesonephros or in the coelomic epithelium. Some believe that the coelomic epithelium is the origin of all ovarian somatic cells; others favor a mesenchymal or dual origin.<sup>5,11</sup> These cells give rise to the pregranulosa cells that surround the oocytes, which have completed the first stage of meiosis. The resulting unit is the **primordial follicle—an oocyte arrested in prophase of meiosis, enveloped by a single layer of spindle-shaped pregranulosa cells, surrounded by a basement membrane.** Eventually, all oocytes are covered in this fashion. Residual mesenchyme not utilized in primordial follicle formation is noted in the interstices between follicles, forming the primitive ovarian stroma. This process of primordial follicular development continues until all oocytes in the diplotene stage can be found in follicles, some time shortly after birth.

As soon as the oocyte is surrounded by the rosette of pregranulosa cells, the entire follicle can undergo variable degrees of maturation before arresting and becoming atretic. The formation of a **primary follicle** is marked by a change of the pregranulosa layer to a cuboidal layer of granulosa cells. This change is associated with proliferation. In the human, it is estimated that about 13 pregranulosa cells surround the oocyte, and with the change to a primary follicle, the number increases to about 76 granulosa cells.<sup>53</sup> A later and perhaps more accurate study concluded that the primary follicle contains about 105 granulosa cells, associated with an increase in average diameter from 40 to 54  $\mu\text{m}$ .<sup>54</sup>

Further differentiation into a **preantral follicle** is marked by more complete granulosa proliferation. Call-Exner body formation (which will later coalesce to form an antrum) and occasionally a minor theca layer system that differentiates from surrounding mesenchymal cells can be seen. Preantral follicles can be found in the 6th month of gestation, and **antral follicles** (the graafian follicle, characterized by a fluid-filled space) are present by the end of pregnancy but not in large numbers. It is only during the last 3rd of gestation that theca cells can be found surrounding follicles.<sup>42</sup>

Even in fetal life, the cycle of follicle formation, variable ripening, and atresia occurs. Although these steps are precisely those typical of adult reproductive life, full maturity, as expressed in ovulation, does not occur. Estrogen production does not occur until late in pregnancy when follicular development takes place, and even then,

steroidogenesis is not significant. Unlike the male, gonadal steroid production is not required for development of a normal female phenotype. The development of the müllerian duct into the fallopian tubes, the uterus, and the upper third of the vagina is completely independent of the ovary.

The ovary at birth and in the first year of life can contain cystic follicles of varying size, undoubtedly stimulated by the reactive gonadotropin surge accompanying the withdrawal of the neonatal hypothalamus and pituitary from the negative feedback of fetoplacental steroids.<sup>55</sup> Ovarian cysts can also be occasionally detected in fetuses by ultrasonography.

The anterior pituitary begins development between 4 and 5 weeks of fetal life. The median eminence is apparent by week 9 of gestation, and the hypothalamic-pituitary portal circulation is functional by the 12th week. Pituitary levels of FSH peak at 20–23 weeks and circulating levels peak at 28 weeks.<sup>56</sup> Levels are higher in female fetuses than in males until the last 6 weeks of gestation. Ovaries in anencephalic fetuses, which lack gonadotropin-releasing hormone (GnRH) and gonadotropin secretion, lack antral follicles and existing follicles are smaller at term, but progression through meiosis and development of primordial follicles occurs, obviously not dependent on gonadotropins.<sup>4</sup> The ovary develops receptors for gonadotropins only in the second half of pregnancy. Thus, the loss of oocytes during fetal life cannot be solely explained by the decline in gonadotropins. The follicular growth and development observed in the second half of pregnancy, however, is gonadotropin dependent, and hypophysectomy of a fetal monkey is followed by an increase in oocyte loss by atresia.<sup>57,58</sup>

# THE NEONATAL OVARY

---

The total cortical content of germ cells falls to 500,000–2 million by birth as a result of prenatal oocyte depletion.<sup>59,60,61</sup> This huge depletion of germ cell mass (close to 4–5 million) has occurred over as short a time as 20 weeks. No similar rate of depletion will be seen again. Because of the fixed initial endowment of germ cells, the newborn female enters life, still far from reproductive potential, having lost 80% of her oocytes.

The ovary is approximately 1 cm in diameter and weighs about 250–350 mg at birth, although sizable cystic follicles can enlarge the total dimensions. Intriguingly, the gonad on the right side of the body in both males and females is larger, heavier, and greater in protein and DNA content than the gonad on the left side.<sup>62</sup> Compartmentalization of the gonad into cortex and a small residual medulla has been achieved. In the cortex, almost all the oocytes are enclosed in primordial follicle units. Each ovary contains a similar total number of follicles.<sup>63</sup> Varying degrees of maturation in some units can be seen as in the fetal state.

There is a sex difference in fetal gonadotropin levels. There are higher pituitary and circulating FSH and pituitary LH levels in female fetuses. The lower male levels are undoubtedly due to testicular testosterone and inhibin production. In infancy, the postnatal FSH rise is more marked and more sustained in females, whereas LH values are not as high. The FSH levels are greater than the levels reached during a normal adult menstrual cycle, decreasing to low levels usually by 1 year of age but sometimes later.<sup>64</sup> LH levels are in the range of lower adult levels. This early activity is accompanied by inhibin levels comparable to the low range observed during the follicular phase of the menstrual cycle. Follicular growth to the antral stage is relatively common in the first 6 months of life in response to these elevated gonadotropin levels. The most common cause of abdominal masses in fetuses and newborns is ovarian cysts, a consequence of gonadotropin stimulation.<sup>65</sup>

Interference with the postnatal rise in gonadotropins in monkeys is associated with disturbances in normal hypothalamic-pituitary function at puberty.<sup>66</sup> Indeed, in male monkeys, the administration of a GnRH analogue in the neonatal period has an adverse impact on subsequent immunologic and behavioral functions as well as normal reproduction.<sup>66</sup> After the postnatal rise, gonadotropin levels reach a nadir during early childhood (by about 6 months of age in males and 1–2 years in females) and then rise slightly between ages 4 and 10 years.

# THE OVARY IN CHILDHOOD

The childhood period is characterized by low levels of gonadotropins in the pituitary and in the blood, little response of the pituitary to GnRH, and maximal hypothalamic suppression. The ovary, however, is not quiescent during childhood. Follicles begin to grow at all times and frequently reach the antral stage. Ultrasonography can commonly demonstrate ovarian follicular cysts during childhood, ranging in size from 2 to 15 mm.<sup>67</sup> These small unilocular ovarian cysts are not clinically significant.<sup>68</sup> The process of atresia with an increasing contribution of follicular remnants to the stromal compartment yields progressive ovarian enlargement during childhood, about a 10-fold increase in weight.<sup>69</sup> Of course, the lack of gonadotropin support prevents full follicular development and function. There is no evidence that ovarian function is necessary until puberty. However, the oocytes during this time period are active, synthesizing messenger RNAs and protein. Furthermore, ovariectomy in prepubertal monkeys indicates that the prepubertal suppression of GnRH and gonadotropins is partially dependent on the presence of ovaries, suggesting some functional activity of the ovary in childhood<sup>70</sup> (Figure 2.4).

## FIGURE 2.4

# THE ADULT OVARY

---

At the onset of puberty, the germ cell mass has been reduced to 300,000 to 500,000 units.<sup>12,71</sup> During the next 35–40 years of reproductive life, 400–500 will be selected to ovulate, and the primary follicles will eventually be depleted to a point at menopause when only a few hundred to a thousand remain.<sup>72,73,74</sup> A gradually increasing rate of follicular depletion occurs throughout life accounting for a progressively declining number of follicles. In the last 10–15 years before menopause, follicular depletion correlates with a subtle but real increase in FSH and decrease in inhibin-B as well as insulin-like growth factor-1 (IGF-1), and AMH.<sup>34,75,76,77,78,79</sup> Fewer follicles grow per cycle as a woman ages, and cycles are at first shorter because follicular growth begins sooner during the late luteal phase, a consequence of a greater rise in FSH between cycles, and then longer as anovulation becomes more common.<sup>80,81,82,83,84</sup> These changes, including the increase in FSH (which is probably due to the decrease in inhibin-B), may partly reflect the reduced quality and capability of aging follicles. Beginning in their late 30s, women have smaller oocytes and smaller follicles, perhaps of lesser quality.<sup>54</sup> However, the rise in FSH due to a decrease in inhibin-B is also believed to be the consequence of a decreasing number of follicles in each cohort of active follicles.<sup>85</sup>

The acceleration of follicular loss in the later reproductive years has been questioned by a mathematical analysis of normal human ovaries.<sup>86</sup> This model indicates a constantly accelerating loss of follicles from birth to menopause. The rise in FSH and decrease in inhibin-B in the late 30s could still reflect both lesser quality in the remaining follicles and fewer follicles participating in each menstrual cycle.

The classic concept that the mammalian ovary cannot produce new oocytes (and follicles) after fetal life has been challenged. Experimental work that is not without controversy identified stem cells in blood and bone marrow, which after transplantation to a chemically or genetically sterile recipient could generate oocytes within follicles,<sup>87</sup> raising the intriguing possibility of a new approach to treatment for men and women with infertility or reproductive diseases.<sup>88</sup> In addition, putative stem cells have even been isolated from the ovarian surface endothelium, obtained from postmenopausal women and women with premature ovarian failure.<sup>89</sup> This work suggesting neo-oogenesis in adult life is an area of intense debate, including a number of well-designed studies that support the conventional wisdom that each female mammal is born with a finite number of oocytes that were formed in fetal life.<sup>90,91,92</sup>

The loss of oocytes (and follicles) through atresia is a response to changes in many factors. Certainly, gonadotropin stimulation and withdrawal are important, but ovarian

steroids and autocrine and paracrine factors are also involved. The consequence of these unfavorable changes, atresia, is a process called **apoptosis**, programmed cell death. This process is heralded by alterations in mRNAs required for cell proteins that maintain follicle integrity.<sup>93</sup> Indeed, the process is a consequence of an orderly expression of key gene products that either promote or repress the apoptotic events.

Human ovaries and nonhuman primate ovaries are innervated by sympathetic and sensory neurons.<sup>94</sup> This neuronal network innervates the ovarian vasculature, interstitial tissue, and developing follicles. The neurons are connected synaptically to the paraventricular nucleus of the hypothalamus.<sup>95</sup> These neuronal cells produce catecholamines and nerve growth factor. The precise function of this unique ovarian nervous system is not known. Vasoactive intestinal peptide derived from these nerve fibers suppresses follicular atresia (apoptosis) in a mechanism that also involves IGF-1.<sup>96</sup> It has been suggested that sympathetic innervation of the ovary continues to develop at puberty and that neurotransmitters are involved in the process in which follicles acquire FSH receptors and respond to FSH.<sup>97,98</sup>

During the reproductive years, the typical cycle of follicle maturation, including ovulation and corpus luteum formation, is realized. This results from the complex but well-defined sequence of hypothalamic-pituitary-gonadal interactions in which follicle and corpus luteum steroid hormones, pituitary gonadotropins, and autocrine and paracrine factors are integrated to yield ovulation. These important events are described in detail in [Chapters 4](#) and [5](#). For the moment, our attention is exclusively directed to a description of the events as the gonad is driven inexorably to final and complete exhaustion of its germ cell supply. The major feature of this reproductive period in the ovary's existence is the full maturational expression of some follicle units in ovulation and corpus luteum formation and the accompaniment of varying steroid output of estradiol and progesterone. For every follicle that ovulates, close to 1,000 will pursue abortive growth periods of variable length.

# Follicular Growth

In the adult ovary, the stages of follicle development observed in the prenatal period are repeated but to a more complete degree. Progression from primordial to primary follicle occurs, and the zona pellucida begins to form, followed by further enlargement of the oocyte enlarges and marked proliferation of the granulosa cells. A solid sphere of cells encasing the oocyte is formed. At this point, the theca interna is noted in initial stages of formation.

The time that elapses in progressing from a primary follicle to ovulation is approximately 85 days.<sup>99,100</sup> The majority of this time passes in development that is independent of gonadotropins, achieving a state of readiness that will yield further growth in response to FSH stimulation. If gonadotropin increments are available, as can be seen early in a menstrual cycle, a further FSH-dependent stage of follicle maturation is seen. The number of follicles that mature is dependent on the amount of FSH available to the gonad and the sensitivity of the follicles to the gonadotropins. FSH receptor expression is greatest in granulosa cells, but significant expression can be detected in ovarian surface epithelium and fallopian tube epithelium, where the function is uncertain, but a role in epithelium-derived tumors is possible.<sup>101</sup>

The antrum first appears as a coalescence of numerous cavities between granulosa cells called Call-Exner bodies, which were described by Emma Call and Siegmund Exner in Vienna, in 1875. Emma Call was one of the first woman physicians in the United States.<sup>102</sup> After receiving her medical degree from the University of Michigan in 1873, she went to Vienna as Exner's postgraduate student. She returned to Boston and practiced as an obstetrician for more than 40 years. Emma Call was the first woman elected to the Massachusetts Medical Society (in 1884). Her description of the Call-Exner bodies was her only publication.

Whether Call-Exner bodies represent liquefaction or granulosa cell secretion is uncertain. At first, the cavity is filled with a coagulum of cellular debris. Soon a liquor accumulates, which is essentially a transudation of blood filtered through the avascular granulosa from the theca vessels. With antral formation, the theca interna develops more fully, expressed by increased cell mass, increased vascularity, and the formation of lipid-rich cytoplasmic vacuoles within the theca cells. As the follicle expands, the surrounding stroma is compressed and is called the theca externa.

The granulosa cells that surround the oocyte are avascular and separated from the surrounding stroma by a basement membrane. Deprived of a vascular supply until after ovulation, the granulosa cells depend on specialized gap junctions that connect cells and communicate with the oocyte for the purpose of metabolic exchange and the transport of signaling molecules. It is this structure that allows repression and stimulation for the

correct timing of meiosis. The granulosa cells differ in function and activity; for example, LH receptor concentrations are highest in those cells closest to the basement membrane and lowest in those that surround the oocyte.<sup>103</sup>

At any point during follicle development, individual follicles may become arrested and eventually regress through an apoptotic process known as atresia. At first, the granulosa component begins to disrupt. The antral cavity constituents are resorbed, and the cavity collapses and obliterates. The oocyte degenerates in situ. Finally, a ribbon-like scarred streak surrounded by theca is seen. Eventually, this theca mass loses its lipid and becomes indistinguishable from the growing mass of stroma. Thus, the process of apoptosis is extensive in the granulosa, and the theca layer is largely spared to be incorporated into the interstitial tissue. Prior to regression, cystic follicles can be retained in the cortex for variable periods of time.

# Ovulation

If gonadotropin stimulation is adequate, one of the several follicle units propelled to varying degrees of maturity will advance to ovulation. Morphologically, these events include distention of the antrum by increments of antral fluid and compression of the granulosa against the limiting membrane separating the avascular granulosa and the luteinized, vascularized theca interna. In addition, the antral fluid increment gradually pinches off the cumulus oophorus, the mound of granulosa enveloping the oocyte. The mechanisms of the thinning of the theca over the surface of the now protruding, distended follicle, the creation of an avascular area weakening the ovarian capsule, and the final acute distention of the antrum with rupture and extrusion of the oocyte in its cumulus are multiple and complex (discussed in [Chapter 6](#)). Repeated evaluation of intrafollicular pressures has failed to indict an explosive factor in this crucial event ([Figure 2.5](#)).

**FIGURE 2.5**

As demonstrated in a variety of animal experiments, the physical expulsion of the oocyte is dependent on a preovulatory surge in prostaglandin synthesis within the follicle. Inhibition of this prostaglandin synthesis produces a corpus luteum with an entrapped oocyte. Both prostaglandins and the midcycle surge of gonadotropins are thought to increase the concentration and activity of local proteases, such as plasminogen conversion to plasmin. As a result of generalized tissue weakening (loss of intercellular gap junction integrity and disruption of elastic fibers), there is swift accumulation of antral fluid followed by rupture of the weakened tissue envelope surrounding the follicle.

# Corpus Luteum

Shortly after ovulation, profound alterations in cellular organization occur in the ruptured follicle that go well beyond simple repair. After tissue integrity and continuity are retrieved, the granulosa cells hypertrophy markedly, gradually filling in the cystic, sometimes hemorrhagic, cavity of the early corpus luteum. In addition, for the first time, the granulosa becomes markedly luteinized by incorporation of lipid-rich vacuoles within its cytoplasm. Both these properties had been the exclusive features of the theca prior to ovulation. For its part, the theca of the corpus luteum becomes less prominent, vestiges being noted eventually only in the interstices of the typical scalloping of the mature corpus luteum. As a result, a new yellow body is formed, now dominated by the enlarged, lipid-rich, fully vascularized granulosa. In the 14 days of its life, dependent on the low but important quantities of LH available in the luteal phase, this unit produces estradiol and progesterone. Unless rescued by rising levels of hCG from a successful implantation, the corpus luteum rapidly ages. Its vascularity and lipid content wane, and the sequence of scarification (albicantia) ensues.

# Modulators of Function

The complex events that yield an ovum for fertilization and ovarian structures that provide hormonal secretion are the products of essentially every regulating mechanism in human biology. This includes classic endocrine signals, autocrine and paracrine/intracrine regulation, neuronal input, and immune system contributions. Representatives of the white blood cell series constitute a major component of the ovarian stromal (interstitial) compartment. Macrophages present in permanent, noncyclic numbers may influence ovarian function through the secretion of regulatory cytokines.<sup>104</sup> During the adult ovarian cycle, there is an infiltration of white blood cells in a pattern characterized by increasing numbers of mast cells culminating in degranulation and release of histamine that is associated with hyperemia at ovulation.<sup>105</sup> The corpus luteum attracts eosinophils and T lymphocytes, which signal and activate monocytes and macrophages involved in luteolysis. However, this immune mechanism should be viewed not just as a healing and resolving response but also as an important regulatory system (involving the secretion of cytokines and growth factors) for ovarian function.<sup>104</sup>

# The Uterus, Endometrial Physiology, and Menstruation

Anatomic knowledge of the uterus was slow to accumulate.<sup>1,2</sup> Papyrus writings from 2500 B.C. indicate that the ancient Egyptians made a distinction between the vagina and uterus. Because the dead had to be embalmed, dissection was precluded, but prolapse was recognized because it was important to return the uterus into its proper place prior to mummification. Next to the Egyptian papyri in antiquity were Hindu writings in which descriptions of the uterus, tubes, and vagina indicate knowledge gained from dissections. This was probably the earliest description of the fallopian tubes.

There is little information in Greek writings about female anatomy; however, Herophilus (fourth century B.C.), the great anatomist in Alexandria and the originator of scholarly dissection, recorded the different positions of the uterus. Soranus of Ephesus (98–138 A.D.) accurately described the uterus (probably the first to do so), obviously from multiple dissections of cadavers. He recognized that the uterus is not essential for life, acknowledged the presence of leiomyomas, and treated prolapse with pessaries.

Herophilus and Soranus were uncertain about the function of the fallopian tubes, but Galen, Rufus, and Aetisu correctly guessed their function. Galen promoted the practice of bleeding for the treatment of almost every disorder. In his argument that nature prevented disease by discharging excess blood, Galen maintained that women were healthier because their superfluous blood was eliminated by menstruation.<sup>3</sup> The writings of Galen (130–200 A.D.) represented the knowledge of medicine for over 1,000 years until the end of the medieval Dark Ages. Galen's description of the uterus and tubes indicates that he had only seen the horned uteri of animals.

In the 16th century, Berengarius, Vesalius, Eustachius, and Fallopius made significant contributions to the anatomic study of the female genitalia. Berengarius (Giacomo Berengario da Carpi) was the first anatomist to work with an artist. His anatomic text, published in 1514, depicted dissected subjects as if they were still alive.

Gabriele Fallopio (or Fallopius) published his work, *Observationes Anatomicae*, in Venice in 1561, 1 year before his death from pleurisy at age 40. He provided the first descriptions of the clitoris and the hymen and the first exact descriptions of the ovaries and the tubes. He named the vagina and the placenta and called the tubes the uteri tuba (the trumpet of the uterus), but soon they were known universally as the fallopian tubes.

It was his professor and mentor at the University of Padua, however, Andreas Vesalius, who was the first to accurately reveal the presence of the endometrial cavity.

# DEVELOPMENT OF THE MÜLLERIAN SYSTEM

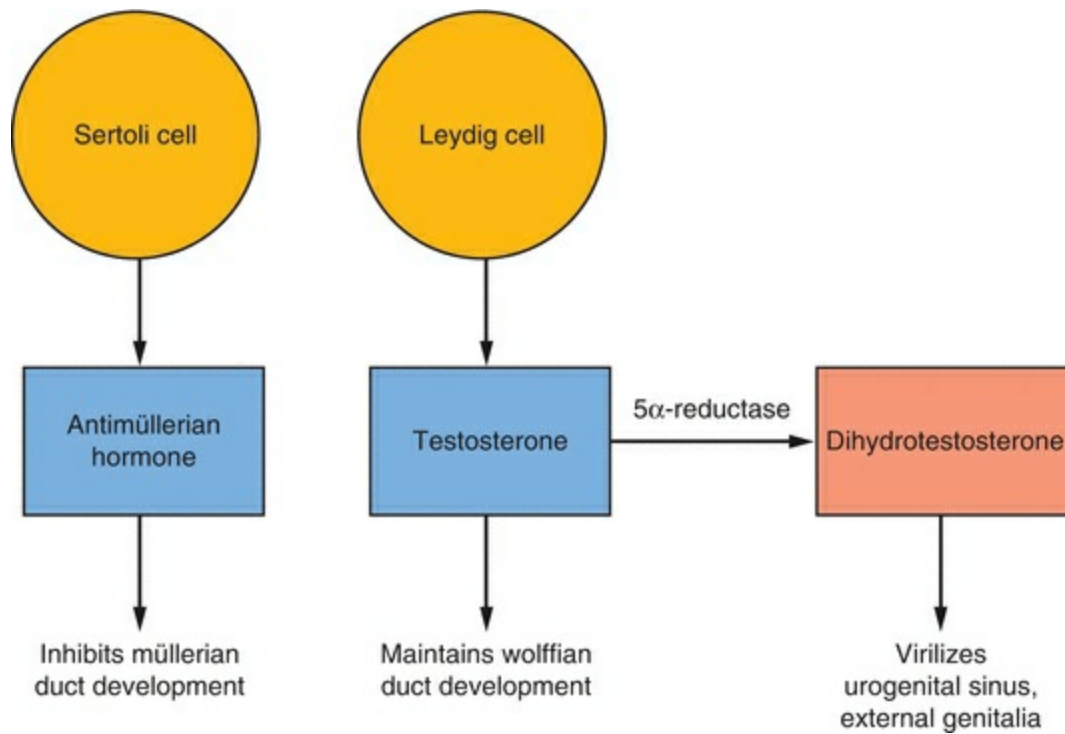

---

The Wolffian (mesonephric) and müllerian (paramesonephric) ducts are discrete primordia that temporarily coexist in all embryos during the ambisexual period of development (up to 8 weeks). Thereafter, one type of duct system persists normally and gives rise to special ducts and glands, whereas the other disappears during the 3rd fetal month, except for nonfunctional vestiges.

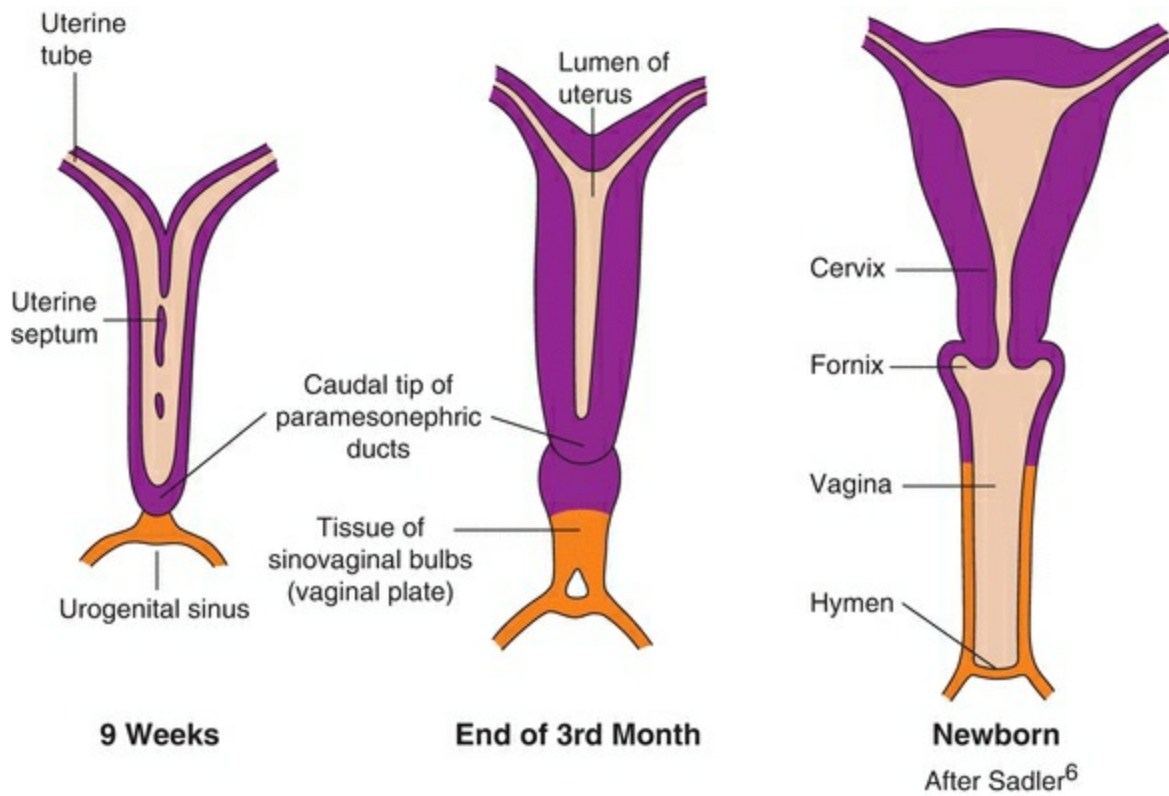

Hormonal control of mammalian somatic sex differentiation was established by the classic experiments of Alfred Jost.<sup>4</sup> In Jost's landmark studies, the active role of male-determining factors, as opposed to the constitutive nature of female differentiation, was defined as the directing feature of sex differentiation. This principle applies not only to the internal ducts but to the gonad, the external genitalia, and even the brain. The critical factors in determining which of the duct structures stabilize or regress are the secretions from the testes: AMH (antimüllerian hormone, also known as müllerian-inhibiting substance or müllerian-inhibiting factor) and testosterone.

The internal genitalia possess the intrinsic tendency to feminize. In the absence of a Y chromosome and a functional testis, the lack of AMH allows retention of the müllerian system and development of fallopian tubes, uterus, and upper vagina. In the absence of testosterone, the Wolffian system regresses. In the presence of a normal ovary or the absence of any gonad, müllerian duct development takes place. This process is discussed in greater detail in [Chapter 8](#).

AMH is a member of the transforming growth factor- $\beta$  (TGF- $\beta$ ) family of glycoprotein differentiation factors that include inhibin and activin. During fetal development, AMH shows a sex-dimorphic expression pattern as it is only expressed by the fetal testis but not ovary. AMH is synthesized by Sertoli cells soon after testicular differentiation and acts upon their respective type II receptors located on the surface of the müllerian ducts resulting in their ipsilateral regression by 8 weeks. Mutations in the AMH gene, located on chromosome 19p13.3, cause persistent müllerian duct syndrome (PMDS), characterized by the presence of a uterus, fallopian tubes, and the upper part of the vagina in otherwise phenotypically normal males.<sup>5</sup> In the absence of AMH, the fetus will develop fallopian tubes, uterus, and upper vagina from the paramesonephric ducts (the müllerian ducts). This development requires the prior appearance of the mesonephric ducts, and for this reason, abnormalities in the development of the tubes, uterus, and upper vagina are associated with abnormalities in the renal system ([Figures 3.1 and 3.2](#)).<sup>6</sup>

**FIGURE 3.1**

**FIGURE 3.2**

In the late fetal life of human, the sex-dimorphic AMH expression pattern is lost as AMH begins to be produced by the granulosa cells within the ovary, the timing of which is well-coordinated since müllerian duct differentiation is complete by this point. For many years, the function of AMH was thought to be restricted to in utero fetal sexual differentiation until the late 20th century, when other discoveries revealed that AMH plays an important role in postnatal ovarian biology, transforming the field of clinical reproductive medicine.<sup>7</sup> The role of AMH in female ovarian biology is discussed in [Chapter 5](#) in greater detail.

The paramesonephric ducts come into contact in the midline to form a Y-shaped structure, the primordium for the uterus, tubes, and the upper approximately one-third of the vagina.<sup>8</sup> The fallopian tubes, the uterus, and the upper portion of the vagina are created by the fusion of the müllerian ducts by the 10th week of gestation. Canalization to create the uterine cavity, the cervical canal, and the vagina is complete by the 22nd week of gestation. Under the epithelium lies mesenchymal tissue that will be the origin of the uterine stroma and smooth muscle cells. By the 20th week of pregnancy, the uterine mucosa is fully differentiated into the endometrium.

The endometrium, derived from the mucosal lining of the fused müllerian ducts, is essential for reproduction and may be one of the most complex tissues in the human body. It is always changing, responding to the cyclic patterns of estrogen and progesterone of the ovarian menstrual cycle and to a complex interplay among its own autocrine and paracrine factors.

# THE HISTOLOGIC CHANGES IN THE ENDOMETRIUM DURING AN OVULATORY CYCLE

---

The sequence of endometrial changes associated with an ovulatory cycle has been carefully studied by Noyes in the human and Bartlemez and Markee in the subhuman primate.<sup>9,10,11,12,13</sup> From these data, a description of menstrual physiology has been developed based on specific anatomic and functional changes within glandular, vascular, and stromal components of the endometrium.<sup>14,15,16</sup> These changes will be discussed in five phases: (1) the menstrual endometrium, (2) the proliferative phase, (3) the secretory phase, (4) the preparation for implantation, and (5) finally, the phase of endometrial breakdown. Although these distinctions are not entirely arbitrary, it must be recalled that the entire process is an integrated evolutionary cycle of endometrial growth and regression, which is repeated some 400 times during the adult life of the human female.

The endometrium can be divided morphologically into an upper two-thirds “functionalis” layer and a lower one-third “basalis” layer. The purpose of the functionalis layer is to prepare for the implantation of the blastocyst; therefore, it is the site of proliferation, secretion, and degeneration. The purpose of the basalis layer is to provide the regenerative endometrium following menstrual loss of the functionalis<sup>17</sup> (**Figure 3.3**).

**FIGURE 3.3**

# The Uterine Vasculature

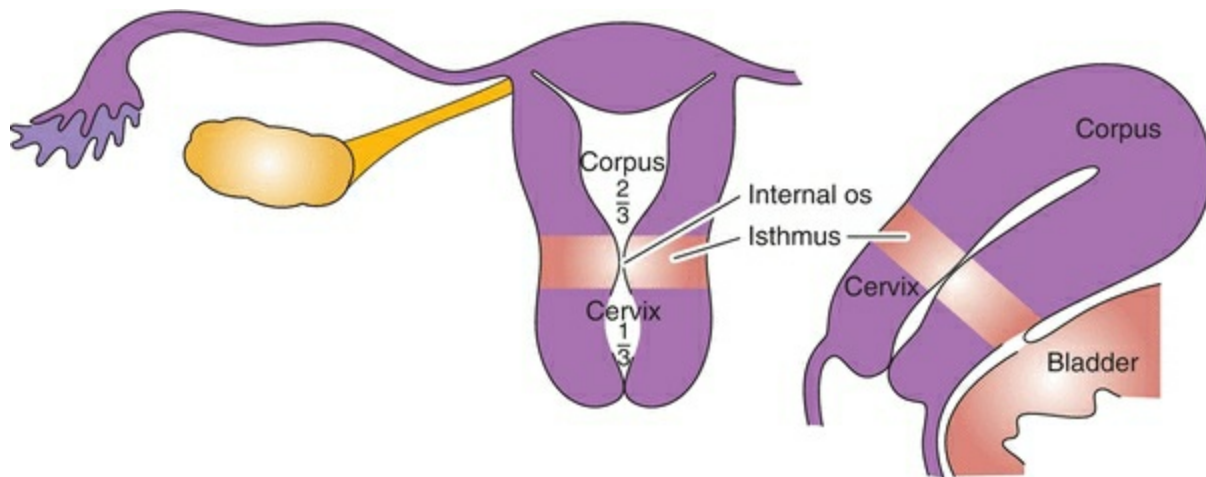

The two uterine arteries that supply the uterus are branches of the internal iliac arteries. At the lower part of the uterus, the uterine artery separates into the vaginal artery and an ascending branch that divides into the arcuate arteries. The arcuate arteries run parallel to the uterine cavity and anastomose with each other, forming a vascular ring around the cavity. Small centrifugal branches (the radial arteries) leave the arcuate vessels, perpendicular to the endometrial cavity, to supply the myometrium. When these arteries enter the endometrium, small branches (the basal arteries) extend laterally to supply the basalis layer. These basal arteries do not demonstrate a response to hormonal changes. The radial arteries continue in the direction of the endometrial surface, now assuming a corkscrew appearance (and now called the spiral arteries), to supply the functionalis layer of the endometrium. It is the spiral artery (an end artery) segment that is very sensitive to hormonal changes. One reason that the functionalis layer is more vulnerable to vascular ischemia is that there are no anastomoses among the spiral arteries. The endometrial glands and the stromal tissue are supplied by capillaries that emerge from the spiral arteries at all levels of the endometrium. The capillaries drain into a venous plexus and eventually into the myometrial arcuate veins and into the uterine veins. This unique vascular architecture is important in allowing a repeated sequence of endometrial growth and desquamation.

# The Menstrual Endometrium

The menstrual endometrium is a relatively thin but dense tissue. It is composed of the stable, basalis component and a variable, but small, amount of residual stratum spongiosum. At menstruation, this latter tissue displays a variety of functional states including disarray and breakage of glands, fragmentation of vessels and stroma with persisting evidence of necrosis, white cell infiltration, and red cell interstitial diapedesis. Even as the remnants of menstrual shedding dominate the overall appearance of this tissue, evidence of repair in all tissue components can be detected. Endometrial regeneration originates in epithelial and stromal stem cells. The first evidence for the existence of adult stem cells in the endometrium was provided in 2004. It was reported by the group of Taylor at Yale that some epithelial cells and stromal cells of human endometrium in HLA-antigen-mismatched bone marrow transplant recipients were of donor origin.<sup>7</sup> Concurrently, the group of Caroline Gargett showed rare clonogenic cell populations in purified populations of human endometrial epithelial and stromal cells isolated from hysterectomy tissues.<sup>8</sup> Since then, adult endometrial stem cells have been further characterized in humans and animal models. Endometrial epithelial stem cells have been found in glands within the basalis layer and are thought to be responsible for the reepithelialization of the exposed surface of the endometrium and subsequent glandular proliferation to regenerate the functionalis layer under the influence of increasing estrogen levels following menses.<sup>19</sup> Endometrial mesenchymal stem/progenitor cells are found around blood vessels in the basalis layer. These progenitor cells are thought to contribute to regeneration and growth of the endometrial functionalis stroma.<sup>19</sup>

The menstrual endometrium is a transitional state bridging the more dramatic proliferative and exfoliative phases of the cycle. Its density implies that the shortness of height is not entirely due to desquamation. Collapse of the supporting matrix also contributes significantly to the shallowness. Reticular stains in rhesus endometrium confirm this “deflated” state (**Figure 3.4**). Nevertheless, as much as two-thirds of the functioning endometrium is lost during menstruation. The more rapid the tissue loss, the shorter the duration of flow. Delayed or incomplete shedding is associated with heavier flow and greater blood loss.

**FIGURE 3.4**

DNA synthesis is occurring in those areas of the basalis that have been completely denuded by days 2–3 of the menstrual cycle (the endometrium in the isthmic area, the narrow area between the cervix and the corpus, and the endometrium in the cornual recesses at the ostia of the tubes remain intact). The new surface epithelium emanates from the flanks of stumps of glands in the basalis layer left standing after menstrual desquamation.<sup>20</sup> Rapid re-epithelialization follows the proliferation of the cells in the basalis layer and the surface epithelium in the isthmic and tubal ostial endometrium. This epithelial repair is supported by underlying fibroblasts and stem cells. The stromal fibroblast layer forms a compact mass over which the resurfacing epithelium can “migrate.” In addition, it is likely that the stromal layer contributes important autocrine and paracrine factors for growth and migration. Because hormone levels are at their nadir during this repair phase, the response may be due to injury rather than hormone mediated. However, the basalis layer is rich in its content of estrogen receptors. This “repair” is fast; by day 4 of the cycle, more than two-thirds of the cavity is covered with new epithelium.<sup>20</sup> By days 5–6, the entire cavity is re-epithelialized, and stromal growth begins.

## The Proliferative Phase

The proliferative phase is associated with ovarian follicle growth and increased estrogen secretion. Undoubtedly as a result of this steroidal action, reconstruction and growth of the endometrium are achieved. The glands are most notable in this response. At first, they are narrow and tubular, lined by low columnar epithelium cells. Mitoses become prominent, and pseudostratification is observed. As a result, the glandular epithelium extends peripherally and links one gland segment with its immediate neighbor. A continuous epithelial lining facing the endometrial cavity is formed. The stromal component evolves from its dense cellular menstrual condition through a brief period of edema to a final loose syncytial-like status. Coursing through the stroma, spiral vessels extend (unbranched and uncoiled in the early proliferative phase) to a point immediately below the epithelial binding membrane. Here, they form a loose capillary network. All of the tissue components (glands, stromal cells, and endothelial cells) demonstrate proliferation, which peaks on days 8–10 of the cycle, reflecting rising estradiol levels in the circulation and maximal estrogen receptor concentration in the endometrium.<sup>21</sup> This proliferation is marked by increased mitotic activity and increased nuclear DNA and cytoplasmic RNA synthesis, which is most intense in the functionalis layer in the upper two-thirds of the uterus, the usual site of blastocyst implantation.

During proliferation, the endometrium grows from approximately 0.5 mm to 3.5–6.0 mm in height of each singular apposed layer, corresponding to the trilaminar endometrium seen on ultrasound imaging; this image includes endometrium originating from both sides of the uterus and the junction of the two. Restoration of tissue constituents has been achieved by estrogen-induced new growth as well as incorporation of ions, water, and amino acids. The stromal ground substance has reexpanded from its menstrual collapse. Although true tissue growth has occurred, a major element in the achievement of endometrial height is “re-inflation” of the stroma. Factors that regulate the limits of endometrial growth are not well defined. While estrogen exposure is necessary, normal endometrial growth reaches its peak by cycle days 9–10, a time when estradiol levels have not yet reached its peak.<sup>22</sup> The factors that limit endometrial growth remain to be characterized.

An important feature of this estrogen-dominant phase of endometrial growth is the increase in ciliated and microvillous cells. Ciliogenesis begins on days 7–8 of the cycle.<sup>20</sup> This response to estrogen is exaggerated in hyperplastic endometrium that is the result of hyperestrogenism. The concentration of these ciliated cells around gland openings and the ciliary beat pattern influence the mobilization and distribution of endometrial secretions during the secretory phase (**Figure 3.5**). Cell surface microvilli, also a response to estradiol, are cytoplasmic extensions and serve to increase the active

surface of cells.

Early Proliferative

**FIGURE 3.5**

At all times, a large number of hematopoietic cells derived from the bone marrow are present in the endometrium. These include lymphocytes and macrophages, diffusely distributed in the stroma (**Figure 3.6**).

Late Proliferative

**FIGURE 3.6**

# The Secretory Phase

After ovulation, the endometrium now demonstrates a combined reaction to estrogen and progesterone activity (**Figure 3.7**). Most impressive is that total endometrial height is fixed at roughly its preovulatory extent (5–6 mm) despite continued availability of estrogen. Epithelial proliferation ceases 3 days after ovulation.<sup>23</sup> Progesterone receptor expression in endometrial cells is stimulated by rising estrogens in the follicular phase via estrogen receptor- $\alpha$  (ER- $\alpha$ ), leading to augmented progesterone responsiveness during the luteal phase.<sup>24</sup> Conversely, ER- $\alpha$  expression in endometrial cells is inhibited by progesterone via progesterone receptors.<sup>25</sup>

Early Secretory

**FIGURE 3.7**

Progesterone action is central to the changes that the endometrium undergoes in the secretory phase, which are geared toward preparing it for embryo implantation. Differential effects of progesterone on endometrial epithelial and stromal cells are

thought to be due to cell type-specific differences in PR-A and PR-B expression and function. PR-A and PR-B are present in endometrial epithelium during the proliferative phase and increase with rising estrogen levels, consistent with the known induction of PR expression by estrogen. In the endometrial epithelial compartment, PR-A levels decline toward the end of the secretory phase, whereas PR-B levels remain constant, suggesting that PR-B plays a role in the control of glandular secretion. In the stromal cell compartment, in contrast, PR-A is the predominant isoform throughout the menstrual cycle, which likely reflects the requirement for prolonged progesterone-PR-A signaling in this compartment to support decidualization and the establishment of pregnancy.<sup>26,27</sup>

The action of progesterone in the uterus has been revealed through studies utilizing PR antagonists such as mifepristone (RU486) for emergency contraception as well as knockout mice. Administration of RU486 at low doses in the mid or late follicular phase causes infertility by delaying endometrial maturation, while it delays the LH surge and inhibits ovulation at higher doses.<sup>28,29</sup> If administered during pregnancy, it induces abortion, fetal loss, or parturition depending on the gestational age.<sup>30,31</sup>

Genetic mouse models harboring defects in PR expression have been instrumental in dissecting the crucial roles of PRs in mediating progesterone actions on the uterus. Mice with global PR knockout are infertile due to defects in ovulation and implantation. Their endometrium is characterized by hypertrophy and inflammation of the glandular epithelium and failure to undergo decidualization.<sup>32</sup> Mice with PR-B-specific knockout, however, have normal ovarian function, implantation, pregnancy, and parturition, suggesting that PR-A is sufficient for normal uterine function.<sup>33</sup> PR-A-null mice exhibit endometrial epithelial hyperplasia and inflammation, and no decidualization in the endometrial stroma,<sup>34</sup> suggesting that PR-A is critical for normal function of the endometrial epithelium and stroma and that PR-B functions to promote hyperplasia of the epithelium, an effect which is repressed by PR-A.

The progesterone-induced limitation of growth is associated with a decline in mitosis and DNA synthesis, significantly due to progesterone interference with estrogen receptor expression and progesterone stimulation of 17 $\beta$ -hydroxysteroid dehydrogenase and sulfotransferase, which convert estradiol to estrone sulfate (which is rapidly excreted from the cell).<sup>35,36</sup> In addition, estrogen stimulates many oncogenes that probably mediate estrogen-induced growth. Progesterone antagonizes this action by suppressing the estrogen-mediated transcription of oncogene mRNA.<sup>37</sup>

Individual components of the tissue continue to display growth, but confinement in a fixed structure leads to progressive tortuosity of glands and intensified coiling of the spiral vessels. The secretory events within the glandular cells, with progression of vacuoles from intracellular to intraluminal appearance, are well known and take place over a 7-day postovulatory interval. At the conclusion of these events, the glands appear

exhausted, the tortuous lumina variably distended, and individual cell surfaces fragmented in a sawtooth appearance. Stroma is increasingly edematous, and spiral vessels are prominent and densely coiled.

The first histologic sign that ovulation has occurred is the appearance of subnuclear intracytoplasmic glycogen vacuoles in the glandular epithelium on cycle days 17–18 (**Figure 3.8**). Giant mitochondria and the “nucleolar channel system” appear in the gland cells. The nucleolar channel system has a unique appearance due to progesterone, an infolding of the nuclear membranes. These structural alterations are soon followed by active secretion of glycoproteins and peptides into the endometrial cavity. Transudation of plasma also contributes to the endometrial secretions. Important immunoglobulins are obtained from the circulation and delivered to the endometrial cavity by binding proteins produced by the epithelial cells. The peak secretory level is reached 7 days after the midcycle gonadotropin surge, coinciding with the time of blastocyst implantation.

Late Secretory

**FIGURE 3.8**

# The Implantation Phase

Significant changes occur within the endometrium from the 7th to the 13th day of postovulation (days 21–27 of the cycle). At the onset of this period, the distended tortuous secretory glands have been most prominent with little intervening stroma. By 13 days of postovulation, the endometrium has differentiated into three distinct zones. Something less than one-fourth of the tissue is the unchanged basalis fed by its straight vessels and surrounded by indifferent spindle-shaped stroma. The midportion of the endometrium (approximately 50% of the total) is the lace-like **stratum spongiosum**, composed of loose edematous stroma with tightly coiled but ubiquitous spiral vessels and exhausted dilated glandular ribbons. Overlying the spongiosum is the superficial layer of the endometrium (about 25% of the height) called the **stratum compactum**. Here, the prominent histologic feature is the stromal cell, which has become large and polyhedral. In its cytoplasmic expansion, one cell abuts the other, forming a compact, structurally sturdy layer. The necks of the glands traversing this segment are compressed and less prominent. The subepithelial capillaries and spiral vessels are engorged.

At the time of implantation, on days 21–22 of the cycle, the predominant morphologic feature is edema of the endometrial stroma. This change may be secondary to the estrogen- and progesterone-mediated increase in prostaglandin and vascular endothelial growth factor (VEGF) production by the endometrium that cause an increase in capillary permeability. Receptors for the sex steroids are present in the muscular walls of the endometrial blood vessels, and the enzyme system for prostaglandin synthesis is present in both the muscular walls and the endothelium of the endometrial arterioles. Mitoses are first seen in endothelial cells on cycle day 22. Vascular proliferation leads to the coiling of the spiral vessels, a response to the sex steroids, the prostaglandins, and the autocrine and paracrine factors produced in response to estrogen and progesterone.

During the secretory phase, ovulation and rising ovarian P4 production promote a marked increase in leukocyte numbers, reaching up to 40% of all endometrial cells in the mid-late secretory phase of the menstrual cycle. This gain in leukocyte numbers is primarily due to the accumulation of uterine natural killer (uNK) cells, reaching a peak concentration in the first trimester of pregnancy. These are specialized granulocytes that have an immunoprotective role in implantation and placentation. Their role in promoting decidual spiral artery vascular remodeling has been recently recognized, which may have important implications for pregnancy pathologies.<sup>38</sup> They are located perivascularly and are believed to be derived from the blood. By days 26–27, the endometrial stroma is infiltrated by many leukocytes, the majority of which are natural killer cells and macrophages, believed to be involved in the process of endometrial breakdown and menstruation. The appearance and function of these cells are regulated

by the complex array of peptides and cytokines in the endometrium in response to hormonal signaling. In addition to uNK cells and macrophages, the endometrium contains scattered T cells with no apparent cycle-dependent changes and uterine dendritic cells (uDCs), which are rare in the luteal endometrium but more abundant in the decidua of pregnancy.<sup>39</sup>

The gene expression pattern in the endometrium throughout the menstrual cycle is being established, with a focus on the implantation window.<sup>40,41,42,43,44</sup> As expected, microarray analyses reveal a changing pattern of gene expression that correlates with each hormonal and morphologic stage in the endometrial menstrual cycle.<sup>45</sup> Ultimately, this will yield a comprehensive picture, with the gene signature of each event in the estrogen and progesterone regulation of the endometrium. The regulating growth factors, cytokines, and peptide hormones that are essential for implantation as well as the aberration in their expression, which may underlie endometrial pathologies such as recurrent implantation failure, will be identified.

The stromal cells of the endometrium respond to hormonal signals, synthesize prostaglandins, and, when transformed into decidual cells, produce an impressive array of substances, some of which are prolactin, relaxin, renin, insulin-like growth factors (IGFs), and insulin-like growth factor-binding proteins (IGFBPs). The endometrial stromal cells, the progenitors of decidual cells, were originally suggested to be derived from the bone marrow (from cells invading the endometrium during fetal life), but they were later considered to originate from the primitive uterine mesenchymal stem cells.<sup>46</sup> More recent evidence from humans and animal models supports the notion that at least some of these endometrial stromal cells are derived from adult bone marrow progenitors.<sup>18,47,48,49</sup> Interestingly, recent evidence in mice suggests that a substantial population of decidual cells is derived from adult bone marrow progenitors and that this nonhematopoietic contribution of bone marrow may be important to implantation and pregnancy.<sup>50</sup>

The decidualization process begins in the luteal phase under the influence of progesterone and mediated by autocrine and paracrine factors. On cycle days 22–23, predecidual cells can be identified, initially surrounding blood vessels, characterized by cytonuclear enlargement, increased mitotic activity, and the formation of a basement membrane. The decidua, derived from stromal cells, becomes an important structural and biochemical tissue of pregnancy. Decidual cells control the invasive nature of the trophoblast, and the products of the decidua play important autocrine and paracrine roles in fetal and maternal tissues. This is discussed in greater detail in [Chapter 7](#).

Decidual cells play a key role in both the process of endometrial bleeding (menstruation) and the process of endometrial hemostasis (implantation and placentation).<sup>51,52,53</sup> Implantation requires endometrial hemostasis and the maternal

uterus requires resistance to invasion. Inhibition of endometrial hemorrhage can be attributed, to a significant degree, to appropriate changes in critical factors as a consequence of decidualization, for example, lower plasminogen activator levels, reduced expression of the enzymes that degrade the stromal extracellular matrix (such as the metalloproteinases), and increased levels of plasminogen activator inhibitor-1 (PAI-1). Withdrawal of estrogen and progesterone support, however, leads to changes in the opposite directions, consistent with endometrial breakdown.

# The Phase of Endometrial Breakdown

Predecidual transformation has formed the “compacta” layer in the upper part of the functionalis layer by day 25 (3 days before menstruation). In the absence of fertilization and implantation and the consequent lack of sustaining quantities of human chorionic gonadotropin from the trophoblast, the otherwise fixed life span of the corpus luteum is completed, and estrogen and progesterone levels wane.

The withdrawal of estrogen and progesterone initiates important endometrial events: vasomotor reactions, the process of apoptosis, tissue loss, and, finally, menstruation. The most prominent immediate effect of this hormone withdrawal is a modest shrinking of the tissue height and remarkable spiral arteriole vasomotor responses. The classic concept of the vascular sequence was constructed from direct observations of rhesus endometrium transplanted to the anterior chamber of the eye.<sup>9,10</sup> With shrinkage of height, blood flow within the spiral vessels diminished, venous drainage was decreased, and vasodilation ensued. Thereafter, the spiral arterioles underwent rhythmic vasoconstriction and relaxation. Each successive spasm was more prolonged and profound, leading eventually to endometrial blanching. Thus, these reactions were proposed to lead to menstruation because of endometrial ischemia and stasis caused by vasoconstriction of the spiral arterioles. A new model of menstruation, as discussed in [Chapter 15](#), emphasizes enzymatic autodigestion of the functional layer of the endometrium and its capillary plexus.

In the first half of the secretory phase, acid phosphatase and potent lytic enzymes are confined to lysosomes. Their release is inhibited by progesterone stabilization of the lysosomal membranes. With the waning of estrogen and progesterone levels, the lysosomal membranes are not maintained, and the enzymes are released into the cytoplasm of epithelial, stromal, and endothelial cells and eventually into the intercellular space. These active enzymes will digest their cellular constraints, leading to the release of prostaglandins, extravasation of red blood cells, tissue necrosis, and vascular thrombosis. This process is one of **apoptosis** (programmed cell death, characterized by a specific morphologic pattern that involves cell shrinkage and chromatin condensation culminating in cell fragmentation) mediated by cytokines.<sup>54</sup> An important step in this breakdown is the dissolution of cell-to-cell adhesion by key proteins. Binding of endometrial epithelial cells utilizes transmembrane proteins, **cadherins** that link intercellularly with each other and intracellularly with catenins that are bound to actin filaments<sup>55</sup> ([Figure 3.9](#)).

Menstruation

**FIGURE 3.9**

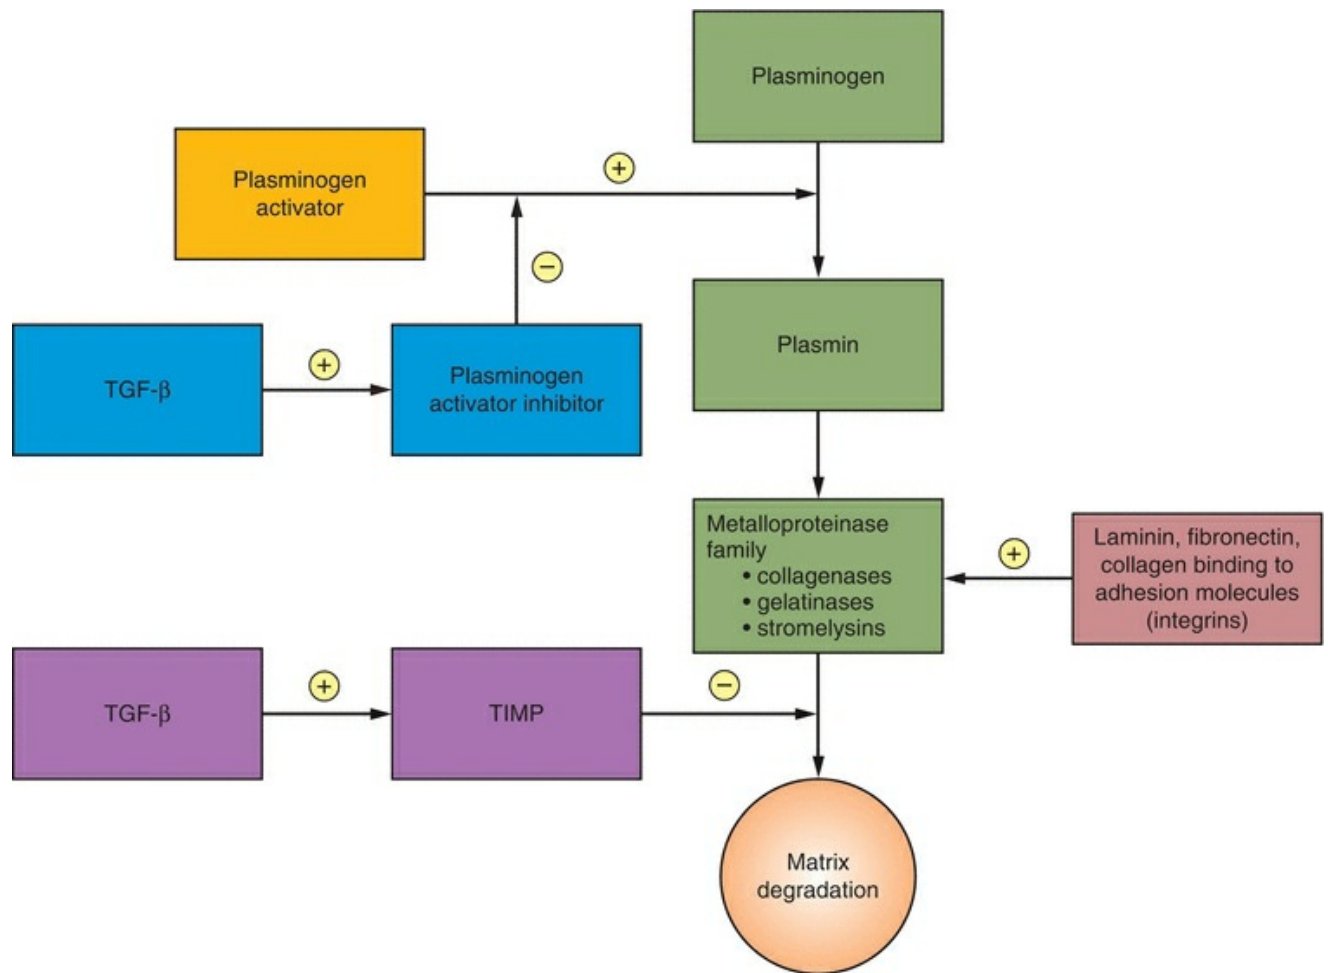

Endometrial tissue breakdown also involves a family of enzymes, matrix metalloproteinases (MMPs), that degrade components (including collagens, gelatins, fibronectin, and laminin) of the extracellular matrix and basement membrane.<sup>56,57</sup> The metalloproteinases include collagenases that degrade interstitial and basement membrane collagens, gelatinases that further degrade collagens, and stromelysins that degrade fibronectin, laminin, and glycoproteins. The expression of metalloproteinases in human endometrial stromal cells follows a pattern correlated with the menstrual cycle, indicating a sex steroid response as part of the growth and remodeling of the endometrium with a marked increase in late secretory and early menstrual endometrium.<sup>58</sup> Progesterone withdrawal from endometrial cells increases VEGF production and induces MMP secretion, probably from both endometrial stromal cells and leukocytes, which is followed by the irreversible breakdown of cellular membranes and the dissolution of extracellular matrix.<sup>59,60,61</sup> Appropriately, this enzyme expression increases in the decidualized endometrium of the late secretory phase, during the time of declining progesterone levels. With the continuing progesterone secretion of early pregnancy, the decidua is maintained, and metalloproteinase expression is suppressed, in a mechanism mediated by TGF- $\beta$ .<sup>62</sup> In a nonpregnant cycle, metalloproteinase expression is suppressed after menses, presumably by increasing estrogen levels.

Metalloproteinase activity is restrained by specific tissue inhibitors designated as tissue inhibitor of metalloprotein (TIMP).<sup>63</sup> The balance of metalloproteinase and TIMP activity is an important event in successful implantation. Thus, progesterone withdrawal

can lead to endometrial breakdown through a mechanism that is independent of vascular events (specifically ischemia), a mechanism that involves cytokines.<sup>54</sup> During bleeding, both normal and abnormal, there is evidence indicating that specific genes are activated in the endometrium; one such gene has the structural features of the TGF- $\beta$  family.<sup>64</sup>

There is considerable evidence to support a major role for a cytokine, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), in menstruation.<sup>54</sup> TNF- $\alpha$  is a transmembrane protein whose receptor belongs to the nerve growth factor/TNF family for inducing apoptotic signals. The key change is an increase in secretion because TNF- $\alpha$  secretion by endometrial cells reaches a peak at menstruation, but there is no cycle change in receptor content. TNF- $\alpha$  inhibits endometrial proliferation and induces apoptosis; this cytokine causes a loss of adhesion proteins (the cadherin-catenin-actin complex) and induces cell-to-cell dissolution. In addition to endometrial cells, TNF- $\alpha$  also causes damage to vascular endothelium.

Progesterone withdrawal is also associated with an increase in VEGF receptor concentrations in the stromal cells of the layers of endometrium destined to be sloughed.<sup>65</sup> Although the VEGF system is usually involved with angiogenesis, in this case, these factors are involved in the preparation for menstrual bleeding, perhaps influencing the expression of MMPs. Endometrial genes without classic steroid response elements can respond to the sex steroids either indirectly or by tethering to a family of proteins that mediate transcriptional activity. These proteins, induced by progesterone in stromal (decidual) and epithelial cells, can activate tissue factor (TF), PAI-1, IGF-binding protein-1, uteroglobin, and uteroferrin. TF is involved in the clotting mechanism to sustain hemostasis. Uteroglobin is a small protein expressed in endometrial epithelial cells.<sup>66</sup> The physiologic function of uteroglobin is uncertain. Uteroglobin, with high affinity, binds progestins and may play a role in immunosuppression. Uteroglobin gene expression is stimulated by estrogen, and this response is enhanced by progesterone. Human endometrium can secrete  $\beta$ -endorphin, yet another candidate for involvement in endometrial immunologic events, and its release is inhibited by both estrogens and glucocorticoids<sup>67</sup> (**Figure 3.10**).

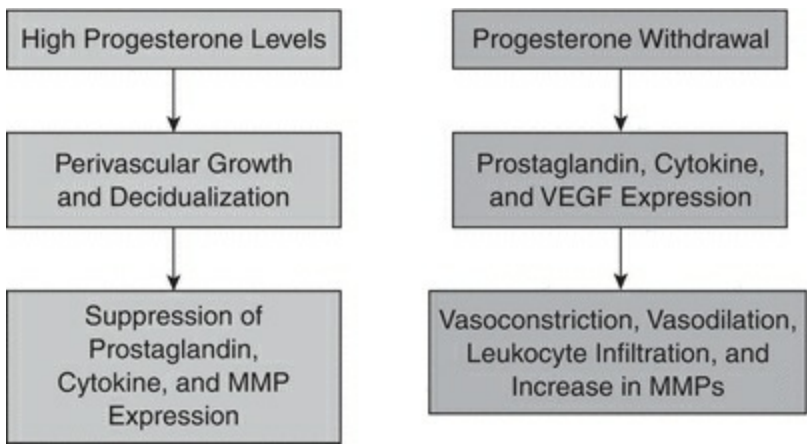

**FIGURE 3.10**

Eventually, considerable leakage occurs as a result of diapedesis, and finally, interstitial hemorrhage occurs due to breaks in superficial arterioles and capillaries. White cells migrate through capillary walls, at first remaining adjacent to vessels but then extending throughout the stroma. The leukocytes add important regulatory cytokines, chemokines, and enzymes that are involved in the degradation of the extracellular matrix. During arteriolar vasomotor changes, red blood cells escape into the interstitial space. Thrombin-platelet plugs also appear in superficial vessels. The prostaglandin content ( $\text{PGF}_2\text{-}\alpha$  and  $\text{PGE}_2$ ) in the secretory endometrium reaches its highest levels at the time of menstruation. The vasoconstriction and myometrial contractions associated with the menstrual events are believed to be significantly mediated by prostaglandins from perivascular cells and the potent vasoconstrictor endothelin-1, derived from stromal decidual cells.

As ischemia and weakening progress, the continuous binding membrane is fragmented, and intercellular blood is extruded into the endometrial cavity. New thrombin-platelet plugs form intravascularly upstream at the shedding surface, limiting

blood loss. Increased blood loss is a consequence of reduced platelet numbers and inadequate hemostatic plug formation. Menstrual bleeding is influenced by activation of clotting and fibrinolysis. Fibrinolysis is principally the consequence of the potent enzyme plasmin, formed from its inactive precursor plasminogen. Endometrial stromal cell TF and plasminogen activators and inhibitors are involved in achieving a balance in this process. TF stimulates coagulation, initially binding to factor VII. TF and PAI-1 expression accompany decidualization, and the levels of these factors may govern the amount of bleeding.<sup>53,68</sup> PAI-1, in particular, exerts an important restraining action on fibrinolysis and proteolytic activity.<sup>69</sup> Blood loss is also controlled by constriction of the spiral arteries, mediated by the perivascular cells, myofibroblasts that surround the spiral arteries.<sup>70</sup> These cells respond to progesterone withdrawal by expressing prostaglandins, cytokines, and MMPs, not only causing cycling vasoconstriction and vasodilation but also modulating leukocyte entry (an important additional source of metalloproteinases) into the endometrium. Disordered growth and function of the perivascular cells are likely contributing factors in menstrual bleeding problems (Figure 3.11).

**FIGURE 3.11**

With progressive enzymatic degradation of the endometrium, the subsurface capillary and venous vascular system is disrupted, causing hemorrhage and escape of blood into the endometrial cavity. Additional ischemic breakdown ensues with necrosis of cells and defects in vessels adding to the menstrual effluvium. Degeneration extends to the deepest extent of the functional layer where rupture of the basal arterioles contributes to bleeding. A natural cleavage point exists between basalis and spongiosum, and, once breached, the loose, vascular, edematous stroma of the spongiosum desquamates and collapses. The process is initiated in the fundus and inexorably extends throughout the uterus. In the end, the typical deflated, shallow, dense, menstrual endometrium results.

Within 13 hours, the endometrial height shrinks from 4 to 1.25 mm.<sup>15</sup> Menstrual flow stops as a result of the combined effects of prolonged vasoconstriction of the radial arteries and the spiral arteries in the basalis, tissue collapse, vascular stasis, and estrogen-induced “healing.” In contrast to postpartum bleeding, myometrial contractions are not important for control of menstrual bleeding. Thrombin generation in the basal endometrium in response to extravasation of blood is essential for hemostasis. Thrombin promotes the generation of fibrin, the activation of platelets and clotting cofactors, and angiogenesis.

The basalis endometrium remains during menses, and repair takes place from this layer. This endometrium is protected from the lytic enzymes in the menstrual fluid by a mucinous layer of carbohydrate products that are discharged from the glandular and stromal cells.<sup>71</sup>

# Normal Menses

Approximately 50% of the menstrual detritus is expelled in the first 24 hours of menstrual flow. The menstrual fluid is composed of the autolyzed functionalis, inflammatory exudate, red blood cells, and proteolytic enzymes (at least one of which, plasmin, lyses fibrin clots as they form). The high fibrinolytic activity advances emptying of the uterus by liquefaction of tissue and fibrin. If the rate of flow is great, clotting can and does occur.

Most women (90%) have menstrual cycles with an interval of 24–35 days ([Chapter 5](#)).<sup>72,73</sup> Menarche is followed by approximately 5–7 years of increasing regularity as cycles shorten to reach the usual reproductive-age pattern. In the 40s, cycles begin to lengthen again. The usual duration of flow is 4–6 days, but many women have flow for as little as 2 days and as much as 8 days. The normal volume of menstrual blood loss is 30 mL; greater than 80 mL is abnormal. Normal and abnormal characteristics and definitions of menstrual flow are discussed in detail in [Chapter 15](#).

# A TELEOLOGIC THEORY OF ENDOMETRIAL-MENSTRUAL EVENTS

---

Menstruation is a very recent phenomenon in the evolutionary time line. It occurs in very few species, even among viviparous animals. An unabashedly teleologic view of menstrual events was offered many years ago by Rock et al.<sup>74</sup> The basic premise of this thesis is that every endometrial cycle has, as its only goal, nourishing support of an early embryo. Failure to accomplish this objective is followed by orderly elimination of unutilized tissue and prompt renewal to achieve a more successful cycle.

The ovum must be fertilized within 12–24 hours of ovulation. Over the next 4 days, it remains unattached within the tubal lumen, utilizing tubal fluids and residual cumulus cells to sustain nutrition and energy for early cellular cleavage. After this stay, the solid ball of cells (morula), which is the embryo, leaves the tube and enters the uterine cavity. Here, the embryo undergoes another 2–3 days of unattached but active existence. Fortunately, by this time, endometrial gland secretions have filled the cavity and they bathe the embryo in nutrients. This is the first of many neatly synchronized events that mark the conceptus-endometrial relationship. By 6 days after ovulation, the embryo (now a blastocyst) is ready to attach and implant. At this time, it finds an endometrial lining of sufficient depth, vascularity, and nutritional richness to sustain the important events of early placentation to follow. Just below the epithelial lining, a rich capillary plexus has been formed and is available for creation of the trophoblast-maternal blood interface. Later, the surrounding zona compactum, occupying more and more of the endometrium, will retain endometrial architecture despite the invasive inroads of the burgeoning trophoblast.

Failure of the appearance of human chorionic gonadotropin, despite otherwise appropriate tissue reactions, leads to the vasomotor changes associated with estrogen-progesterone withdrawal and menstrual desquamation. However, not all the tissue is lost, and, in any event, a residual stem cell containing basalis is always available, making resumption of growth with estrogen a relatively rapid process. Indeed, even as menses persists, early regeneration can be seen. As soon as follicle maturation occurs (in as short a time as 10 days), the endometrium is ready once again to perform its reproductive function.

# **THE UTERUS IS AN ENDOCRINE ORGAN**

---

The uterus is dynamic. It not only responds and changes in a sensitive fashion to classic hormonal signals (the endocrine events of the menstrual cycle), but it is also composed of complex tissues, with important autocrine and paracrine functions that serve not only the uterus but also the contiguous tissues of the fetoplacental unit during pregnancy. The most dynamic component of the uterus is the endometrium.

# Endometrial Products

The endometrium secretes many substances, the functions of which (and their interrelationships) represent a major investigative challenge.<sup>75</sup> In addition to producing a nourishing, supportive environment for the early embryo, the endometrium plays an important role in suppressing the immune response within the pregnant uterus. The mechanisms controlling the immune response and induction of fetal tolerance within the decidua are not well understood, but hormonal influence, decidual cells, NK cells, and regulatory T (Treg) cells along with their downstream array of secretory products are undoubtedly important.

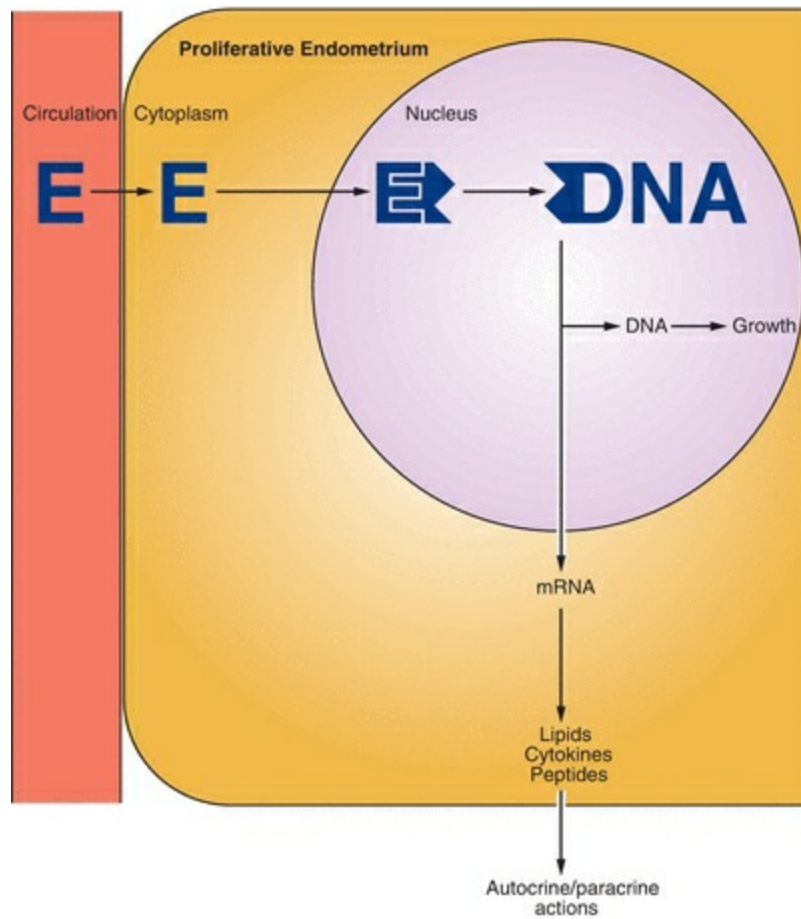

The presence of the cytokine family, involved in inflammation and immune responses, is not surprising in a tissue that undergoes cyclic degeneration. The interleukins stimulate the production of prostaglandins as well as other cytokines.<sup>76</sup> Colony-stimulating factor-1 is a cytokine that influences cellular proliferation and the presence of macrophages. Interferon- $\gamma$  is produced by activated T lymphocytes and inhibits endometrial epithelial proliferation. Leukemia-inhibiting factor (LIF) is expressed in response to a variety of other cytokines and growth factors. Like the interleukins, LIF is most abundant during the progesterone-dominated secretory phase and early decidua and likely plays an important role in embryo implantation.<sup>77,78</sup> TNF- $\alpha$  gene expression is present in the endometrium, and its activity is increased during the proliferative phase, decreased early in the secretory phase, and increased again in the midsecretory phase.<sup>79</sup> TNF- $\alpha$  exerts multiple influences on cellular growth (Table 3.1).

## TABLE 3.1 A Partial List of Endometrial Regulating Molecules

Lipids	Cytokines	Peptides
Prostaglandins	Interleukin-1 $\alpha$	Prolactin
Thromboxanes	Interleukin-1 $\beta$	Relaxin
Leukotrienes	Interleukin-6	Prorenin and renin
	Interferon- $\gamma$	Endorphin
	Colony-stimulating factor-1	Endothelin-1
	Tumor necrosis factor- $\alpha$	Corticotropin-releasing hormone
	Leukemia-inhibiting factor	Fibronectin
		Uteroglobin
		Lipocortin-1
		Parathyroid hormone-like protein
		Integrins
		Epidermal growth factor family
		EGF
		Heparin-binding EGF
		TGF- $\alpha$
		Insulin-like growth factor family
		IGF-1
		IGF-2
		IGFBPs 1–6
		Transforming growth factor- $\beta$ family
		Activins
		Inhibins
		Follistatin
		Platelet-derived growth factor
		Fibroblast growth factor
		Vascular endothelial growth factor
		Gonadotropin-releasing hormone (GnRH)

Growth factors are peptides that bind to specific cell membrane receptors and initiate intracellular signaling pathways. Because the growth factors are potent mitogens, it is also not surprising that the follicular phase of the cycle, associated with proliferative activity of the endometrium, is marked by dramatic alterations in growth factors. Estrogen stimulates gene expression for epidermal growth factor (EGF) (and its receptor) and IGF production. In turn, EGF elicits estrogen-like actions by interacting with the estrogen receptor mechanism.<sup>80</sup> EGF, a potent mitogen, is present in

endometrial stromal and epithelial cells during the follicular phase of the cycle and in the stromal cells during the luteal phase.<sup>81</sup> TGF- $\alpha$  and EGF work through the same receptor and are important mediators of estrogen-induced growth of the endometrium. TGF- $\alpha$  levels peak at midcycle, in contrast to EGF levels, which are relatively stable and noncyclic.<sup>82,83,84</sup> Platelet-derived growth factor is a potent mitogen localized to stromal cells (**Figure 3.12**).

**FIGURE 3.12**

The IGFs promote cellular mitosis and differentiation. They are expressed in a pattern controlled by estrogen and progesterone. IGF-1 is predominant in the proliferative and early secretory endometrium, and IGF-2 appears in the mid to late secretory phase and persists in early pregnancy decidua.<sup>85</sup> Endometrial IGF-1 expression is correlated with the circulating estrogen levels during the menstrual cycle.<sup>86</sup> This suggests that IGF-1 synthesis is regulated by estrogen and mediates estrogen-induced growth of the endometrium and IGF-2 is involved in differentiation in response to progesterone. Evidence in the monkey indicates that IGF-1 is the primary regulator of myometrial

growth in response to estrogen as well as to estrogen plus progesterone.<sup>87</sup>

As elsewhere in the body, the myometrial IGF activity is modulated by the IGF-binding proteins, which respond to the sex steroids in a differential manner; IGFBP-2 parallels IGF-1 response, whereas IGFBP-3 is decreased in the muscle but increased in vascular endothelium by estrogen.<sup>88</sup> IGFBP-4 and IGFBP-5 respond to estrogen but are unaffected by the addition of progesterone. IGFBP-1, as discussed later, is a major product of decidualized endometrium.

Gonadotropin-releasing hormone (GnRH) is present in the endometrium and in increased amounts in secretory endometrium and decidua.<sup>89</sup> In human decidual cells, GnRH increases the expression of MMPs, suggesting a role for GnRH in the regulation of the enzymes involved in implantation.<sup>90</sup> Like all of these molecules, GnRH is involved in signaling pathways associated with cell proliferation and breakdown, interacting with adhesion factors such as integrins, enzymes, and angiogenic substances.<sup>91</sup>

Human myometrial smooth muscle and endometrial stromal cells express mRNA for parathyroid hormone-like protein, the function of which is unknown.<sup>92</sup> TGF- $\beta$  stimulates the production of the parathyroid hormone-like protein. TGF- $\beta$  production is greatest in the secretory phase and may inhibit cellular proliferation by increasing IGFBP-3 synthesis.

Prostaglandins are produced by both epithelial and stromal cells, and the prostaglandin content in the endometrium reaches a peak level in the late secretory endometrium. The predominant prostaglandin produced by the endometrium is prostaglandin F<sub>2 $\alpha$</sub> , a potent stimulus for myometrial contractions.<sup>93</sup> Endometrial prostaglandin production decreases dramatically after implantation, suggesting the presence of an active mechanism for suppression.<sup>94</sup> The production of prostaglandins requires estrogen support, but the increased production by secretory endometrium indicates progesterone enhancement, and acute withdrawal of progesterone promotes a further increase.<sup>93</sup> Endometrial stromal cells produce prostacyclin and thromboxane in response to estrogen, a response that can be blocked by progestins.<sup>95</sup> The myometrium principally produces prostacyclin, utilizing precursors derived from the endometrium. However, receptors for all members of the prostaglandin family are present on human myometrial cells, and contraction of the myometrium is a major consequence of prostaglandin F<sub>2 $\alpha$</sub> .<sup>96</sup>

Thromboxane is synthesized by uterine tissues. Gene expression for the thromboxane synthase and for the thromboxane receptor can be identified in endometrial glands, stromal cells, myometrial smooth muscle, and uterine blood vessels.<sup>97</sup>

Thromboxane A<sub>2</sub> is a potent vasoconstrictor and stimulator of smooth muscle cells. Because of its rapid metabolism, it is limited to autocrine and paracrine activity.

Women with excessive menstrual bleeding have alterations in the normal rates of prostaglandin production. For this reason, effective reductions in menstrual blood loss can be achieved with treatment utilizing one of the nonsteroidal anti-inflammatory agents that inhibit prostaglandin synthesis. These agents are also effective treatment for prostaglandin-mediated dysmenorrhea.

Fibronectin and laminin are extracellular matrix substances that are secreted by stromal cells of the endometrium in response to progesterone.<sup>98</sup> These proteins are important adhesion molecules during implantation. Integrins are a family of glycoproteins that function as receptors for proteins such as collagen, fibronectin, and laminin. The integrins are highly expressed in the endometrium and are important for cell-to-cell and cell-to-matrix interactions.<sup>99</sup> The expression of integrins is regulated by cytokines and growth factors, not estrogen and progesterone.<sup>100</sup>

Endothelins are potent vasoconstrictors produced in the vascular endothelial cells. The vasoconstrictor activity of endothelin-1, present in the endometrium, is balanced by the fact that it promotes the synthesis of the vasodilators nitric oxide and prostacyclin. Endothelin-1 is synthesized in endometrial stromal cells and the glandular epithelium, stimulated by both TGF- $\beta$  and interleukin-1 $\beta$ .<sup>101</sup> Endothelin-1 is at least one agent responsible for the vasoconstriction that shuts off menstrual bleeding. It is also a potent stimulator of myometrial contractions and can contribute to dysmenorrhea. Finally, endothelin-1 is a mitogen and can promote the healing and re-epithelialization of the endometrium. Human decidual cells also synthesize and secrete endothelin-1, from where it may be transported into the amniotic fluid.<sup>102</sup>

Angiogenesis, the formation of new blood vessels, is an essential process in tissue growth and development. Angiogenesis is necessary for tumor growth, and, in normal tissues, it is usually kept in check by regulating factors. The female reproductive tissues (specifically ovarian follicles, the trophoblast, and the endometrium), however, must experience periodic and rapid growth and regression (**Figure 3.13**). In these tissues, angiogenesis is part of normal events. The endometrium is a major source for angiogenic factors during the menstrual cycle and during pregnancy.<sup>103</sup> The sex steroids estrogen and progesterone are the primary regulators of uterine angiogenesis in all mammalian species.<sup>104,105</sup> VEGFs, a collection of specific mitogens for endothelial cells, are abundantly expressed in human endometrium, reaching a peak that correlates with the maximal angiogenesis reached during the secretory phase.<sup>106,107</sup> The VEGF family contains six growth factors and utilizes three different receptors. During the proliferative phase, estrogen stimulates VEGF synthesis. VEGF expression is also

stimulated by hypoxia, specifically the hypoxia associated with endometrial breakdown, and the new blood vessel growth and the re-epithelialization of the endometrium in the new proliferative phase are dependent on these growth factors in response to estrogen.<sup>108,109</sup>

**FIGURE 3.13**

Angiogenesis is also influenced by many other growth factors and other substances such as fibronectin and prostaglandins. The fibroblast growth factor family, in particular, is highly mitogenic for endothelial cells and endometrial stromal cells. Angiopoietins sustain the endometrium by preventing apoptosis and stabilizing blood vessels. The endometrium also produces inhibitory proteins, and the final growth of blood vessels reflects the balance between the inhibitory and stimulatory factors.

In all types of endometrial and myometrial cells, estrogen receptor expression reaches a maximum in the late proliferative phase.<sup>110,111</sup> The concentration is greatest in the glandular epithelium. During the early secretory phase, estrogen receptor expression declines, followed by an increase in the mid and late secretory phases. These changes reflect the cyclic changes in estradiol (which increases estrogen receptor expression)

and progesterone (which decreases estrogen receptor expression). Although estrogen receptor-beta is present in human endometrium, it is less prominent than estrogen receptor-alpha and exhibits less change during the cycle, except when it becomes the predominant estrogen receptor in the endometrial vasculature in the late secretory period.<sup>112</sup> Estrogen stimulation of proliferation is largely, if not totally, mediated by estrogen receptor-alpha.

Progesterone receptor expression in endometrial glandular epithelium reaches a maximum in the late proliferative and early secretory phases (reflecting induction of progesterone receptor by estrogen) and then declines to nearly undetectable levels by the midpoint of the secretory phase. Stromal cells in the endometrium show only minor fluctuations in progesterone receptors during the menstrual cycle. Decidualizing stromal cells exhibit strong progesterone receptor expression, although progesterone receptors are absent from decidual epithelial cells. Smooth muscle cells of the uterus demonstrate strong progesterone receptor expression throughout the menstrual cycle. Many of the events in uterine growth and function are regulated by the interplay between estrogen and progesterone. In general, progesterone antagonizes estrogen stimulation of proliferation and metabolism. This antagonism can be explained by the effects of progestins on the estrogen receptor (a decrease in levels), on the enzymes that lead to excretion of estrogen from cells, and by progesterone suppression of estrogen-mediated transcription of oncogenes.

Androgen receptor is present in the endometrium at all stages of the menstrual cycle, in postmenopausal endometrium, and in the decidua of pregnancy.<sup>113</sup> Surprisingly, the androgen receptor concentration is constant throughout the cycle. Androgens suppress the proliferative effects of estrogen on the endometrium, and experimental evidence suggests that the suppressive effects on the endometrium induced by antiprogestational agents are mediated by the androgen receptor.<sup>114</sup>

The complexity of the endometrium can be appreciated by viewing the results of complementary DNA microarray studies. In one effort directed just to the endometrial breakdown associated with menstruation, 571 transcripts were identified that were involved in 131 biochemical pathways, including thyroid hormone synthesis and metabolism!<sup>115</sup> Gene expression studies are just beginning to profile the patterns associated with specific hormones and pharmacologic agents.<sup>116</sup>

# The Decidua

The decidua is the specialized endometrium of pregnancy. The term decidua is derived from the Latin verb *dêciduus*, meaning shedding or falling off, reflecting the periodic sloughing of the endometrium—just like a tree shedding its leaves only to grow new leaves in the next season, which are essential to maintain its life. Decidualization is the process of transformation of endometrial stromal cells into decidual cells, which is essential for supporting the implanting embryo and pregnancy. The biochemical dialogue between the fetoplacental unit and the mother must pass back and forth through the decidua. The classic view of the decidua conformed to its designation as a thin line in anatomic diagrams, a minor, inactive structural component. We now know that the decidua is a vigorous, active tissue.

Decidual cells are derived from the stromal cells of the endometrium, under the stimulation of progesterone. Increasing evidence from human and mouse studies supports a crucial role for transcriptional coregulators (coactivators and corepressors) such as repressor of estrogen receptor activity (REA) and steroid receptor coactivator-2 (Src-2) in this cellular transformation process.<sup>117,118</sup> Once the decidual process is initiated, differentiating stromal cells secrete a number of cytokines, growth factors, and morphogens involved in propagating this process. This transformation is regulated by members of the TGF- $\beta$  family, including activin A.<sup>119,120</sup> In addition, ghrelin acting via the growth hormone receptor is involved in this process.<sup>121</sup> Moreover, interleukins such as IL-1 $\beta$ <sup>122</sup> and leukemia inhibitory factor (LIF),<sup>123</sup> HOX genes, as well as members of the Notch signaling pathway play crucial roles in the transformation of stromal cells to decidualized cells.<sup>124,125,126,127,128</sup>

In the proliferative phase, endometrial stromal cells have a fibroblast-like appearance with little cytoplasm with elongated indented nuclei. Decidual cells appear during the secretory phase and continue to proliferate during early pregnancy, eventually lining the entire uterus including the implantation site. Decidual transformation is associated with rounding of the nucleus, increased number of nucleoli, and accumulation of glycogen and lipid droplets in the expanding cytoplasm. The decidual cell is characterized by the new expression of a host of substances, including prolactin, relaxin, renin, IGFs, and IGFbps. There is no evidence that these proteins are secreted into the circulation; therefore, they serve as autocrine and paracrine agents.<sup>129,130</sup>

Riddick was the first to detect prolactin in the decidualizing endometrium of the late luteal phase.<sup>131</sup> The amino acid sequence and the chemical and biologic properties of decidual prolactin are identical to those of pituitary prolactin. Decidual prolactin synthesis and release are controlled by the placenta, fetal membranes, and decidual factors. Dopamine, bromocriptine, and thyrotropin-releasing hormone (TRH), in

contrast to their action in the pituitary, have no effect on decidual synthesis and release of prolactin. A protein named decidual prolactin-releasing factor has been purified from the placenta, and an inhibiting protein, which blocks the stimulatory activity of the releasing factor, has been purified from decidua.<sup>130</sup> IGF-1, relaxin, and insulin all stimulate decidual prolactin synthesis and release, each through its own receptor. The same decidual cells produce both prolactin and relaxin. Prolactin exerts an overall inhibitory effect on the process of decidualization, perhaps an autocrine mechanism to limit the extent of decidualization.<sup>132</sup>

Lipocortin-1 is a calcium- and phospholipid-binding protein, present in the placenta and decidua, that inhibits phospholipase A<sub>2</sub> and responds to glucocorticoids. Lipocortin-1 inhibits decidual prolactin release but in a mechanism independent of phospholipase action and independent of glucocorticoids. The prostaglandin system is not involved in decidual prolactin production, and corticosteroids do not affect decidual prolactin release.<sup>133</sup>

In 1978, it was discovered that the source of amniotic fluid prolactin is not the pituitary but the decidua,<sup>134</sup> for which there is very strong supporting evidence. In vitro experiments indicate that the passage of prolactin across the fetal membranes is in the direction of the amniotic cavity. The amniotic fluid concentration correlates with the decidual content, not with maternal circulating levels. The proportion of prolactin-expressing cells in the decidua increases throughout pregnancy, and the level of expression correlates positively with decidual cell size.<sup>135,136</sup> Amniotic fluid prolactin reaches peak levels in the first half of gestation (about 4,000 ng/mL) when maternal plasma levels are approximately 50 ng/mL and fetal levels about 10 ng/mL. Maternal circulating prolactin reaches maximal levels near term. Finally, amniotic fluid prolactin is unaffected by bromocriptine treatment (which reduces both fetal and maternal circulating levels to baseline levels).

It is believed that decidual prolactin regulates amniotic fluid volume and electrolyte concentrations. Prolactin regulates water and ion transport in lower animals, and prolactin binds to amniotic membranes. Disorders in human pregnancy associated with abnormal amniotic fluid volumes may be explained by this mechanism, especially idiopathic polyhydramnios, which is associated with a decrease in the number of prolactin receptors in the membranes. Prolactin may be involved in the regulation of surfactant synthesis in the fetus, and prolactin may inhibit uterine muscle contractility. Prolactin suppresses the immune response and helps to prevent immunologic rejection of the conceptus. Prolactin in the uteroplacental unit has also been suggested to stimulate trophoblast growth and invasion, to promote angiogenesis, and to modulate uNK cell survival.<sup>137,138</sup>

Fibroblast growth factor, derived from decidua, stimulates blood vessel growth in

early pregnancy. Another factor, endothelial cell-stimulating angiogenesis factor (a nonprotein mitogen), is also derived from decidua and contributes to the vascularization of the decidua during the first trimester of pregnancy.<sup>139</sup> The expression of corticotropin-releasing hormone (CRH) has been demonstrated in human decidua, and many actions for decidual CRH are possible: activation of prostaglandins, stimulation of myometrial contractions, and a contribution to both maternal and fetal stress responses during pregnancy and labor.<sup>140</sup>

Prorenin (the inactive precursor of renin) is produced in decidua in response to IGF-1, insulin, endothelin, and relaxin.<sup>141,142,143</sup> A uterine role for renin has not been determined.

The IGFbps, IGFBP-1, IGFBP-2, IGFBP-3, and IGFBP-4, are produced by endometrial stromal cells.<sup>144</sup> Large amounts of IGFBP-1 are present in amniotic fluid. The IGFbps appear to be regulated by insulin, the IGFs, and relaxin.<sup>145</sup> Relaxin is related structurally to insulin and the IGFs, and it stimulates IGFBP-1 production in endometrial stromal cells.<sup>146</sup> IGFBP-1 is considered to be a marker for decidualization. Because it binds growth-promoting IGFs, the appearance of IGFBP-1 contributes to differentiation rather than proliferation of the endometrial stromal cells.

IGFBP-1 begins to appear in the midsecretory phase endometrium and reaches a level of major production in decidua late in the first trimester of pregnancy. IGFBP-1 levels peak around 16 weeks of gestation, preceding those of PRL. IGFBP-1, when first identified, was known as placental protein 12 and then as pregnancy-associated  $\alpha$ -globulin. By the second trimester of pregnancy, high levels of IGFBP-1 are present in the amniotic fluid and the circulation and then fall significantly during the third trimester. The decidual production of IGFBP-1 is correlated with the morphologic and histologic changes induced by progesterone and regulated by progesterone, relaxin, insulin, IGF-1, and IGF-2. In fact, IGFBP-1 is a mediator of progesterone-induced decidualization of endometrial stromal cells.<sup>147</sup> Binding of the IGFs to the IGFbps would limit further mitogenic activity in the endometrium in the secretory phase and during pregnancy. In addition, decidual IGFBP-1 may contribute to the limitation of trophoblast invasion.

The continuous stimulation of IGFBP-1 production by human endometrium can be maintained in women as long as they retain an intrauterine device that releases a progestin into the endometrial cavity.<sup>148</sup> In endometrial samples from these women, areas of endometrial atrophy correlate with intense staining for IGFBP-1. This makes a strong argument for the importance of IGFs for endometrial growth and the potential for prevention of endometrial growth by providing IGFBP-1.

The glycoprotein  $\alpha$ -subunit, common to follicle-stimulating hormone (FSH),

luteinizing hormone (LH), thyroid-stimulating hormone (TSH), and hCG, is secreted into the circulation by the pituitary and placenta. A specific role for the  $\alpha$ -subunit has not been apparent; however, gonadotropin receptors are present in the endometrium, and  $\alpha$ -subunit acts synergistically with progesterone to induce decidualization of endometrial cells in vitro.<sup>149</sup> In addition, the  $\alpha$ -subunit stimulates decidual prolactin secretion.<sup>150</sup>

The chorion laeve, villous trophoblast, and decidua are all sites of TGF- $\beta$  production.<sup>151</sup> TGF- $\beta$  can signal its own production; thus, TGF- $\beta$  can be a messenger from fetal tissues to decidua. TGF- $\beta$  is also believed to play a role in limiting trophoblastic invasion.<sup>152</sup> This may be accomplished by stimulating the production of PAI and the factor that causes tissue inhibition of metalloproteinases.<sup>153</sup>

# **SUMMARY: THE UTERINE ENDOMETRIUM**

---

**It is helpful to keep in mind a fundamental and relatively simple description: the endometrium is necessary for reproduction, and the synchronous, complex cycle of events is dependent on the endocrine guidance of estradiol and progesterone, modulated and mediated by the plethora of locally produced biochemical agents. Each and every signaling substance utilizes one of the pathways discussed in [Chapter 1](#) and makes a contribution to the dynamic sequence of morphologic and molecular events repeatedly dedicated to nourishing and supporting an early embryo.**

# ANATOMICAL ABNORMALITIES OF THE UTERUS

---

Congenital abnormalities of the müllerian ducts are relatively common, occurring in 7–10% of all women, and contributing to the problems of infertility, recurrent pregnancy loss, and poor pregnancy outcomes that occur in approximately 25% of women with uterine anomalies.<sup>154,155,156,157,158,159</sup> Major anomalies are about 3 times more common in women with recurrent miscarriages.<sup>160</sup> The problems encountered in pregnancy include preterm labor, breech presentations, intrauterine growth restriction, abnormal placentation, and other complications that lead to interventions and greater perinatal mortality. Cervical cerclage is often indicated for prevention of preterm labor due to these anomalies. In addition, these abnormalities can produce the symptoms of dysmenorrhea and dyspareunia and even amenorrhea. Endometriosis in young women, especially adolescents, should raise clinical suspicion of genital tract malformations. Because the embryologic origin of the ovaries is separate and distinct from that of the müllerian structures, patients with müllerian anomalies have normal ovaries and ovarian function. Conception and implantation are not prevented. Surgical correction is recommended for pain, endometriosis due to obstruction, and poor obstetrical outcomes (Table 3.2).

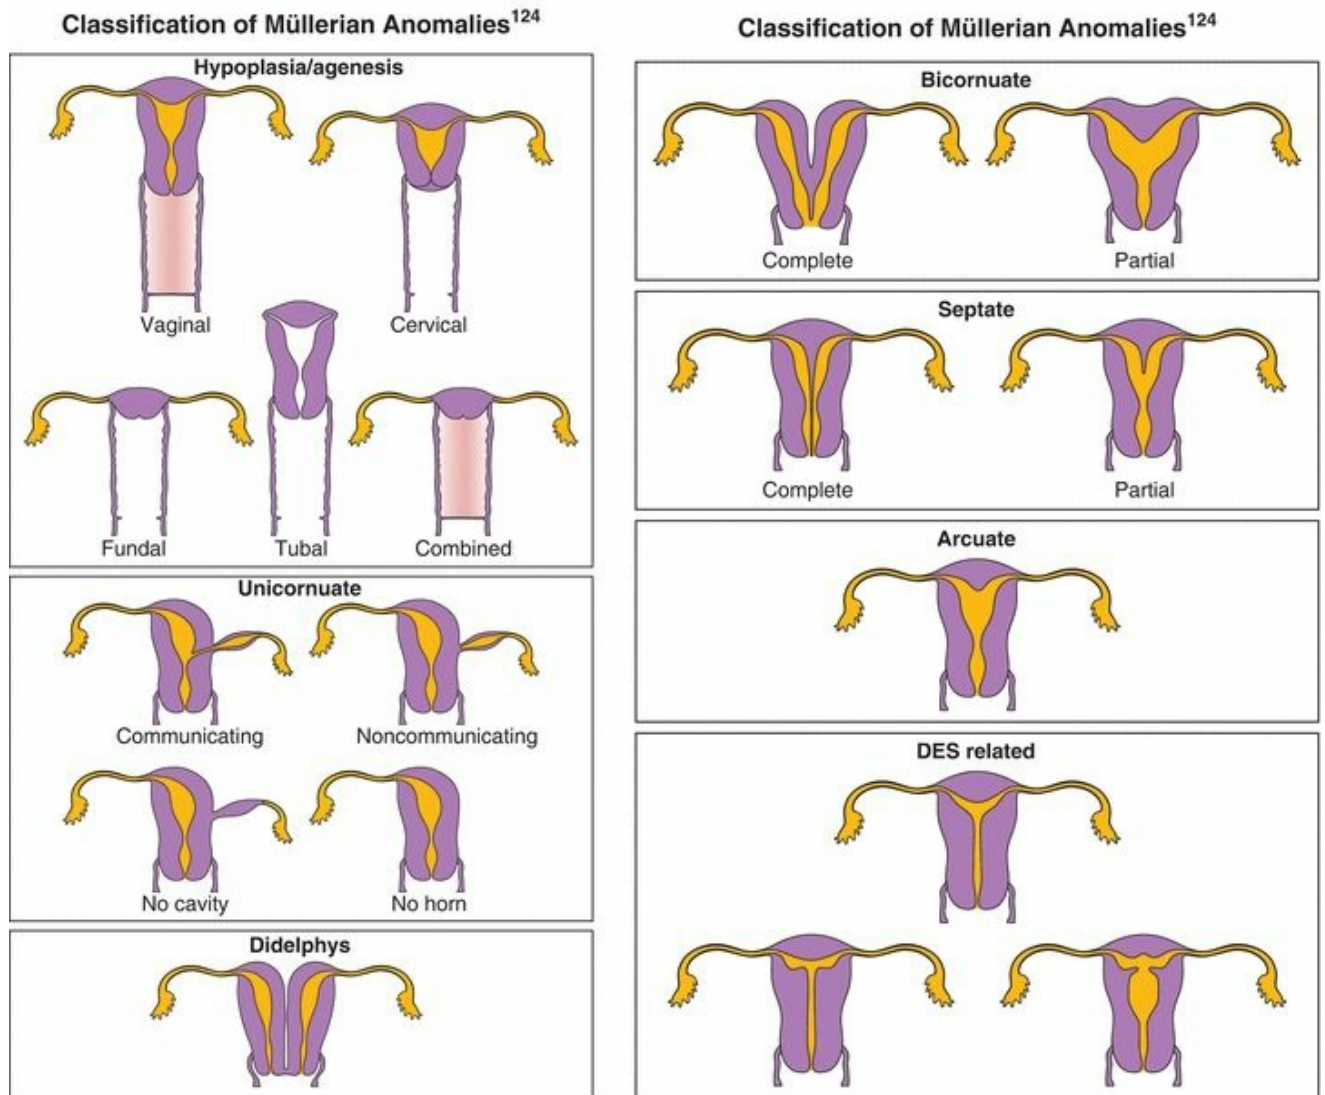

## TABLE 3.2 Incidence of Müllerian Defects

Fertile and infertile women	3–4% <sup>161</sup>
Women with recurrent miscarriages	5–10% <sup>158</sup>
Women with late miscarriages and preterm deliveries	>25% <sup>158</sup>

Anomalies can result from the failure of the müllerian ducts to fuse in the midline, to connect with the urogenital sinus, or to create the appropriate lumen in the upper vagina and uterus by resorption of the central vaginal cells and the septum between the fused müllerian ducts. Because fusion begins in the midline and extends cephalad, abnormal results are more common at the fundal portion of the uterus (bicornuate uterus). Formation of the uterine cavity begins at the lower pole and extends cephalad with dissolution of midline tissue; hence, incomplete resorption of tissue commonly yields persistence of the midline uterine wall (septum) intruding into the cavity. The molecular pathophysiology of these abnormalities has been insufficiently studied; however, the association with other somatic anomalies and occasional reports of familial transmission suggest genetic linkages.

Vaginal outflow tract obstruction can be minimal with a transverse septum or complete due to agenesis. A septum is the result of a defect in the connection of the fused müllerian ducts to the urogenital sinus or a failure of canalization of the vagina (**Figure 3.14**). The location of the septum varies, although it is usually in the upper or middle third of the vagina. Vaginal agenesis is the result of a complete failure in canalization; these patients present with amenorrhea or pain due to accumulated menstrual effluvium. Surgical correction is frequently necessary to relieve the relative constriction (and obstruction) of the vaginal canal. An absent vagina is usually accompanied by an absent uterus and tubes, the classic müllerian agenesis of the Mayer-Rokitansky-Kuster-Hauser syndrome (discussed in **Chapter 11**) (**Table 3.3**).

**FIGURE 3.14**

Adapted from **Grimbizi GF, Camus M, Tarlatzis BC, Bontis JN, Devroey P**, Clinical implications of uterine malformations and hysteroscopic treatment results, Hum Reprod Update 7:161, 2001.

Uterine anomalies can be organized into the following categories.<sup>162</sup> Each of these can be associated with obstructions that present during adolescence with amenorrhea and cyclic pain.<sup>163</sup>

## Uterus Didelphys (Double Uterus)

Complete lack of fusion of the two müllerian ducts results in duplication of the corpus, cervix, and upper vagina. These patients usually have no difficulties with menstruation and coitus, except when there are problems with the two hemivaginas. Fifteen to twenty percent of women with didelphic uterus also have unilateral anomalies, such as an obstructed hemivagina (often with ipsilateral renal agenesis); the anomalies are on the right in 65% of cases.<sup>164</sup> Early diagnosis and excision of the obstructing vaginal septum will preserve fertility. Pregnancy is associated with an increased risk of miscarriage, malpresentations, and preterm labor, although many patients will have no reproductive difficulties.<sup>161,165,166</sup> Unification of the two endometrial cavities by metroplasty is generally not indicated and should only be considered in patients with repeated poor obstetrical outcomes. Unification of the two hemivaginas should be considered only in symptomatic cases and only when there is considerable fusion with no intervening bowel or bladder between the two.

# Unicornuate Uterus

An abnormality that is unilateral obviously is due to a failure of development in one müllerian duct (probably a failure of one duct to migrate to the proper location). The altered uterine configuration is associated with an increase in endometriosis and in obstetrical complications (early spontaneous miscarriage, ectopic pregnancy, abnormal presentations, intrauterine growth retardation, and preterm labor).<sup>165,167,168,169,170</sup> There may be a rudimentary horn present, and implantation in this horn is followed by a very high rate of pregnancy wastage or tubal pregnancies. A rudimentary horn can also be a cause of chronic pain, and surgical excision is worthwhile. However, most rudimentary horns are asymptomatic because they are noncommunicating, and the endometrium is not functional. Because of the potential for problems, prophylactic removal of the rudimentary horn is recommended when it is encountered during a surgical procedure. Patients with a unicornuate uterus have a particularly high incidence (40%) of urinary tract anomaly (usually of the kidney).<sup>171</sup> Surgical reconstructive procedures do not improve obstetrical outcomes; however, cervical cerclage may be beneficial when indicated.

# The Bicornuate Uterus

This anomaly results from partial rather than complete lack of fusion of the two müllerian ducts, producing a single cervix with a varying degree of separation in the two uterine horns. A bicornuate uterus has a fundal indentation that is  $\geq 1$  cm. This anomaly is relatively common, and pregnancy outcome has usually been reported to be near normal. Some, however, find a high rate of early miscarriage, preterm labor, and breech presentations.<sup>157,165</sup> Even with a history of repeated poor pregnancy outcomes that are thought to be related to the anomaly, surgical metroplasty is rarely considered. The cervical length should be assessed during pregnancy due to an association between bicornuate uterus and cervical insufficiency.

# The Septate Uterus

The septate uterus is the most common uterine anomaly, accounting for 35–90% of uterine malformations. Partial lack of resorption of the midline septum between the two müllerian ducts results in fibromuscular defects that range from a slight midline septum (the arcuate, heart-shaped cavity) to a significant midline division of the endometrial cavity. There is variation in the composition of the septum in terms of thickness, the relative amounts of fibrous and muscular tissue, and the degree of vascularization. A total failure in resorption can leave a longitudinal vaginal septum. This defect is not a cause of infertility, but once pregnant, the greater the septum, the greater the risk of recurrent spontaneous miscarriage, especially in the second trimester. The complete septate uterus is associated with a high risk of spontaneous miscarriage, preterm labor, intrauterine growth retardation, and breech presentation.<sup>157,172,173</sup> Even a small septum is associated with these poor obstetrical outcomes.<sup>174</sup> Outcomes are excellent with treatment by hysteroscopy.<sup>161,173,175,176,177,178,179</sup> Posttreatment miscarriage rates are approximately 10% in contrast to the 21–44% pretreatment rates with a septum. Longer septa appear to be associated with a higher risk of recurrent miscarriage, but this is controversial and many women with septa are asymptomatic and have good pregnancy outcomes. When the septum includes the cervix, it may appear as two cervixes. A cervical septum should be left in place so as not to promote cervical incompetence; the septum will dissipate in labor or can be lysed at that time. A longitudinal vaginal septum usually does not have to be excised (unless dyspareunia is a problem). Prophylactic surgery is considered appropriate for a septate uterus in older women when adverse pregnancy outcomes may lead to delays until the age of diminishing fertility or in women being treated with in vitro fertilization.

# Arcuate Uterus

**An arcuate uterus has a slight midline indentation with minimal, and often broad, fundal cavity indentation. Although it was previously believed to have clinical consequence, an arcuate uterus is now classified as a normal variant and is not associated with adverse impact on reproductive outcome.<sup>180</sup> A surgical procedure is not indicated for the arcuate uterus.**

## Very Rare Anomalies

Isolated agenesis of the cervix or the endometrium is incredibly rare. The absence of the cervix can lead to so much pain and obstruction that hysterectomy is the best solution. Attempts to preserve fertility by creating a fistulous communication between the uterus and vagina have achieved some success, but repeat surgery due to reappearance of obstruction is common.<sup>181,182</sup> In asymptomatic patients or those with a strong desire for pregnancy, consideration should be given to the preservation of structures for the possibility of pregnancy that can be achieved by means of one of the techniques of assisted reproduction ([Chapter 28](#)). With no normal outflow tract, retrograde menstruation is inevitable leading to endometriosis. In these women, complete endometrial suppression with an oral contraceptive or GnRH agonist/antagonist is appropriate until the time of conception.

# The Diethylstilbestrol-Associated Anomaly

Diethylstilbestrol (DES) is a nonsteroidal estrogen first synthesized in 1938. It was initially used for postpartum lactation suppression and treatment of postmenopausal symptoms, but its use later expanded to prevention of miscarriage, preterm birth, and other pregnancy problems. It is estimated that a total of 5 million women worldwide received DES to improve pregnancy outcome.

Abnormalities related to DES are becoming increasingly more rare since the U.S. Food and Drug Administration (FDA) advised against its use in pregnancy in 1971, following reports of vaginal clear cell adenocarcinoma in offspring of patients who used this drug. DES crosses the placenta, and exposure to DES during a critical period of organogenesis causes multiple uterine malformations, maldevelopment of the uterine muscle layers, lack of stratification of the vaginal epithelium, and resorption of vaginal glands leading to vaginal adenosis. Mothers who were treated in 1938–1971 with high doses of DES early in their pregnancies had children who developed a variety of anomalies, ranging from the hypoplastic T-shaped uterus to irregular cavities with adhesions.<sup>183</sup> Women with uterine abnormalities usually also have cervical defects. In these individuals, the chance of term pregnancy is decreased because of higher risks of ectopic pregnancy, spontaneous miscarriage, and premature labor.<sup>184</sup> An incompetent cervix is common. Poor outcome is correlated with an abnormal uterus on hysterosalpingography. No treatment is available beyond cervical cerclage.

# Accurate Diagnosis of Anomalies

In the past, full diagnosis required surgical intervention, first laparotomy and then, more recently, laparoscopy. Today, vaginal ultrasonography, especially three-dimensional ultrasound, sonohysterography, and magnetic resonance imaging are highly accurate, and surgical intervention is usually not necessary.<sup>185,186,187</sup> Hysterosalpingography alone can yield inaccurate results due to a failure to perfuse both uterine horns on either side of a midline division and due to the inability to clearly visualize the outer portion of the fundus. One cannot reliably distinguish bicornuate and septate uteri; both appear as two separate patent endometrial compartments. Decisions should not be based on hysterosalpingography alone. Congenital anomalies of the müllerian ducts are frequently accompanied by abnormalities in the urinary tract, such as a horseshoe or pelvic kidney. Renal agenesis can be present on the same side as a müllerian defect.

# LEIOMYOMAS (UTERINE FIBROIDS)

---

Uterine leiomyomas are benign neoplasms that arise from uterine smooth muscle and cause abnormal uterine bleeding and symptoms secondary to a large pelvic mass. It is hypothesized that leiomyomas originate from somatic mutations in myometrial cells, resulting in progressive loss of growth regulation.<sup>188,189</sup> The tumor grows as genetically abnormal clones of cells derived from a single progenitor cell (in which the original mutation took place). Studies indicate that leiomyomas are monoclonal.<sup>190</sup> Different rates of growth can reflect the different chromosomal abnormalities present in individual tumors. Multiple myomas within the same uterus are not clonally related; each myoma arises independently.

The presence of multiple myomas (which have a higher recurrence rate than single myomas) argues in favor of a genetic predisposition for myoma formation. There is about a 2.5-fold increased risk of developing myomas in the first-degree relatives of women with these tumors,<sup>191</sup> and monozygotic twins' concordance for uterine leiomyoma diagnosis is almost twice that of dizygotic twins.<sup>192</sup> Hereditary leiomyomatosis and renal cell carcinoma are autosomal dominant syndromes with both cutaneous and uterine leiomyomas. The risk of renal cell carcinoma and that of leiomyosarcoma is increased in this syndrome.<sup>193,194</sup> The gene involved is **fumarate hydratase**, coding for an enzyme involved in the Krebs cycle. A family history of cutaneous leiomyomas should trigger screening for this gene mutation. Renal cell cancer occurs in 10–16% of women with this syndrome. Moreover, two recent genome-wide association studies identified several single nucleotide polymorphisms that are significantly associated with uterine leiomyoma diagnosis.<sup>195,196</sup> Such studies will likely yield patterns identifying women at high risk for uterine leiomyomas and perhaps risk for recurrence following ablation treatments and for malignant progression to leiomyosarcoma. Thus far, chromosomal abnormalities have been described in about 40% of myomas.<sup>197</sup> Mutations in the Med12 gene have been described as a key driver of but do not explain all fibroids.<sup>198</sup>

It is not certain whether leiomyosarcomas arise independently or from leiomyomas. However, the incidence of leiomyosarcomas in patients with leiomyomas is very low (<1%).<sup>199</sup> Gene profiling has not discovered shared abnormalities or a common molecular pathway comparing myomas with leiomyosarcomas.<sup>200</sup>

If surgical specimens are serially sectioned, about 77% of women who come to hysterectomy will have myomas, many of which are occult.<sup>201</sup> By the age of menopause, ultrasound can identify myomas in about 80% of black American women and 70% of white American women.<sup>202</sup> Approximately 25% of women will have symptomatic

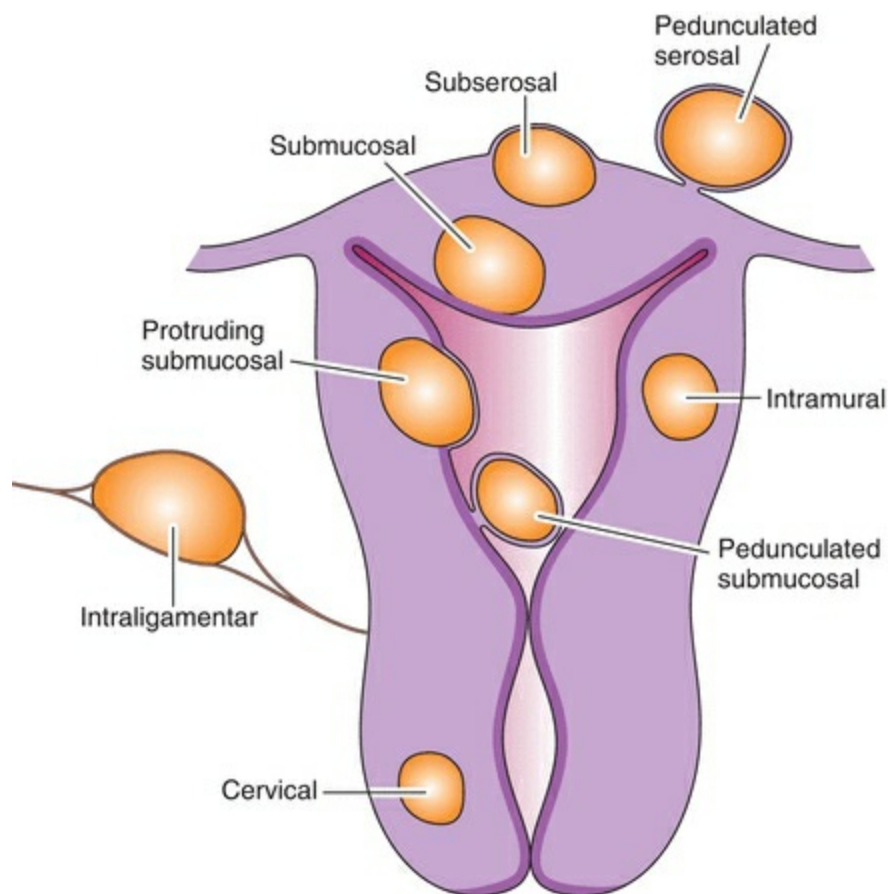

fibroids during their reproductive years. In the United States, about 40% of abdominal hysterectomies and 17% of vaginal hysterectomies are performed for leiomyomas.<sup>203</sup> The peak incidence for myomas requiring surgery occurs around age 45, approximately 8 cases per 1,000 women each year.<sup>204</sup> In the United States, approximately 10–15% of women require hysterectomy for myomas. For unknown reasons, uterine leiomyomas are 2–3 times more prevalent in black women compared with white, Hispanic, and Asian women and account for 75% of hysterectomies among black women.<sup>202,205,206</sup>

Myomas are present (diagnosed by ultrasonography) in about 30% of women and in about 1–2% of pregnancies.<sup>207,208</sup> The risk of myoma is decreased with increasing parity and with increasing age at last term birth.<sup>208,209</sup> Women with at least two full-term pregnancies have half the risk for myomas. Smoking decreases the risk (presumably by decreasing estrogen levels), and obesity increases the risk (presumably by increasing estrogen levels). Although a lower risk for myomas is associated with factors that decrease estrogen levels, including leanness, smoking, and exercise, the use of oral contraceptives is not associated with an increased risk of uterine myomas, although the Nurses' Health Study reported a slightly increased risk when oral contraceptives were first used in early teenage years.<sup>209,210,211</sup>

The hormone sensitivity of leiomyomas is further indicated by the following clinical observations. Leiomyomas develop during the reproductive (hormonally active) years and regress after menopause. Occasionally, leiomyomas grow during pregnancy, and the hypogonadal state induced by treatment with GnRH agonists often causes shrinkage of myomas.

The environment within the leiomyoma is hyperestrogenic. The estradiol concentration is increased, and leiomyomas contain more estrogen and progesterone receptors.<sup>212,213,214,215</sup> Aromatase gene and enzyme expression are present in significant levels in leiomyomas.<sup>216</sup> Indeed, leiomyoma tissue is hypersensitive to estrogen and appears to have lost a regulatory influence that limits estrogen response.<sup>217</sup> Endometrial hyperplasia can be observed at the margins of submucosal myomas.<sup>218</sup> In the myometrium and in leiomyomas, peak mitotic activity occurs during the luteal phase, and mitotic activity is increased by the administration of high doses of progestational agents.<sup>219,220</sup> These facts indicate that progesterone stimulates mitotic activity in leiomyomas. Similarly, clinicians have reported both regression and growth with progestational treatment (**Figure 3.15**). Nevertheless, clear evidence supports a growth-promoting role for progestins. The association with estrogen can be explained by the estrogen enhancement of progesterone receptor expression.<sup>221,222</sup> Treatment with mifepristone, the progesterone antagonist, or with asoprisnil or ulipristal, selective progesterone receptor agonist/antagonists, is associated with a reduction in leiomyoma

size.<sup>223,224</sup>

**FIGURE 3.15**

At least one pathway for the growth-promoting effect of progestins is the induction of BCL2 gene expression increasing the production of the Bcl-2 protein that inhibits apoptosis and promotes cell replication.<sup>225</sup> Bcl-2 protein expression is increased in leiomyoma cells and markedly increases in response to progesterone.<sup>226</sup> In contrast, normal myometrial cells do not respond to estradiol or progesterone with Bcl-2 protein expression, and there is no cyclic change throughout the menstrual cycle.

As in the normal uterus, the effects of estrogen and progestins on leiomyomas are mediated by growth factors.<sup>227</sup> EGF is overexpressed in myomas, EGF receptors are present in leiomyomas, and GnRH agonist treatment (and hypogonadism) decreases EGF concentration in myomas (but not in normal myometrium).<sup>228,229</sup> IGF-1 and IGF-2 and their receptors are abundant in myometrium and actively overexpressed in leiomyomas.<sup>230,231</sup> Leiomyomas express more IGF-2 and less IGFBP-3 than myometrium, a situation that would enhance growth factor availability and activity in the

tumor.<sup>232</sup> Leiomyoma cells express more parathyroid hormone–related protein (another growth factor) than normal myometrium.<sup>233</sup> Like the endometrium and myometrium, leiomyomas secrete prolactin, and prolactin functions in the uterus as a growth factor.<sup>234</sup> Even hematopoiesis is possible in a leiomyoma.<sup>235</sup>

Multiple angiogenic growth factors such as VEGF, basic FGF, and PDGF display altered expression in leiomyomas and are likely responsible for the vascular abnormalities seen in this disease.<sup>236,237</sup> These vascular abnormalities have been described by classical studies showing that fibroids have an abnormal vasculature and are generally much less vascular than the surrounding myometrium.<sup>238,239,240</sup> This decreased vasculature likely accounts for the severe hypoxia noted in fibroid tissue.<sup>241</sup> These vascular changes probably contribute to the heavy menstrual bleeding associated with submucosal myomas. Understanding this vascular dysregulation may help to delineate the pathophysiology of this important disorder and may lead to innovative targeted treatments.

Uterine growth and signaling molecules are highly expressed in leiomyomas.<sup>242</sup> As with all tumors, these pathways in leiomyomas may one day be targeted by gene therapy. For example, specific adenoviruses can deliver altered genes to myoma cells that can interfere with the gene expression required for tumor growth and cellular functions.

# Reproductive Function and Leiomyomas

Leiomyomas are an infrequent cause of infertility, either by mechanical obstruction or distortion (and interference with implantation).<sup>243,244</sup> When a mechanical obstruction of fallopian tubes, cervical canal, or endometrial cavity is present and no other cause of infertility or recurrent miscarriage can be identified, myomectomy is usually followed by a prompt achievement of pregnancy in a high percentage of patients (usually within the 1st year).<sup>244,245</sup> Small submucosal myomas are best treated by hysteroscopic resection. Preoperative visualization is important, and mapping of myomas by sonohysterography or magnetic resonance imaging (MRI) is superior to standard ultrasonography (which is relatively inaccurate).<sup>246</sup> It is difficult to distinguish between submucosal myomas and endometrial polyps with ultrasonography.<sup>247</sup> Very large myomas (>4–5 cm) and myomas that do not have greater than 50% protrusion into the cavity are not good candidates for hysteroscopic removal.

The 5-year recurrence rate after abdominal myomectomy for a single myoma is about 10%, and 25% with multiple myomas, with subsequent hysterectomy necessary in one-third of patients with recurrence.<sup>248</sup> In a series with long-term follow-up, the recurrence rate over 10 years after single myomectomy reached 27%.<sup>249</sup> Women who gave birth after myomectomy had a recurrence rate (over 10 years) of 16%, compared to a rate of 28% in those who did not give birth. In an Italian study of recurrence, the rate at 5 years reached 55% in those who did give birth after surgery and 42% in those with no childbirth.<sup>250</sup> These differences may reflect the diligence and sensitivity of the ultrasonographic assessments.

Myomectomy for infertility or recurrent miscarriage requires a deliberate and careful decision after all factors have been considered. Intracavitary myomas, however, usually require surgery. Submucosal myomas are associated with general cavity alterations in the expression of proteins involved with implantation, not just an effect confined to the endometrium over the myoma.<sup>251,252,253</sup> Subserous myomas do not typically affect fertility unless there is compression of the fallopian tubes. Intramural myomas that do not distort the endometrial cavity probably have less effect on implantation and the risk of miscarriage<sup>254</sup> than those that distort the cavity; however, they may still have an effect if the myoma is large or in close proximity to the endometrium.<sup>255,256</sup> Because of the rapid regrowth of myomas following cessation of GnRH agonist therapy, medical therapy for infertility is not recommended.

Most myomas do not grow during pregnancy.<sup>257</sup> When they do, most of the growth is in the first trimester, and most myomas regress in size after the pregnancy. The size of a myoma will not predict its course; large myomas will not necessarily grow more than

small ones. Most pregnancies, in the presence of myomas, will, therefore, be uncomplicated (although a higher incidence of cesarean section has been observed).<sup>207,258</sup> Nevertheless, the risks of malpresentations, preterm delivery, and spontaneous miscarriage are increased.<sup>259</sup> The so-called red degeneration of myomas is occasionally observed during late pregnancy, a condition that is due to central hemorrhagic infarction of the myoma. Pain is the hallmark of this condition, occasionally associated with rebound tenderness, mild fever, leukocytosis, nausea, and vomiting. Usually, pain is the only symptom and resolution follows rest and analgesic treatment.<sup>260</sup> Surgery should be a last resort. The larger the myoma, the greater the risk of premature labor.<sup>261</sup>

# Medical Therapy of Leiomyomas

The goals of medical therapy for leiomyomas are to **temporarily** reduce symptoms and to reduce myoma size, and the therapy of choice is treatment with a GnRH agonist.<sup>262</sup> Any treatment that lowers endogenous estrogen levels should be effective, and therefore, the use of aromatase inhibitors is another option.<sup>263</sup> Medical therapy is provided preoperatively to improve anemia and reduce surgical complexity and recovery times.<sup>264</sup> Prolonged medical regimens have traditionally been expensive and complicated; however, the introduction of oral GnRH antagonists opens the potential for long-term use in fibroids. Similarly, medical therapy from fibroids using selective progesterone receptor modulators (SPRMs) has become popular in Europe and Canada where they are available; currently, no SPRM is available for this indication in the United States. Currently, with few exceptions, surgical treatment is preferred for symptomatic uterine leiomyomas until these new medical therapies are available.

The short half-life of GnRH is due to rapid cleavage of the bonds between amino acids 5–6, 6–7, and 9–10. By altering amino acids at these positions, analogues of GnRH can be synthesized with different properties. Substitution of amino acids at the 6 position or replacement of the C-terminal glycine amide (inhibiting degradation) produces agonists. An initial agonistic action (the so-called flare effect) is associated with an increase in the circulating levels of FSH and LH. This response is greatest in the early follicular phase when GnRH and estradiol have combined to create a large reserve pool of gonadotropins. After 1–3 weeks, desensitization and down-regulation of the pituitary produce a hypogonadotropic, hypogonadal state. The initial response is due to desensitization, the uncoupling of the receptor from its effector system, whereas the sustained response is due to a loss of receptors by down-regulation and internalization. Furthermore, postreceptor mechanisms lead to secretion of biologically inactive gonadotropins, which, however, can still be detected by immunoassay.

The GnRH analogues cannot escape destruction if administered orally. Higher doses administered subcutaneously can achieve nearly equal effects as those observed with intravenous treatment; however, the smaller blood peaks are slower to develop and take longer to return to baseline. Other forms of administration include nasal spray, sustained-release implants, and intramuscular injections of biodegradable microspheres.

## Treatment with GnRH Agonists

Summarizing the experience with GnRH agonist treatment of leiomyomas, the mean uterine size decreases 30–64% after 3–6 months of treatment.<sup>262</sup> Maximal response is usually achieved by 3 months. Menorrhagia, anemia, pelvic pressure, and urinary

frequency all respond favorably to GnRH agonist treatment.<sup>265,266</sup> GnRHa treatment results in a reduction in uterine and fibroid blood supply as measured by Doppler ultrasound and microvascular density.<sup>267,268</sup> A decrease in operative blood loss can be achieved when the pretreatment uterus is as large as a 16-week pregnancy or larger. However, some studies find no benefit in terms of surgical blood loss or length of hospital stay, and surgical dissection may be more difficult because of softening of the myoma.

Why is there a variation in response? When one considers the many factors involved in myoma growth (progesterone, estrogen, growth factors, and receptors), it makes sense that not every myoma is the same. After cessation of GnRH agonist therapy, menses return in 4–10 weeks, and myoma and uterine size return to pretreatment levels in 3–4 months. The rapid regrowth is consistent with the fact that reduction in size is not due to a cytotoxic effect. The shrinkage is due to loss of water and extracellular matrix.

Preoperative GnRH agonist therapy offers several advantages for hysteroscopic removal of submucosal tumors. In addition to a decrease in myoma size, endometrial atrophy will improve visualization, and decreased vascularity will reduce blood loss.

**Leiomyomatosis peritonealis disseminata** is a condition in which multiple small nodules of benign smooth muscle are found throughout the abdominal cavity and occasionally in the pulmonary cavity. This condition appears to be sensitive to estrogen and progestins because it has been aggravated by postmenopausal estrogen treatment and regression has been achieved with GnRH agonist treatment.<sup>269</sup>

**Adenomyosis** is the ectopic presence of endometrial glands within the myometrium. This diagnosis can be made by magnetic resonance imaging, and successful treatment with a GnRH agonist has been reported.<sup>270,271</sup>

## Side Effects of GnRH Agonists

Hot flushes are experienced by more than 75% of patients, usually in 3–4 weeks after beginning treatment. Approximately 5–15% of patients will complain of headache, mood changes, vaginal dryness, joint and muscle stiffness, and depression. About 30% of patients will continue to have irregular (although light) vaginal bleeding. It is useful to measure the circulating estradiol level. If the level is greater than 30 pg/mL, suppression is inadequate. A small number (10%) of patients will experience a localized allergic reaction at the site of injection of depot forms of GnRH analogues. More serious reaction is rare, but immediate and delayed anaphylaxis can occur, requiring intense support and management.<sup>272</sup>

Bone loss occurs with GnRH therapy if used without add-back hormone therapy, but not in everyone, and it is reversible if the course does not exceed 1 year. A significant

vaginal hemorrhage 5–10 weeks after beginning treatment is encountered in about 2% of treated women, due to degeneration and necrosis of submucosal myomas.<sup>273</sup> A disadvantage of agonist treatment is a delay in diagnosis of a leiomyosarcoma. Keep in mind that almost all leiomyosarcomas present as the largest or only uterine mass. Close monitoring is necessary, and surgery has been the usual recommendation when either enlargement or no shrinkage of myomas occurs during GnRH agonist treatment.<sup>274</sup> The use of Doppler ultrasonography or magnetic resonance imaging offers greater accuracy of evaluation. However, the incidence of leiomyosarcoma, even in patients with “rapidly growing leiomyomas,” is very low (<0.5%) and almost unheard of in premenopausal women.<sup>199</sup> In premenopausal women, a conservative approach is warranted.

Escape of suppression can result in an unexpected pregnancy. No adverse effects of fetal exposure to GnRH agonists have been reported, even when exposure has persisted throughout the early weeks of pregnancy.<sup>275</sup>

## **GnRH Agonists and Steroid Add-Back**

Treatment with a GnRH agonist with steroid add-back has been deployed to permit long-term therapy without bone loss.<sup>262</sup> Two strategies have been employed: simultaneous agonist and steroid add-back treatment or a sequential regimen in which the agonist is used alone for 3 months, followed by the combination of the agonist and steroid add-back. This long-term treatment is attractive for women who are perimenopausal, perhaps avoiding surgery. In addition, long-term treatment would be useful for women with coagulopathies and in women with medical problems who need to postpone surgery.

Simultaneous treatment with agonist and medroxyprogesterone acetate (20 mg daily) or norethindrone (10 mg daily) effectively reduced hot flushing but was less effective (consistent with the major growth-promoting role of progestins in myomas) in reducing uterine volume.<sup>262,276</sup> A sequential program, adding a traditional postmenopausal hormone regimen (conjugated estrogens/medroxyprogesterone acetate or estradiol/norethindrone), effectively reduced uterine volume and maintained the reduced volume for 2 years (and avoided any loss in bone density).<sup>262</sup> A daily 2.5-mg dose of tibolone also prevents bone loss and inhibits vasomotor symptoms without reducing the therapeutic efficacy of GnRH agonist treatment.<sup>277</sup> The addition of raloxifene to GnRH agonist treatment appeared to produce a greater reduction in leiomyoma size,<sup>278</sup> but the effect was not sufficiently different to be of clinical significance. Raloxifene treatment by itself, even in a large dose, failed to reduce leiomyoma size in premenopausal women, although in postmenopausal women, raloxifene produced a 30–40% reduction

in size after 1 year.<sup>279,280</sup> Treatment with raloxifene, alendronate, or tibolone prevents the bone loss associated with agonist therapy, but only tibolone also prevents hot flushing.<sup>277,281,282,283</sup>

We recommend 1 month of GnRH agonist treatment followed by agonist treatment combined with a daily, continuous add-back of estrogen and progestin using one of the available postmenopausal daily regimens. In view of the sensitivity of leiomyoma tissue to progestational agents, it makes sense to keep the dose of progestin relatively low. Preoperative GnRH agonist treatment is not indicated in every patient with uterine leiomyomas. The best candidates for treatment are women with bleeding and anemia to allow time for a response to iron supplementation and when the surgeon's clinical judgment suggests that a reduction in size may influence the choice of technique (e.g., laparoscopic or vaginal hysterectomy instead of laparotomy).

## **Treatment with a GnRH Antagonist**

GnRH antagonist treatment can suppress pituitary-gonadal function without the initial stimulatory (flare) response observed with GnRH agonists. Initial results with depot cetrorelix preoperative treatment of uterine fibroids were similar to those with GnRH agonist treatment; however, the response was faster (a maximal reduction in size within 14 days), probably because there is no initial flare response.<sup>284,285</sup>

More recently, a placebo-controlled trial showed that treatment with the GnRH antagonist elagolix alone or in combination with add-back therapy results in significant reduction of heavy menstrual bleeding in premenopausal women with fibroids. Hot flushes were the most common side effect, but this was much lower when add-back therapy was given in combination with elagolix.<sup>286</sup> This regiment avoids the initial flare effect seen with the GnRH agonists, is administered orally, and may be potentially used for long-term therapy. GnRH antagonist's approval of this indication is anticipated; however, the dose will be a higher one than that currently approved for use in the treatment of endometriosis.

## **Treatment with Mifepristone**

Mifepristone, the progestin antagonist, effectively reduces the size of uterine leiomyomas and produces amenorrhea in most patients. The initial study was relatively short term (12 weeks), and fibroid shrinkage was observed with doses of 25 and 50 mg daily.<sup>223</sup> A lower dosage is effective without the high rate of hot flushing observed at higher doses. In a 6-month study, a dose of 5-mg mifepristone daily was associated with a 48% reduction in uterine volume, a decrease in pressure and pain, an increase in hemoglobin levels, and a nonsignificant increase in hot flushing.<sup>287</sup> A similar reduction

in uterine volume was observed in a 3-month study with the 5-mg dose, also with improvements in pain and bleeding.<sup>288</sup> However, long-term mifepristone treatment can result in endometrial hyperplasia, a consequence of the antiprogestin action of the drug. This endometrial effect makes mifepristone an unacceptable choice for ongoing treatment of leiomyomas until large clinical trials are performed to establish its safety. Short-term treatment prior to surgery is appropriate. Asoprisnil, a SPRM, has also successfully reduced uterine volume and bleeding.<sup>224</sup> Ulipristal acetate, another SPRM, has been increasingly used to treat women with fibroids associated with heavy menstrual bleeding or with other moderate or severe symptoms. Data from available trials showed that endometrial changes were present in almost 70% of patients during treatment, appeared to be benign and reversible.<sup>289</sup> However, SPRMs have not been approved yet in the United States for this indication due to concerns over liver toxicity in Europe and Canada where these drugs have been widely used in the treatment of fibroids.

## **Treatment with the Levonorgestrel-Releasing Intrauterine System**

When uterine enlargement because of leiomyomas is no greater than the size of a 12-week pregnancy, the insertion of a levonorgestrel-releasing intrauterine system is followed by a decrease in uterine size in many but not all patients and a dramatic reduction in menstrual blood loss, with 40% of patients achieving amenorrhea.<sup>290,291,292</sup> The contraceptive efficacy is not diminished, but expulsion rates are higher. This method of treatment is not recommended when distortion of the uterine cavity is evident on examination with ultrasonography. The beneficial effect of locally applied levonorgestrel is unexplained, contrasting with the studies that indicate growth promotion of myomas by progestins; it likely functions by endometrial suppression rather than a direct effect on the fibroids.

## **Treatment with Uterine Artery Embolization**

Uterine artery embolization effectively reduces bleeding, pain, and fibroid size.<sup>293,294,295,296</sup> In a procedure under local anesthesia that takes about 1 hour, a catheter is advanced from the femoral artery to the uterine arteries to allow direct injection of polyvinyl particles or gelatin microspheres that occlude the blood flow. Myomas undergo necrosis in response to the transient ischemia, but normal tissue generates fibrinolysis and survives. The procedure is not recommended for large fibroids. After 5 years, recurrence of symptoms is about 10–25%. Most patients experience pain, nausea, and low-grade fever with a very high white blood count for 1–2 days following the procedure. In addition, serious complications occur, including complication-related

hysterectomy, amenorrhea, premature menopause, septicemia from uterine infection, bowel obstruction, and pulmonary embolus. Several deaths have been reported, giving a rate comparable to that with hysterectomy. A significant number of patients with larger myomas acquire intra-abdominal adhesions after the procedure.<sup>297</sup> The general recommendation is that embolization should not be performed in women who desire to retain their fertility. However, a substantial number of completed pregnancies have been reported after the procedure<sup>298,299</sup>; nevertheless, the fertility rates and the complication rates after pregnancy is achieved are not known with certainty. A randomized comparison with myomectomy indicated a higher rate of infertility and miscarriages after embolization.<sup>300</sup>

## Treatment with Ultrasound

A magnetic resonance mapping system for heat can be used to visualize myomas and direct high-energy ultrasound to destroy myomas.<sup>301,302</sup> The temperature achieved produces instant necrosis within a limited volume of tissue, and, therefore, the method requires multiple treatments over several hours. Thermal injuries to skin and normal tissues are potential side effects. MR-guided focused ultrasound (MRg-FUS) is FDA approved to treat patients who desire fertility, given that it is not associated with increased risks of spontaneous abortion and placental disorders. Data on successful term pregnancies after MRg-FUS are limited but appear comparable to surgical options.<sup>303,304</sup>

Transient uterine ischemia can be produced by placing vaginal clamps in the vaginal fornices, guided by ultrasonography, to compress the uterine arteries against the cervix for about 6 hours.<sup>305</sup> Short-term studies have demonstrated efficacy comparable to embolization, and long-term follow-up data have been reassuring.<sup>304</sup>

# Neuroendocrinology

There are two major sites of action within the brain that are important in the regulation of reproductive function—the hypothalamus and the pituitary gland. In the past, the anterior pituitary was viewed as the master controller of reproductive biology. Then a new concept emerged in which the pituitary was relegated to a subordinate role as part of an orchestra, with the hypothalamus serving as the conductor, responding on one hand to messages from the peripheral nervous system and central nervous system (CNS), and on the other, exerting its influence on the anterior pituitary by means of neurotransmitters transported directly to the pituitary by a portal vessel network. Regardless of which site was dominant, the conventional view was that the central nervous system-pituitary complex determined and directed the chronology of folliculogenesis and accompanying steroidogenic events within a responsive ovary. It is currently understood that the hypothalamus (acting as a conductor), and under its direction the pituitary and the ovary/ies (each serving as a member of an orchestra), are essential for the complex cascade of events that constitute the menstrual cycle. As is true for successful performance by any orchestra, synchrony between and responsiveness of each member of the reproductive orchestra are critical to normal reproductive function. The complex sequence of events of the menstrual cycle is further controlled by the sex steroids and peptides produced within the very follicle destined to ovulate, and smooth functioning of this machinery is ensured by endocrine feedback exerted by the ovarian hormones on the anterior pituitary.

A full understanding of the mechanisms of reproductive biology will benefit the clinician in understanding and managing common gynecologic disorders that can result from functional abnormalities of the hypothalamo-pituitary-ovarian (HPO) axis. Understanding of the HPO function will allow clinician to better comprehend the hitherto mysterious but significant effects of stress (psychological as well as physical), diet (restriction as well as surplus), and exercise (mostly excess) on regularity of menstrual cycles. To these ends, this chapter offers a clinically oriented review of the current status of reproductive neuroendocrinology.

# HYPOTHALAMIC-HYPOPHYSEAL PORTAL CIRCULATION

The hypothalamus is a precise region at the base of the brain that lies just above the junction of the optic nerves. In order to influence the anterior pituitary gland, the brain requires a means of signal transmission or connection. A direct nervous connection does not exist. The blood supply of the anterior pituitary, however, originates in the capillaries that richly lace the median eminence area of the hypothalamus. The superior hypophyseal arteries form a dense network of capillaries within the median eminence, which then drains into the portal vessels that descend along the pituitary or neural stalk to the anterior pituitary. The direction of the blood flow in this hypophyseal portal circulation is from the hypothalamus to the pituitary. Disruption of the neural stalk, which interrupts this portal circulation and thereby disrupts signals from the brain to the anterior pituitary, therefore leads to a disruption in the normal function of a number of endocrine targets downstream to the hypothalamus, including the gonads, the adrenal, and the thyroid glands. Inactivity and atrophy of the gonads, along with a decrease in adrenal and thyroid activity to basal levels, ensues after section of the neural stalk. Thus, the anterior pituitary gland is under direct influence of the hypothalamus by means of neurohormones which get released into this portal circulation, and after being carried via portal blood to the anterior pituitary, then mediate control of the anterior pituitary hormones. There also exists some retrograde direction to this signaling, so that the anterior pituitary hormones can also be delivered directly to the hypothalamus, creating an opportunity for pituitary hormones to provide feedback on the hypothalamus ([Figure 4.1](#)). An additional blood supply is provided by short vessels that originate in the posterior pituitary that in turn receives its arterial supply from the inferior hypophyseal arteries.

## **FIGURE 4.1**

# THE NEUROHORMONE CONCEPT

---

The hypothalamus exerts a differential control on the functioning of each of the two endocrine compartments of the pituitary gland (i.e., the anterior and the posterior pituitary). The hypothalamus maintains influence on the pituitary through materials that get secreted by the cells of the hypothalamus into the blood stream of the portal circulation; these agents are then transported to their target cells in the anterior pituitary by the portal vessel system. Indeed, pituitary cell proliferation and gene expression are controlled by hypothalamic peptides and their receptors. In addition to the neural stalk section experiments cited previously, transplantation of the anterior pituitary to an ectopic site (e.g., under the kidney capsule) that does not allow the transplanted tissue access to hypothalamic signals results in failure of gonadal function. With retransplantation of the same pituitary tissue to an anatomic site under the median eminence, followed by regeneration of the portal system, normal pituitary function is regained, underscoring a near absolute dependence of the anterior pituitary on hypothalamic signals. Hence, there is something very special about the blood draining the basal hypothalamus. An exception to this overall pattern of positive influence of hypothalamic signals on anterior pituitary function is the control of prolactin secretion by the anterior pituitary cells (lactotropes). Activity of these cells is normally kept under tonic check by hypothalamic inhibitory signals, as an increase in prolactin levels follows experimental disruption of the pituitary stalk. Furthermore, cultures of the anterior pituitary tissue release prolactin in the absence of coculture with hypothalamic tissue or extracts.

Neuroendocrine factors originating in the hypothalamus are considered as hypothalamic neurohormones and have positive stimulatory effects on a number of anterior pituitary hormones in addition to the gonadotropins (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), including growth hormone (GH), thyroid-stimulating hormone (TSH), and adrenocorticotrophic hormone (ACTH). The hypothalamic neurohormones are named according to their respective target cell population in the anterior pituitary; for example, hypothalamic signal that controls the function of the anterior pituitary gonadotropic cells (FSH- and LH-producing cells) is called the gonadotropin-releasing hormone (GnRH), whereas the neurohormones that control function of the pituitary adrenocorticotrophic (also called adrenocorticotroph's, cells producing ACTH) and thyrotropic cells (or thyrotrophs cells producing TSH) are, respectively, called CRH (corticotropin-releasing hormone) and TRH (thyrotropin-releasing hormone). The hypothalamic neurohormone that controls prolactin secretion by the pituitary lactotropes is called prolactin-inhibiting hormone but is more commonly recognized as dopamine. Of interest is that the hypothalamic neurohormones may influence function of cells other than their specific target cell. For example, while CRH

is the principal regulator of ACTH secretion, it can also activate the sympathetic nervous system, and as we shall see, hypothalamic CRH can suppress gonadotropin secretion, an action partly mediated by endorphin inhibition of GnRH.

In addition to their effects on the pituitary, behavioral effects within the brain have been demonstrated for several of the releasing hormones. TRH antagonizes the sedative action of a number of drugs and also has a direct antidepressant effect in humans. GnRH evokes mating behavior in male and female animals.<sup>1</sup>

Initially, it was believed that there were two separate gonadotropic-releasing hormones, one for FSH and another for LH. It is now accepted that there is a single neurohormone (GnRH) driver for both gonadotropins. GnRH is a small peptide comprised of 10 amino acids, with some variation in the amino acid sequence among various mammals (**Figure 4.2**). Purified or synthesized GnRH stimulates both FSH and LH secretion. Modulating influences of the endocrine environment, specifically the feedback effects of steroids on the anterior pituitary gland, as well as frequency and amplitude of GnRH release, are recognized to explain the divergent patterns of FSH and LH release from the anterior pituitary in response to a single GnRH neurohormone.

Gonadotropin releasing hormone—  
a decapeptide

**FIGURE 4.2**

The classic neurotransmitters are secreted at the nerve terminal. Brain peptides require gene transcription, translation, and posttranslational processing, all within the neuronal cell body. The final product is transported down the axon to the nerve terminal for secretion. Small neuroendocrine peptides share common large precursor polypeptides, called polyproteins or polyfunctional peptides. These proteins can serve as precursors for more than one biologically active peptide.

The gene that encodes for the 92 amino acid precursor protein for GnRH, pro-GnRH, is located on the short arm of chromosome 8.<sup>2</sup> The precursor protein for GnRH contains (in the following order) a 23 amino acid signal sequence, the GnRH decapeptide, a 3 amino acid proteolytic processing site, and a 56 amino acid sequence called GAP (GnRH-associated peptide).<sup>3</sup> GAP is a potent inhibitor of prolactin secretion as well as a stimulator of gonadotropins; however, a physiologic role for GAP has not been established.<sup>4</sup> Its primary role may be to provide appropriate

conformational support for GnRH.

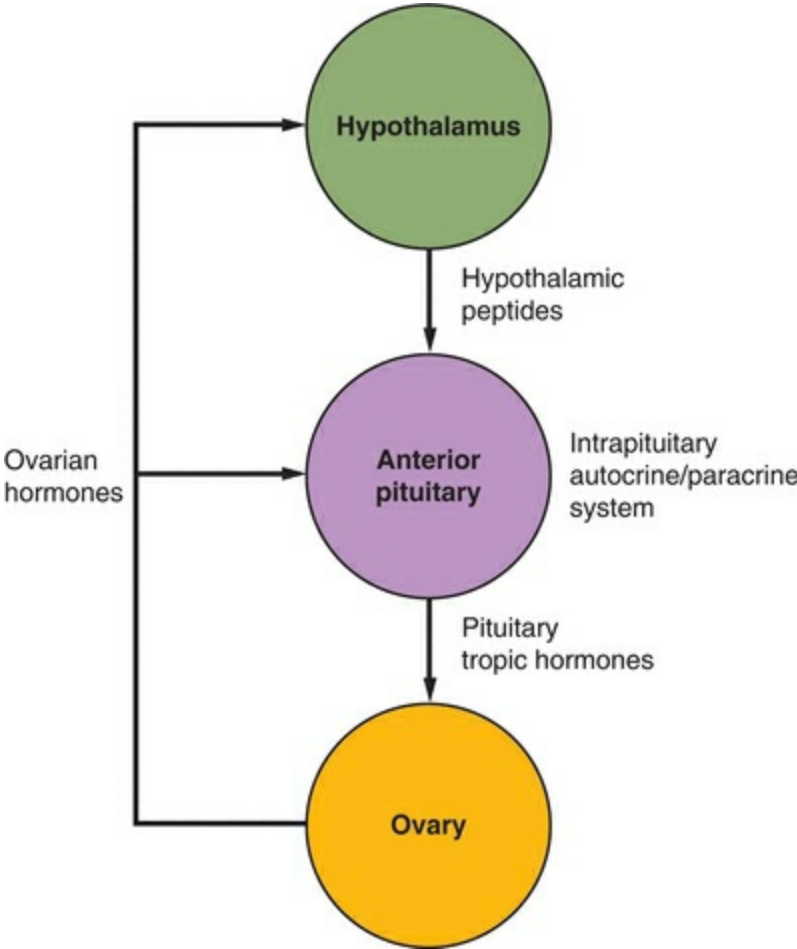

It is now apparent that GnRH has autocrine-paracrine functions throughout the body. It is present in both neural and nonneural tissues, and GnRH receptors are present in many extrapituitary sites (e.g., the ovarian follicle and the placenta). Although the GnRH peptide is identical in all mammals, other nonmammalian forms also exist, indicating that the GnRH molecule has existed for at least 500 million years.<sup>5,6</sup> The central sequence, Tyr-Gly-Leu-Arg, is the nonconserved segment of GnRH, the segment with the most variability across species. Accordingly, substitutions in this fragment of the GnRH neurohormone are well tolerated.

A second form of GnRH, known as GnRH-II, has been known to exist in many other species. GnRH-II consists of the following sequence: pGln-His-Trp-Ser-His-Gly-Trp-Tyr-Pro-Gly. Prompted by its existence in other species, a search for its presence in humans was ultimately successful. A gene encoding GnRH-II is located on the human chromosome 20p13, obviously distinct from the GnRH-I gene on 8p11.2-p21.<sup>7</sup> Similar to GnRH-I, the GnRH-II gene also produces a peptide with a signal sequence, a GnRH decapeptide, a proteolytic site, and a GAP. An analysis of the evolution of GnRH indicates three major forms: GnRH localized to the hypothalamus (GnRH-I), a form in midbrain nuclei and outside the brain (GnRH-II), and yet another variant form that is described in several fish species (GnRH-III), thus indicating appearance of the various forms before the emergence of the vertebrates.<sup>7</sup> In fact, a total of 24 forms of GnRH have been identified in multiple species, but GnRH-I and GnRH-II are the primary GnRH's in mammals.<sup>8</sup> GnRH-I is the main form found in the brain, whereas GnRH-II is widely distributed in other organs with human GnRH-II expression being highest outside the brain.

A hypothalamic 12-amino acid peptide that inhibits pituitary secretion of gonadotropins was isolated from the brain of the Japanese quail.<sup>9</sup> This peptide was identified in mammals as well and labeled as gonadotropin-inhibitory hormone (GnIH), but its presence and possible role/s in primate reproduction remain to be determined.<sup>10</sup>

Despite the aforementioned focus on the hypothalamic signals as drivers of pituitary function, perhaps the notion that the pituitary is a master gland should not be discarded. Although it is highly regulated by input from other sites, its function is essential for sustaining life. The hormones from the pituitary gland regulate puberty, growth, reproduction, metabolism, osmotic balance, and responses to stress. Pituitary development and activity are under the control of the hypothalamus (with input from other CNS sites), and pituitary responses are finely tuned by hormonal messages from tissues that are the targets of the pituitary trophic hormones. In addition, the pituitary has its own autocrine-paracrine system for enhancement and suppression of growth and function. But the pituitary gland is the focus for all of this activity, and this central,

coordinating role executed by the pituitary gland is critical for normal life (Figure 4.3).

**FIGURE 4.3**

# PROLACTIN SECRETION

---

Prolactin gene expression occurs in specialized cells (the lactotrophs) of the anterior pituitary gland, as well as in the decidualized uterine endometrium, and the myometrium. The prolactin hormone secreted in these various anatomical sites is identical, but there are differences in the mRNA indicating differences in prolactin gene regulation.

Transcription of the prolactin gene is regulated by a transcription factor (a protein named Pit-1) that binds to the 5' promoter region and that is also necessary for GH and TSH secretion.<sup>11,12</sup> The expression of Pit-1 is in turn regulated by a transcription factor, Prop1 (Prophet of Pit-1); mutations in the Prop1 binding site in the Pit-1 gene result in deficiencies in multiple pituitary hormones.<sup>12,13</sup> These mutations account for the majority of inherited cases of combined pituitary hormone deficiency. The remainder arise from mutations involving other transcription factors, specifically HESX1, LHX3, LHX4, TBX19, SOX2, and SOX3.<sup>14</sup>

Prolactin gene transcription is regulated by the interaction of estrogen and glucocorticoid receptors with 5' flanking sequences. Mutations in the sequences of these flanking regions or in the gene for the Pit-1 protein can result in a failure to secrete prolactin. The Pit-1 gene is also involved in differentiation and growth of anterior pituitary cells; therefore, mutations in this gene can lead not only to absent secretion of prolactin but also of GH, and TSH, resulting from an absence of their respective tropic cells in the pituitary—the result is significant hypopituitarism.<sup>15</sup> Molecular studies indicate that Pit-1 participates in mediating both stimulatory and inhibitory hormone signals for prolactin gene transcription. However, alterations in Pit-1 gene expression are not involved in pituitary tumor formation.<sup>16</sup>

The main function of the hormone prolactin in mammals is lactogenesis, whereas, in the fish, prolactin is important for osmoregulation. The prolactin gene from the Chinook salmon contains coding sequences that are similar to those in mammals, and it is regulated similarly in the pituitary.<sup>17</sup> Pit-1, the pituitary-specific transcription factor, therefore, appears to be highly conserved among species. Sexual arousal and orgasm in men and women produce marked elevations of circulating levels of prolactin that persist for at least 1 hour, perhaps contributing to the suppression of sexuality immediately after arousal and orgasm.<sup>18,19</sup>

Prolactin gene expression is further regulated by other species-specific factors. Prolactin gene transcription is stimulated by estrogen and mediated by estrogen receptor binding to estrogen-responsive elements. This activation by estrogen requires interaction with Pit-1, in a manner not yet determined. Proximal promoter sequences are

also activated by peptide hormones binding to cell surface receptors, for example, TRH and growth factors. In addition, various agents that control cyclic AMP and calcium channels can stimulate or inhibit prolactin promoter activity.

Pituitary secretion of prolactin is chiefly, if not totally, under the inhibitory control of hypothalamic dopamine released into the portal circulation, a tonic inhibition that requires a high output of dopamine.<sup>20</sup> The action of dopamine in the pituitary is mediated by receptors that are coupled to the inhibition of adenylate cyclase activity. There are five forms of the dopamine receptors, divided into two functional groups. Two of the dopamine receptors, D<sub>1</sub> and D<sub>2</sub>, are encoded by a single gene on chromosome 5, located near the GH receptor gene.<sup>21,22</sup> The D<sub>2</sub> type is the predominant dopamine receptor in the anterior pituitary gland. The structure and function of the dopamine receptors are of the G protein system described in [Chapter 1](#). Binding of dopamine to its receptor leads to suppression of adenylate cyclase and cyclic AMP maintenance of prolactin gene transcription and prolactin secretion. Other mechanisms are also activated, including suppression of intracellular calcium levels. Pit-1-binding sites are involved in this dopamine response. In addition to direct inhibition of prolactin gene expression, dopamine binding to the D<sub>2</sub> receptor also inhibits lactotrope development and growth. These multiple effects of dopamine explain the ability of dopamine agonists to suppress prolactin secretion and the growth of prolactin-secreting pituitary adenomas. No activating or inactivating mutations of the dopamine receptors have been reported.

Several factors exert a stimulatory effect on prolactin secretion (prolactin-releasing factors), especially TRH, vasoactive intestinal peptide (VIP), epidermal growth factor, and perhaps GnRH. These factors also interact with each other, affecting the overall lactotroph responsiveness; however, the only important clinical manifestation is the association of hyperprolactinemia with the elevation in TRH secretion that occurs with primary hypothyroidism. **Prolactin homeostasis is regulated mainly by prolactin itself, feeding back on the dopamine-releasing neurons.**

This dopaminergic mechanism is highly influenced by estrogen, either directly or through other neurotransmitters. Prolactin secretion can be understood by viewing dopamine received through the hypothalamo-pituitary portal system as responsible for its tonic inhibition. The dopaminergic system is itself stimulated by prolactin (prolactin thus decreasing its own secretion) and inhibited by estrogen (with estrogen increasing secretion of prolactin). Modulating influences on the dopaminergic axis include inhibitory influences of endogenous opioids on dopamine release (thereby resulting in an increase in prolactin secretion) and stimulation by other substances, including serotonin and neuropeptide Y (with resulting decrease in prolactin). Prolactin levels are highest during sleep.

Drugs used to treat psychological disorders are dopamine receptor antagonists. The inhibitory activity of dopamine on pituitary secretion of prolactin is blocked by these drugs, and prolactin levels increase in the circulation. Some of the newer drugs in this class do not affect prolactin secretion; these include clozapine, olanzapine, quetiapine, aripiprazole, and ziprasidone. Risperidone and amisulpride, however, act like the older drugs and increase prolactin secretion. The differences reflect the ability of each drug to cross the blood-brain barrier and the variations in affinity for the dopamine receptor.

# THE HYPOTHALAMUS AND GNRH SECRETION

The hypothalamus is the part of the diencephalon at the base of the brain that forms the floor of the third ventricle and part of its lateral walls (**Figure 4.4**). Within the hypothalamus are peptidergic neurohormone secreting neural cells that secrete the earlier described releasing and inhibiting hormones. These cells share the characteristics of both neurons and endocrine gland cells, and hence the name neuroendocrine. They respond to signals in the bloodstream, as well as to neurotransmitters within the brain, by a process known as neurosecretion. In response to appropriate signals, a neurohormone or neurotransmitter gets synthesized by the ribosomes in the cytoplasm of the neuroendocrine cell, is then packaged into a granule in the cellular Golgi apparatus, and then transported by active axonal flow to the neuronal cell terminal for secretion into a blood vessel or across a synapse.

**FIGURE 4.4**

The neuroendocrine cells that produce GnRH originate from the olfactory area or the developing brain. By migration during embryogenesis, these cells move along cranial nerves connecting the nose and the forebrain to their final location, where eventually 1,000–3,000 GnRH-producing cells can be found in the arcuate nucleus of the hypothalamus extending their axons to the median eminence.<sup>23</sup> The GnRH neurons appear in the medial olfactory placode (a thickened plate of ectoderm from which a sense organ develops) and enter the brain with the nervus terminalis, a cranial nerve that projects from the nose to the septal-preoptic nuclei in the brain.<sup>24</sup> Disturbances in this amazing journey characterize the clinical entity Kallmann syndrome; a failure of both olfactory axonal and GnRH neuronal migration from the olfactory placode results in the absence of GnRH as well as defects in the sense of smell that are characteristic of Kallmann syndrome. Three modes of transmission have been documented for Kallmann syndrome: X-linked, autosomal-dominant, and autosomal-recessive.<sup>25</sup> The 5–7-fold increased frequency in the males indicates that X-linked transmission is the most common genetic variant of this disorder. The mutations responsible for this syndrome result in a failure to produce proteins with functions that are necessary for neuronal migration, such as anosmin-1, a protein that is homologous to members of the fibronectin family and responsible for cell adhesion and protease inhibition (in X-linked variants of the syndrome), and receptors for fibroblast growth factor and prokineticin (in autosomal forms of the syndrome).<sup>26,27,28</sup> Normal GnRH neuron development and migration also depend on receptors that are tyrosine kinases, and abnormalities in these receptors might explain some clinical cases of GnRH deficiency.<sup>29</sup>

Like olfactory epithelial cells in the nasal cavity, GnRH neurons have cilia.<sup>30</sup> The olfactory origin and the structural similarity of GnRH neurons and nasal epithelial cells suggest an evolution from reproduction controlled by pheromones. Pheromones are airborne chemicals released by one individual that can affect other members of the same species. Odorless compounds obtained from the axillae of women in the late follicular phase of menstrual cycles accelerated the LH surge and shortened the cycles of recipient women, and compounds from the luteal phase had the opposite effects.<sup>31</sup> This may be one mechanism by which women who are together much of the time have been reported to exhibit a synchrony in menstrual cycle timing.<sup>32,33,34,35,36</sup> However, the work on menstrual synchrony has been criticized, emphasizing that methodologic problems have led to incorrect conclusions.<sup>37</sup>

In primates, GnRH cell bodies are primarily located within the medial basal hypothalamus.<sup>38,39,40</sup> Most of these cell bodies can be seen within the arcuate nucleus where GnRH is synthesized in GnRH neurons. The GnRH neurons exist in a complex network and are connected to each other and to many other neurons. This physical

arrangement allows multiple interactions with neurotransmitters, hormones, and growth factors to modulate GnRH release. The delivery of the neural secreted GnRH to the portal circulation is via an axonal pathway, the GnRH tuberoinfundibular tract. Nerve fibers, identified with immunocytochemical techniques using antibodies to GnRH, can also be visualized in the posterior hypothalamus, descending into the posterior pituitary, and in the anterior hypothalamic area projecting to sites within the limbic system (Figure 4.5).<sup>38</sup> Using hybridization techniques, messenger RNA for GnRH has been localized to the same sites previously identified by immunoreactivity. However, lesions that interrupt GnRH neurons projecting to regions other than the median eminence do not affect pituitary gonadotropin release. Only lesions of the arcuate nucleus in the monkey lead to gonadal atrophy and amenorrhea consequent to loss of gonadotropin signal.<sup>41</sup> **Therefore, the arcuate nucleus can be viewed with the median eminence as a unit, the key locus within the hypothalamus for GnRH secretion into the portal circulation.** GnRH neurons in other locations may be important for a variety of behavioral responses.

**FIGURE 4.5**

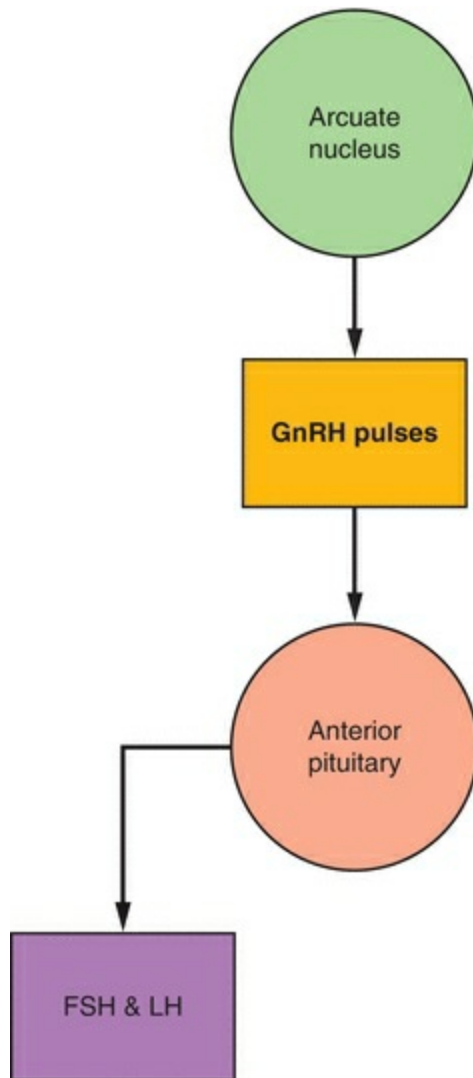

# GnRH Secretion

The half-life of GnRH is only 2–4 minutes. Because of this rapid degradation, combined with the enormous dilution on entry into the peripheral circulation, biologically effective amounts of GnRH do not escape the hypophyseal portal system. Therefore, control of the reproductive cycle depends on constant release of GnRH, which in turn results from complex and coordinated interrelationships among this releasing hormone, other neurohormones, the pituitary gonadotropins, and the gonadal steroids. The interplay among these substances is governed by feedback effects, both positive stimulatory and negative inhibitory. **The long feedback loop** refers to the feedback effects of circulating levels of target gland hormones, and this occurs both in the hypothalamus and the pituitary. **The short feedback loop** indicates a negative feedback of pituitary hormones on their own secretion, presumably via inhibitory effects on releasing hormones in the hypothalamus. **Ultrashort feedback** refers to inhibition by the releasing hormone on its own synthesis. These signals as well as signals from higher centers in the CNS may modify GnRH secretion through an array of neurotransmitters, primarily dopamine, norepinephrine, and endorphin but also serotonin and melatonin. Dopamine and norepinephrine are synthesized in the nerve terminals by decarboxylation of dihydroxyphenylalanine (DOPA), which in turn is synthesized by hydroxylation of tyrosine. Dopamine is the immediate precursor of norepinephrine and epinephrine, but dopamine itself functions as a key neurotransmitter in the hypothalamus and the pituitary (**Figure 4.6**).<sup>20</sup>

**FIGURE 4.6**

**A most useful concept is to view the arcuate nucleus as the central site of action, releasing GnRH into the portal circulation in pulsatile fashion.** In a classic series of experiments, it was demonstrated that normal gonadotropin secretion by the pituitary gonadotrophs requires pulsatile GnRH discharge within a critical range in both frequency and amplitude (Figure 4.7).<sup>42,43</sup>

**FIGURE 4.7**

Experimental manipulations have indicated that the critical range of GnRH pulsatile secretion is rather narrow. The administration (to monkeys) of 1  $\mu\text{g}$  GnRH per minute for 6 minutes every hour (one pulse per hour) produces a portal blood concentration about equal to the peak concentration of GnRH in human portal blood, about 2 ng/mL. Increasing the frequency to two and five pulses per hour extinguishes gonadotropin secretion. A similar decline in gonadotropin secretion is obtained by increasing the dose of GnRH. Decreasing the pulse frequency decreases LH secretion but increases FSH secretion.

Like GnRH, gonadotropins are also secreted in pulsatile fashion, and, indeed, the pulsatile pattern of gonadotropin release reflects the pulsatile GnRH pattern.<sup>44,45</sup> GnRH and gonadotropin secretion are always pulsatile in nature, but an augmentation of the pulsatile pattern of gonadotropin secretion occurs just before puberty with nighttime increases in LH. In puberty, arcuate activity begins with a low frequency of GnRH

release and proceeds through a cycle of acceleration of frequency, characterized by passage from relative inactivity, to nocturnal activation, to the full adult pattern. The progressive changes in FSH and LH reflect this activation of GnRH pulsatile secretion. After puberty, enhanced pulsatile secretion is maintained throughout the 24-hour period, but it varies in both amplitude and frequency. Ovarian steroid release is also pulsatile, coordinated with LH pulses, the major stimulator of ovarian steroidogenesis.<sup>46</sup> In the absence of ovarian regulation, the GnRH pulse frequency is approximately one pulse per hour.<sup>47</sup>

# Timing of GnRH Pulses

The measurement of LH pulses is used as an indication of GnRH pulsatile secretion (the long half-life of FSH precludes its use for this purpose).<sup>48</sup> The characteristics of LH pulses (and presumably of GnRH pulses) during the menstrual cycle are as follows<sup>46,49,50</sup>:

- **LH pulse mean amplitude:**
  - Early follicular phase 6.5 IU/L
  - Midfollicular phase 5.0 IU/L
  - Late follicular phase 7.2 IU/L
  - Early luteal phase 15.0 IU/L
  - Midluteal phase 12.2 IU/L
  - Late luteal phase 8.0 IU/L
- **LH pulse mean frequency:**
  - Early follicular phase 90 minutes
  - Late follicular phase 60–70 minutes
  - Early luteal phase 100 minutes
  - Late luteal phase 200 minutes

The follicular phase of the menstrual cycle is characterized by a higher frequency and lower amplitude of GnRH pulses compared to the luteal phase. The slowing of GnRH pulse frequencies in the late luteal phase is an important change, favoring FSH synthesis and secretion over that of LH; this transition in GnRH pulse characteristics allows the rise in FSH that is essential for the next cycle.<sup>51</sup> An increase in frequency and amplitude in mid-cycle GnRH pulsatile secretion favors the surge of LH that is necessary for ovulation and the beginning of the luteal phase.

It should be emphasized that these numbers are not inviolate. There is considerable variability between and within individuals, and a wide normal range exists.<sup>52</sup> Despite the handicap of the long half-life, it has been ascertained that FSH secretion is correlated with LH secretion. The changes in amplitude are relatively small; therefore, increasing and decreasing circulating levels of the gonadotropins are affected mostly by changes in GnRH pulse frequency. During the luteal-follicular transition, pulse frequency increases approximately 4.5-fold.<sup>50</sup> In rodents, the frequency of GnRH pulses determines which gonadotropin subunit gene will be preferentially expressed.<sup>53</sup>

The anterior pituitary gland and GnRH neurons have an intrinsic pulsatile pattern. Although gonadotropin pulses of significant amplitude are linked to released GnRH, small-amplitude pulses of high frequency represent spontaneous secretion from the

anterior pituitary (at least as demonstrated in isolated pituitary glands in vitro).<sup>54</sup> It is not known whether this has any importance physiologically, and, at the present time, the pituitary secretory pattern is thought to reflect GnRH. The pulsatile secretion of GnRH correlates with episodic GnRH-I gene expression in the hypothalamus.<sup>8</sup> A promoter site in the GnRH-I gene is responsible for the pulsatile nature of the secretions, regulated by the usual array of transcription factors.<sup>55</sup>

# Control of GnRH Pulses

Normal menstrual cycles require the maintenance of the pulsatile release of GnRH within a critical range of frequency and amplitude. Pulsatile, rhythmic activity is an intrinsic property of GnRH neurons, and the effect of various hormones and neurotransmitters must be viewed as modulating actions.<sup>56</sup>

## The Dopamine Tract

Cell bodies for dopamine-producing neurons can be found in the arcuate and periventricular nuclei (Figure 4.8). The dopamine tuberoinfundibular tract arises within the medial basal hypothalamus and its short axons terminate in the median eminence; it provides the major dopaminergic effect on the pituitary.

**FIGURE 4.8**

Administration of dopamine by intravenous infusion to men and women is associated with a suppression of circulating prolactin and gonadotropin levels.<sup>57</sup> Dopamine,

however, does not exert a direct effect on gonadotropin secretion by the anterior pituitary, but this effect is mediated through alteration in GnRH release in the hypothalamus. Dopamine is directly secreted into the portal blood, thus behaving like a neurohormone. Therefore, dopamine may directly suppress arcuate GnRH activity and also be transported via the portal system to directly and specifically suppress pituitary prolactin secretion. The hypothalamic tuberoinfundibular dopamine pathway is only one of two major dopamine pathways in the hypothalamus. But it is this pathway that directly participates in the regulation of prolactin secretion. In addition, prolactin delivered to the intermediate lobe of the pituitary suppresses melanocyte-stimulating hormone (MSH) release.

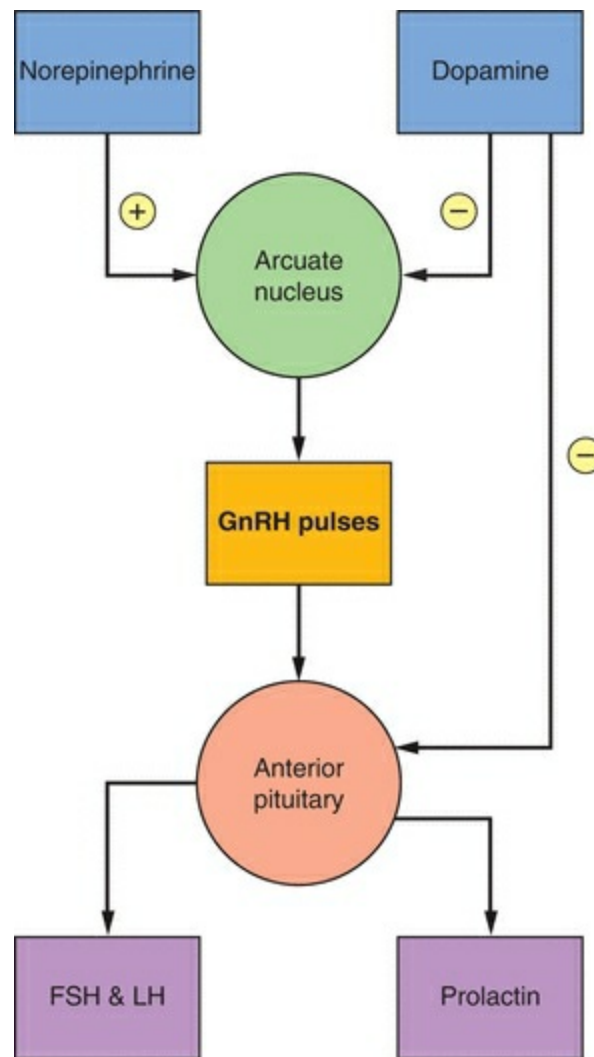

## The Norepinephrine Tract

Most of the cell bodies that synthesize norepinephrine are located in the mesencephalon and lower brainstem (**Figure 4.9**). These cells also synthesize serotonin. Axons for amine transport ascend into the medial forebrain bundle to terminate in various brain structures including the hypothalamus.

**FIGURE 4.9**

The biogenic catecholamines modulate GnRH pulsatile release (Figure 4.10).<sup>58</sup> Norepinephrine is thought to exert stimulatory effects on GnRH, whereas dopamine and serotonin exert inhibitory effects. For an understanding of clinical problems, it is best to view dopamine as an inhibitor of both GnRH and prolactin. Little is known, however, about the role of serotonin. The probable mode of action of catecholamines is to influence the frequency (and perhaps the amplitude) of GnRH discharge. Thus, pharmacologic or psychologic factors that affect pituitary function probably do so by altering catecholamine synthesis or metabolism and, thus, the pulsatile release of GnRH.

**FIGURE 4.10**

## Neuropeptide Y

Neuropeptide Y is an important peptide in the mechanism by which leptin and insulin inform the hypothalamus about the nutritional state of an individual. The secretion and

gene expression of neuropeptide Y in hypothalamic neurons are regulated by gonadal steroids.<sup>59</sup> Neuropeptide Y stimulates appetite and the pulsatile release of GnRH; in the pituitary, it potentiates gonadotropin response to GnRH.<sup>60</sup> It, thus, may facilitate pulsatile secretion of GnRH and gonadotropins. In the absence of estrogen, neuropeptide Y inhibits gonadotropin secretion. Because undernutrition is associated with an increase in neuropeptide Y (see [Chapter 19](#)) and increased amounts have been measured in cerebrospinal fluid (CSF) of women with anorexia and bulimia nervosa, neuropeptide Y is viewed as at least one link between nutrition and reproductive function.<sup>61,62</sup> The level of the neuroendocrine activity involved in reproduction is sensitive to an individual's energy state, or more simply, to the availability of sufficient body fuel to support reproduction.

## **Kisspeptins**

Kisspeptins are peptides encoded by the gene *Kiss1* that is expressed in the hypothalamus. Kisspeptin and its G-protein receptor, GPR54, are essential for the normal pubertal development.<sup>63</sup> This signaling pathway is involved in the activation of GnRH neurons and GnRH secretion.<sup>64,65</sup> The kisspeptin neurons contain estrogen and progesterone receptors and are involved not only in puberty but in the changes associated with ovulatory cycles, in at least one pathway by which the sex steroids affect GnRH secretion.

# PITUITARY GONADOTROPIN SECRETION

---

The gene for the alpha ( $\alpha$ ) subunit of the gonadotropins is expressed in both the pituitary and placenta. The  $\beta$  subunit for human chorionic gonadotropin (hCG) is expressed in the placenta but only minimally (and with alterations in structure) in the pituitary, whereas the LH  $\beta$  subunit, as expected, is expressed in the pituitary but not significantly in the placenta.<sup>66,67</sup> Studies of gonadotropin gene expression confirm the relationships established by earlier studies. The sex steroids decrease and castration increases the rate of gonadotropin gene transcription as reflected by the levels of specific messenger RNAs. In addition, the sex steroids can act at the membrane level, affecting the interaction of GnRH with its receptor.<sup>68</sup>

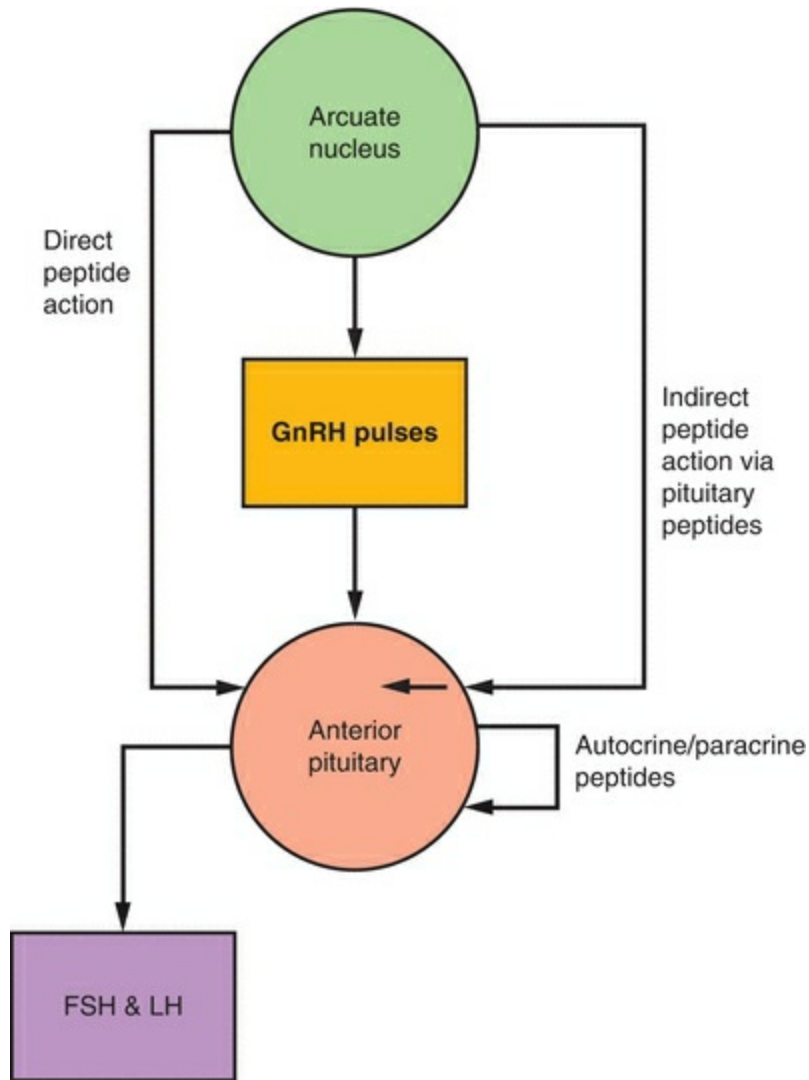

Both LH and FSH are secreted by the same cell, the gonadotrope, localized primarily in the lateral portions of the pituitary gland, and responsive to the pulsatile stimulation by GnRH. GnRH is calcium dependent in its mechanism of action and utilizes inositol 1,4,5-triphosphate ( $IP_3$ ) and 1,2-diacylglycerol (1,2-DG) as second messengers to stimulate protein kinase and cyclic AMP activity (Chapter 2).<sup>69</sup> These responses require a G protein receptor and are associated with cyclical release of calcium ions from intracellular stores and the opening of cell membrane channels to allow entry of extracellular calcium. Thus, calmodulin (a calcium-binding protein), protein kinase, and cyclic AMP are all downstream mediators of GnRH action. Within the gonadotropin secreting cells, gene transcription is mediated by several transcription factors, providing a mechanism by which the various subunits of FSH and LH can be synthesized and secreted by the same cell.<sup>70</sup> The rate-limiting step for the secretion of FSH and LH is the synthesis of the  $\beta$ -subunits of each gonadotropin.

The GnRH type I receptor, a member of the G protein family, is encoded by a gene on chromosome 14q13.1-q21.1.<sup>71,72</sup> The location of the type II receptor is uncertain; in the marmoset, it is on chromosome 1q.<sup>73</sup> The exact roles of the two GnRHs and GnRH receptors in the human are yet to be determined. GnRH receptors are regulated by many agents, including GnRH itself, peptides inhibin and activin, and the sex steroids.<sup>74</sup> The number of GnRH receptors available is significantly regulated by the frequency of GnRH pulses. The signaling pathways include the induction and modification of stimulatory and inhibitory transcription factor proteins. No mutations in the GnRH gene have been described in patients with hypogonadotropic hypogonadism; however, multiple mutations in the GnRH receptor gene have been reported.

Synthesis of gonadotropins takes place on the rough endoplasmic reticulum. The hormones are packaged into secretory granules by the Golgi cisternae of the Golgi apparatus and then stored as secretory granules. Secretion requires migration (activation) of the mature secretory granules to the cell membrane where an alteration in

membrane permeability results in extrusion of the secretory granules in response to GnRH. The rate-limiting step in gonadotropin synthesis is the GnRH-dependent availability of the  $\beta$  subunits.

Binding of GnRH to its receptor in the pituitary activates multiple messengers and responses. The immediate event is a secretory release of gonadotropins, whereas delayed responses prepare for the next secretory release. One of these delayed responses is the self-priming action of GnRH that leads to even greater responses to subsequent GnRH pulses due to a complex series of biochemical and biophysical intracellular events. This self-priming action is important to achieve the large surge in gonadotropin secretion at midcycle; it requires estrogen exposure, and it can be augmented by progesterone. This important action of progesterone depends on estrogen exposure (that results in an increase in the expression of progesterone receptors) and activation of the progesterone receptor by GnRH-stimulated phosphorylation. This latter action is an example of cross-talk between peptide and steroid hormone receptors (**Figure 4.11**).

**FIGURE 4.11**

Five different types of secretory cells coexist within the anterior pituitary gland: gonadotropes (secrete gonadotropins FSH and LH), lactotropes (secrete prolactin), thyrotropes (secrete TSH), somatotropes (GH secreting cells), and corticotropes (ACTH secreting cells). Autocrine and paracrine interactions combine to make anterior pituitary secretion subject to more complicated control than simply reaction to hypothalamic-releasing factors and modulation by feedback signals. Substantial experimental evidence exists to indicate stimulatory and inhibitory influences of various substances on the pituitary secretory cells. Although the GnRH system is a primary mechanism, other hypothalamic peptides can influence gonadotropin secretion by the pituitary gonadotropes. Peptides can interact with GnRH at the pituitary; peptides can be transported to the pituitary gland where they can directly affect the gonadotropes (e.g., oxytocin, CRH, and neuropeptide Y) or indirectly have an effect on FSH and LH secretion by stimulating release of active substances within the pituitary (e.g., galanin,

interleukins).

# THE INTRAPITUITARY AUTOCRINE-PARACRINE SYSTEM

---

Intrapituitary cytokines and growth factors provide an autocrine-paracrine system for regulating pituitary cell development and replication, as well as influence pituitary hormone synthesis and secretion. The pituitary contains the familiar cast of substances encountered in organs throughout the body, including the interleukins, epidermal growth factor, fibroblast growth factors, insulin-like growth factors, nerve growth factor, activin, inhibin, endothelin, and many others.<sup>75,76,77</sup> As in most tissues, the interaction among these substances is a complex story, but the activin-inhibin mechanism deserves emphasis.

# Activin, Inhibin, and Follistatin

Activin and inhibin are peptide members of the transforming growth factor-beta ( $\beta$ ) family.<sup>78</sup> Inhibin consists of two dissimilar peptides ( $\alpha$  and  $\beta$  subunits) linked by disulfide bonds. Two forms of inhibin (inhibin-A and inhibin-B) have been purified, each containing an identical  $\alpha$  subunit and distinct but related  $\beta$  subunits. Thus, there are three subunits for inhibins: alpha, beta-A, and beta-B. Each subunit is a product of different messenger RNA; therefore, each is derived from its own large precursor molecule.

Inhibin is secreted by the ovarian granulosa cells, but messenger RNA for the  $\alpha$  and  $\beta$  chains has also been found in pituitary gonadotropes.<sup>79</sup> Inhibin selectively inhibits FSH but not LH secretion. Indeed, while suppressing FSH synthesis, inhibin may enhance LH activity.<sup>80,81</sup> Cells actively synthesizing LH respond to inhibin by increasing GnRH receptor number; FSH dominant cells are suppressed by inhibin.<sup>80</sup> Inhibin has little or no effect on GH, ACTH, or prolactin production. The mechanism of FSH inhibition may be secondary to inhibin competing with activin for the activin receptor.

Activin, also derived from ovarian granulosa cells, but present as well in the pituitary gonadotropes, contains two subunits that are identical to the  $\beta$  subunits of inhibins A and B. In addition, activins have been identified with variants of the  $\beta$  subunits, designated as beta-C, beta-D, and beta-E.<sup>82</sup> The activin beta-C and beta-E genes have been demonstrated to be nonessential in mouse knockout models.<sup>83</sup> Activin augments the secretion of FSH and inhibits prolactin, ACTH, and GH responses.<sup>81,84,85,86</sup> Activin increases pituitary response to GnRH by enhancing GnRH receptor formation.<sup>74,87</sup> The effects of activin are blocked by inhibin and follistatin.<sup>88</sup> The roles for inhibin and activin in regulating the events of the menstrual cycle are discussed in [Chapter 5](#). In contrast to inhibin's major role in suppressing FSH secretion, activin has a broad range of activities, involving bone, neurons, wound healing, and autocrine-paracrine functions in many organs ([Table 4.1](#)).

Follistatin is a peptide secreted by a variety of pituitary cells, including the gonadotropes.<sup>89</sup> This peptide has also been called FSH-suppressing protein because of its main action: inhibition of FSH synthesis and secretion and the FSH response to GnRH, by binding to activin and in that fashion decreasing the activity of activin.<sup>90,91</sup> Activin in turn stimulates follistatin production, and inhibin prevents this response.

# **SUMMARY: CONTROL OF GONADOTROPIN SECRETION**

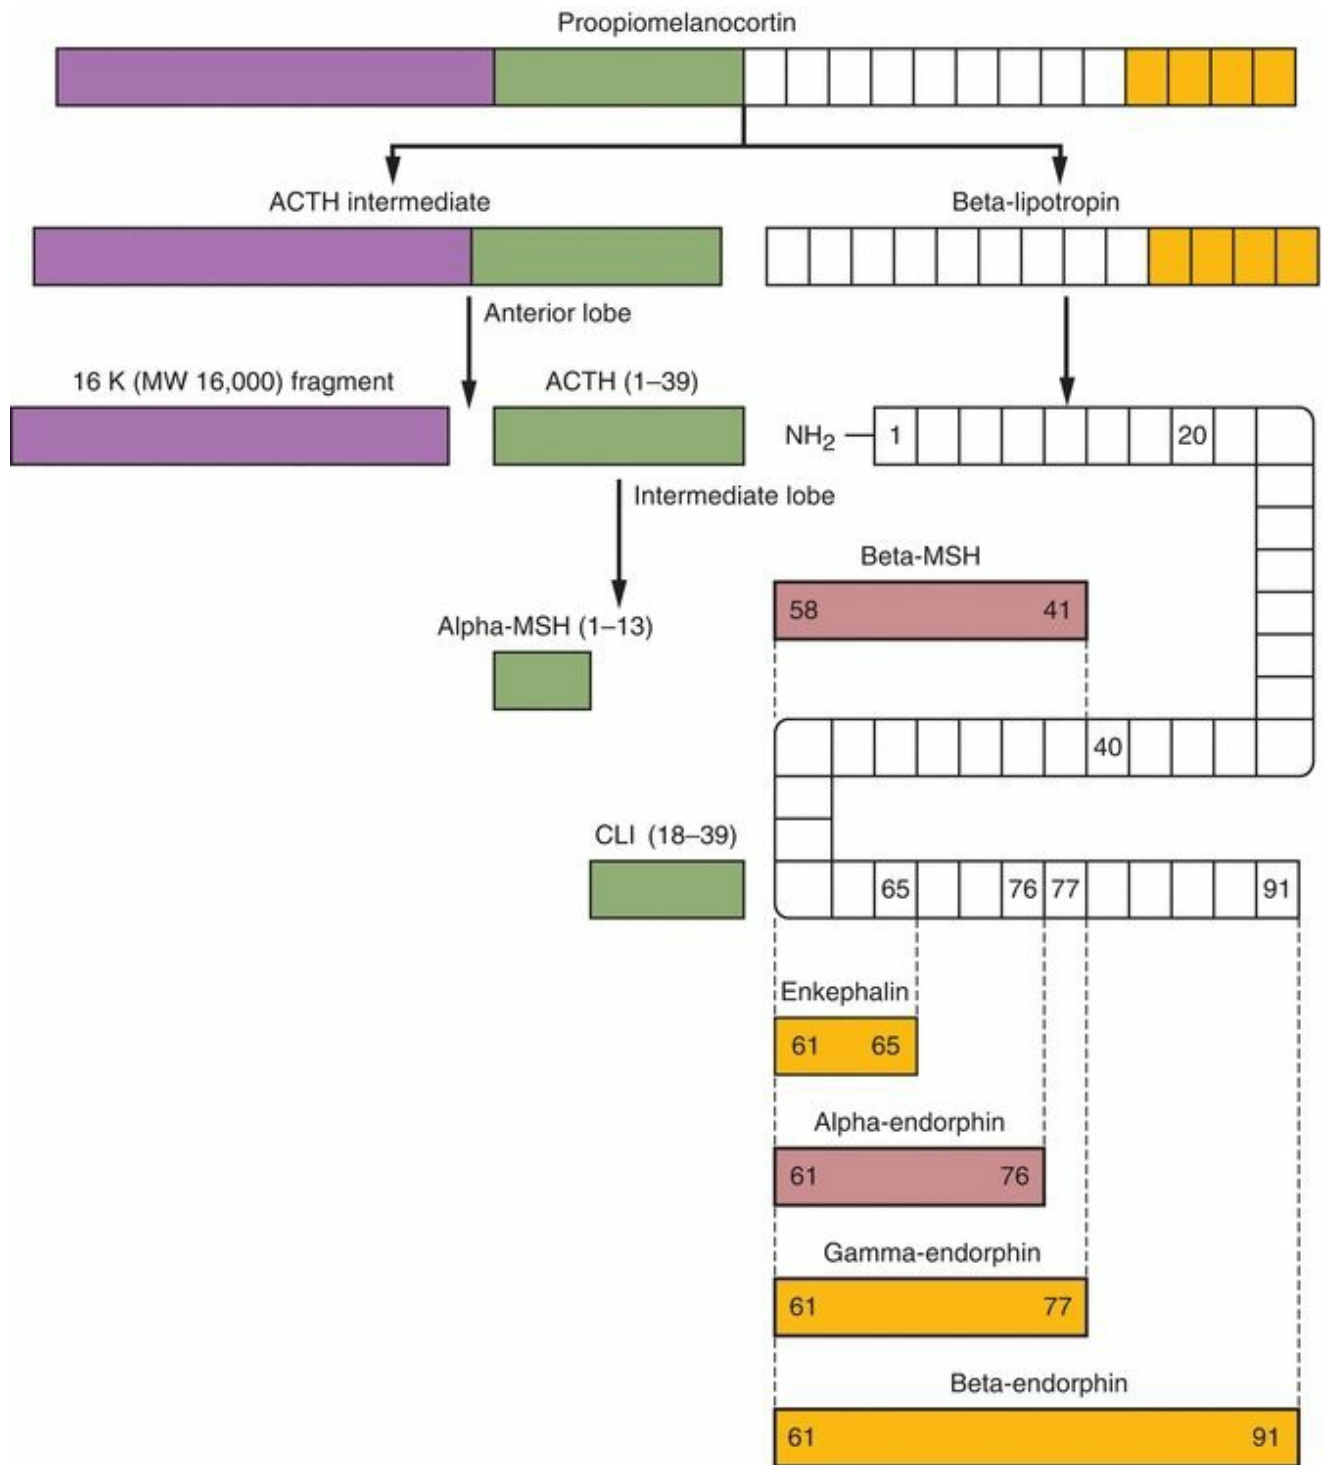

---

**In summary, synthesis and secretion of pituitary gonadotropins are under control of hypothalamic GnRH, as well as influenced to varying degree, by activin, inhibin, and follistatin. Activin enhances and follistatin suppresses GnRH activity. Evidence in vivo and in vitro indicates that gonadotropin response to GnRH requires activin activity, and gonadotropin response can be blocked by follistatin.<sup>92,93,94</sup> This relationship contributes to the down-regulation of pituitary gonadotropin secretion by prolonged GnRH stimulation. Increasing GnRH pulse frequency first increases FSH production, and, then with sustained high frequency or continuous GnRH stimulation, follistatin production is increased.<sup>92</sup> Selective synthesis and secretion of FSH can be explained by the decrease in the inhibiting factors, inhibin and follistatin, allowing activin to enhance the actions of GnRH, involving the transcription factors that promote FSH  $\beta$ -subunit expression.<sup>95</sup> LH secretion is primarily regulated by GnRH, without involvement of the inhibin-activin-follistatin system.**

# THE ENDOGENOUS OPIATES

---

The most fascinating peptide group is the endogenous opioid peptide family (**Figure 4.12**).<sup>96</sup>  $\beta$ -Lipotropin is a 91 amino acid molecule that was first isolated from the pituitary in 1964. Its function remained a mystery for more than 10 years until receptors for opioid compounds were identified, and, by virtue of their existence, it was postulated that endogenous opioid compounds must exist and serve important physiologic roles. Endorphin was a word coined to denote morphine-like action and endogenous origin in the brain.

**FIGURE 4.12**

Opiate production is regulated by gene transcription and the synthesis of precursor peptides and at a posttranslational level where the precursors are processed into the various bioactive smaller peptides.<sup>97</sup> All opiates derive from one of three precursor peptides.

- **Proopiomelanocortin (POMC)**—the source of endorphins
- **Proenkephalin A and B**—yields several enkephalins
- **Prodynorphin**—yields dynorphins

POMC was the first precursor peptide to be identified. It is made in the anterior and intermediate lobes of the pituitary, in the hypothalamus and other areas of the brain, in the sympathetic nervous system and in many other tissues including the gonads, the placenta, the gastrointestinal tract, and lungs; the highest concentrations are found in the pituitary gland.

POMC is split into two fragments, an ACTH intermediate fragment and the  $\beta$ -lipotropin. The  $\beta$ -lipotropin has no opioid activity but is broken down in a series of steps to  $\beta$ -melanocyte-stimulating hormone ( $\beta$ -MSH), enkephalin, and  $\alpha$ -,  $\gamma$ -, and  $\beta$ -endorphins. In lower animals,  $\beta$ -MSH acts to stimulate melanin granules within cells, causing darkening of the skin. In humans, however, there is no known function of  $\beta$ -MSH.

Enkephalin and the  $\alpha$ - and  $\gamma$ -endorphins are active opioids, almost as active as morphine on a molar basis, whereas  $\beta$ -endorphin is 5–10 times more potent. In the adult pituitary gland, the major products are ACTH and  $\beta$ -lipotropin, with only small amounts of endorphin. Thus, ACTH and  $\beta$ -lipotropin blood levels show similar courses, and they are major secretion products of the anterior pituitary in response to stress. In the intermediate lobe of the pituitary (which is prominent only during fetal life), ACTH is cleaved to CLIP (corticotropin-like intermediate lobe peptide) and  $\beta$ -MSH. In the placenta and the adrenal medulla, POMC processing yields  $\alpha$ -MSH-like and  $\beta$ -endorphin peptides.  $\beta$ -Endorphin has also been detected in the ovaries and in the testes.

In the brain, the major products are the opiates, with little ACTH. In the hypothalamus, the major products are  $\beta$ -endorphin and  $\alpha$ -MSH in the region of the arcuate nucleus and the ventromedial nucleus. **The pituitary opiate system is a system for secretion into the circulation, whereas the hypothalamic opiate system allows for distribution via axons to regulate other brain regions and the pituitary gland.**

$\beta$ -Endorphin is appropriately considered a neurotransmitter, a neurohormone, and a neuromodulator and is recognized to influence a variety of hypothalamic functions, including regulation of reproduction, temperature, and cardiovascular and respiratory function; it additionally influences extra-hypothalamic functions such as pain perception and mood. POMC gene expression in the anterior pituitary is controlled mainly by the CRH and influenced by the feedback effects of glucocorticoids. In the hypothalamus, regulation of POMC gene expression is via the sex steroids.<sup>98</sup> In the absence of sex steroids, little, if any, secretion occurs.

Proenkephalin A is produced in the adrenal medulla, the brain, the posterior

pituitary, the spinal cord, and the gastrointestinal tract. It yields several enkephalins: methionine-enkephalin, leucine-enkephalin, and other variants. The enkephalins are the most widely distributed endogenous opioid peptides in the brain and are probably mainly involved as inhibitory neurotransmitters in the modulation of the autonomic nervous system. Prodynorphin, found in the brain (concentrated in the hypothalamus) and the gastrointestinal tract, yields dynorphin, an opioid peptide with high analgesic potency and behavioral effects, as well as  $\alpha$ -neoendorphin,  $\beta$ -neoendorphin, and leumorphin. The last 13 amino acids of leumorphin constitute another opioid peptide, rimorphin. The prodynorphin products probably function in a fashion similar to endorphin.

**It is simpler to say that there are three classes of opiates: enkephalin, endorphin, and dynorphin.**

Opioid peptides are able to act through different receptors, although specific opiates bind predominantly to one of the various receptor types. Naloxone, used in most human studies, does not bind exclusively to any one receptor type, and, thus, results with this opioid antagonist are not totally specific. Localization of opioid receptors explains many of the pharmacologic actions of the opiates. Opioid receptors are found in the nerve endings of sensory neurons, in the limbic system (site of euphoric emotions), in brainstem centers for reflexes such as respiration, and widely distributed in the brain and the spinal cord.

# Opioid Peptides and the Menstrual Cycle

The opioid tone is an important regulator of the menstrual function and menstrual cyclicity.<sup>99</sup> Although estradiol alone increases endorphin secretion, the highest levels of endorphin occur with sequential therapy of both estradiol and progesterone (in ovariectomized monkeys). Endogenous endorphin levels, therefore, increase throughout the cycle from nadir levels during menses (when estradiol levels are at the low) to the highest levels during the luteal phase (when both progesterone and estradiol levels are increased). Normal menstrual cyclicity, thus, requires sequential periods of high (luteal phase) and low (during menses) hypothalamic opioid activity.

A reduction in LH pulse frequency is linked to increased endorphin release.<sup>100</sup> Naloxone increases both the frequency and the amplitude of LH pulses. **Thus, the endogenous opiates inhibit gonadotropin secretion by suppressing the hypothalamic release of GnRH (Figure 4.13).** Opiates have no effect on the pituitary response to GnRH. The gonadal steroids modify endogenous opioid activity, and the negative feedback of steroids on gonadotropins appears to be mediated by endogenous opiates. Because the fluctuating levels of endogenous opiates in the menstrual cycle are related to the changing levels of estradiol and progesterone, it is attractive to speculate that the sex steroids directly stimulate endogenous opioid receptor activity. There is an absence of opioid effect on postmenopausal and oophorectomized levels of gonadotropins, and the response to opiates is restored with the administration of estrogen, progesterone, or both.<sup>101</sup> Both estrogen and progesterone alone increase endogenous opiates, but estrogen enhances the action of progesterone, which could explain the maximal suppression of GnRH and gonadotropin pulse frequency during the luteal phase.<sup>102,103</sup> In pubertal boys and girls, however, naloxone could not prevent the suppression of LH by estradiol administration, indicating that in this circumstance, estradiol may directly inhibit GnRH secretion.<sup>104,105</sup> Nevertheless, the evidence overall indicates that endogenous opiates exert an inhibiting influence over GnRH secretion.<sup>106</sup> The negative feedback of progesterone on GnRH secretion (the major mechanism for the inhibition of ovulation associated with progestin contraception) is definitely partly mediated by endogenous opiates but also by other neural mechanisms not yet determined.<sup>107</sup>

**FIGURE 4.13**

The inhibiting tone of endogenous opiates on GnRH secretion is reduced at the time of the ovulatory surge, allowing a release from suppression.<sup>108</sup> This is probably a response to estrogen, specifically an estrogen-induced decrease in opioid receptor binding and opioid release.<sup>109,110</sup>

Experiments with naloxone administration suggest that the suppression of gonadotropins during pregnancy and the recovery during the postpartum period reflect steroid-induced opioid inhibition, followed by a release from central opioid suppression.

The principal endogenous opiates affecting GnRH release are  $\beta$ -endorphin and dynorphin, and it is probable that the major effect is modulation of the catecholamine pathway, principally norepinephrine. The action does not involve dopamine receptors, acetylcholine receptors, or  $\alpha$ -adrenergic receptors. On the other hand, endorphin may affect GnRH release directly, without the involvement of any intermediary neuroamine.

Because  $\alpha$ -MSH counteracts the effects of  $\beta$ -endorphin, posttranslational processing of POMC can affect hypothalamic-pituitary function by altering the amounts of  $\alpha$ -MSH

and  $\beta$ -endorphin.<sup>111</sup> This introduces another potential site for neuroendocrine regulation of reproductive function. Gonadal hormones likely have multiple sites for feedback signals.

# Clinical Implications

A change in the opioid inhibitory tone is not important in the neuroendocrine events of puberty because the responsiveness to naloxone does not develop until after puberty. Alteration in the opioid tone does seem to mediate the hypogonadotropic state seen with elevated prolactin levels, excessive exercise, and other conditions of hypothalamic amenorrhea, whereas endogenous opioid inhibition does not seem to play a causal role in cases of delayed puberty or hereditary problems such as Kallmann syndrome.<sup>112,113</sup> Treatment of patients with hypothalamic amenorrhea (characterized by suppressed GnRH pulsatile secretion) with a drug (naltrexone) that blocks opioid receptors restores normal function (ovulation, menstrual cycles, and pregnancy).<sup>114</sup> These data suggest that the reduced GnRH secretion associated with hypothalamic amenorrhea is mediated by an increase in endogenous opioid inhibitory tone.

Experimental evidence indicates that hypothalamic CRH inhibits hypothalamic GnRH secretion, both directly and by augmenting endogenous opioid secretion. Women with hypothalamic amenorrhea demonstrate hypercortisolism, suggesting that this is the pathway by which stress interrupts reproductive function.<sup>115</sup> Mathematical analysis of the associations among FSH, LH,  $\beta$ -endorphin, and cortisol pulses support the existence of significant functional coupling between the neuroregulatory systems that control the gonadal and adrenal axes.<sup>116</sup> The CRH gene contains two segments that are similar to estrogen response elements, allowing estrogen enhancement of CRH activity, perhaps explaining the greater vulnerability of the reproductive axis to stress in females.<sup>117</sup> Besides the CRH-induced inhibition of GnRH release, the increase in cortisol generated by CRH stimulation of pituitary ACTH secretion also contributes to the suppression of reproduction; cortisol directly inhibits pituitary responsiveness to GnRH.<sup>118</sup>

Cumming concluded that most studies indicate an exercise-induced increase in endogenous opiates, but a significant impact on mood remains to be substantiated.<sup>119</sup> He noted that runners' high is more common in California than in Canada (euphoria is hard to come by when running in below freezing temperatures!).

Administration of morphine, enkephalin analogs, and  $\beta$ -endorphin causes release of prolactin. The effect is mediated by inhibition of dopamine secretion in the tuberoinfundibular neurons in the median eminence. Most studies have reported no effect of naloxone on basal, stress-induced, or pregnant levels of prolactin nor on prolactin secretion by prolactinomas. Thus, a physiologic role for endogenous opioid regulation of prolactin does not appear to exist in men and women. However, suppression of GnRH secretion associated with hyperprolactinemia does appear to be mediated by endogenous opiates.<sup>120</sup>

Every pituitary hormone appears to be modulated by endogenous opiates. Physiologic effects are important with ACTH, gonadotropins, and possibly vasopressin (posterior pituitary hormone). Opioid compounds, however, have no direct action on the pituitary nor do they alter the action of releasing hormones on the pituitary.

POMC-like mRNA is present in the ovary and the placenta,<sup>121</sup> although reasons for endorphin presence in these tissues are not yet apparent. Expression is regulated by gonadotropins in the ovary but not in the placenta. High concentrations of all of the members of the POMC family are found in human ovarian follicular fluid, but only  $\beta$ -endorphin shows significant changes during the menstrual cycle, reaching highest levels just before ovulation.<sup>122</sup>

# CATECHOL ESTROGENS

The enzyme that converts estrogens to catechol estrogens (2-hydroxylase) is richly concentrated in the hypothalamus; hence, there are higher concentrations of catechol estrogens than of estrone and estradiol in the hypothalamus and the pituitary gland. Because catechol estrogens have two faces (a catechol side and an estrogen side), they have the potential for interacting with both catecholamine and estrogen-mediated systems.<sup>123</sup> To be specific, catechol estrogens can inhibit tyrosine hydroxylase (which would decrease catecholamines) and compete for catechol-O-methyltransferase (which would increase catecholamines). Because GnRH, estrogens, and catechol estrogens are located in similar sites, it is possible that catechol estrogens may serve to interact between catecholamines and GnRH secretion. However, these functions remain speculative because a definite role for catechol steroids has not been established (Figure 4.14).

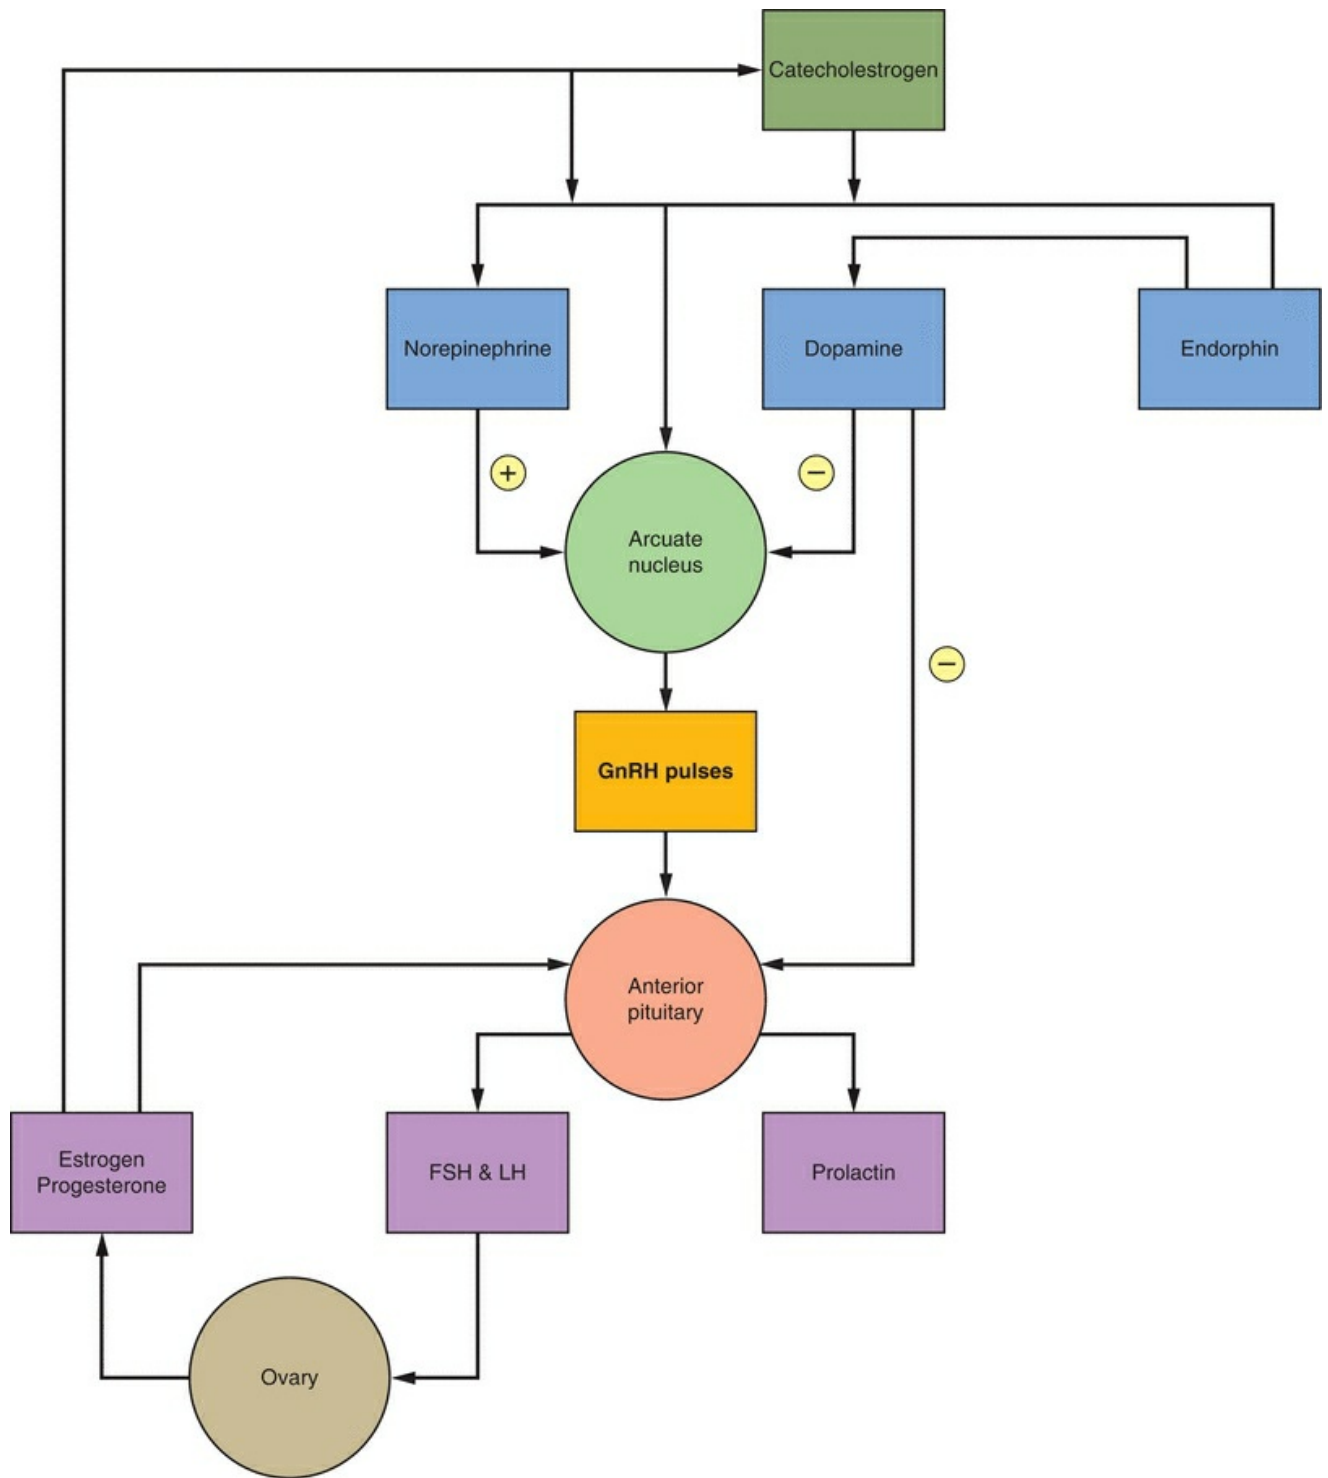

FIGURE 4.14

# **SUMMARY: CONTROL OF GNRH PULSES**

---

The key concept is that normal menstrual function requires GnRH pulsatile secretion in critical ranges of both pulse frequency and amplitude.<sup>45,48,124</sup> The normal physiology and pathophysiology of the menstrual cycle, at least in terms of central control, can be explained by mechanisms that affect the pulsatile secretion of GnRH. The pulses of GnRH are directly under the influence of a dual catecholaminergic system: norepinephrine (facilitatory) and dopamine (inhibitory). In turn, the catecholamine system can be influenced by endogenous opioid activity. The feedback effects of steroids can be mediated through this system via catechol steroid messengers or directly by influencing the various neurotransmitters (**Figure 4.15**).

**FIGURE 4.15**

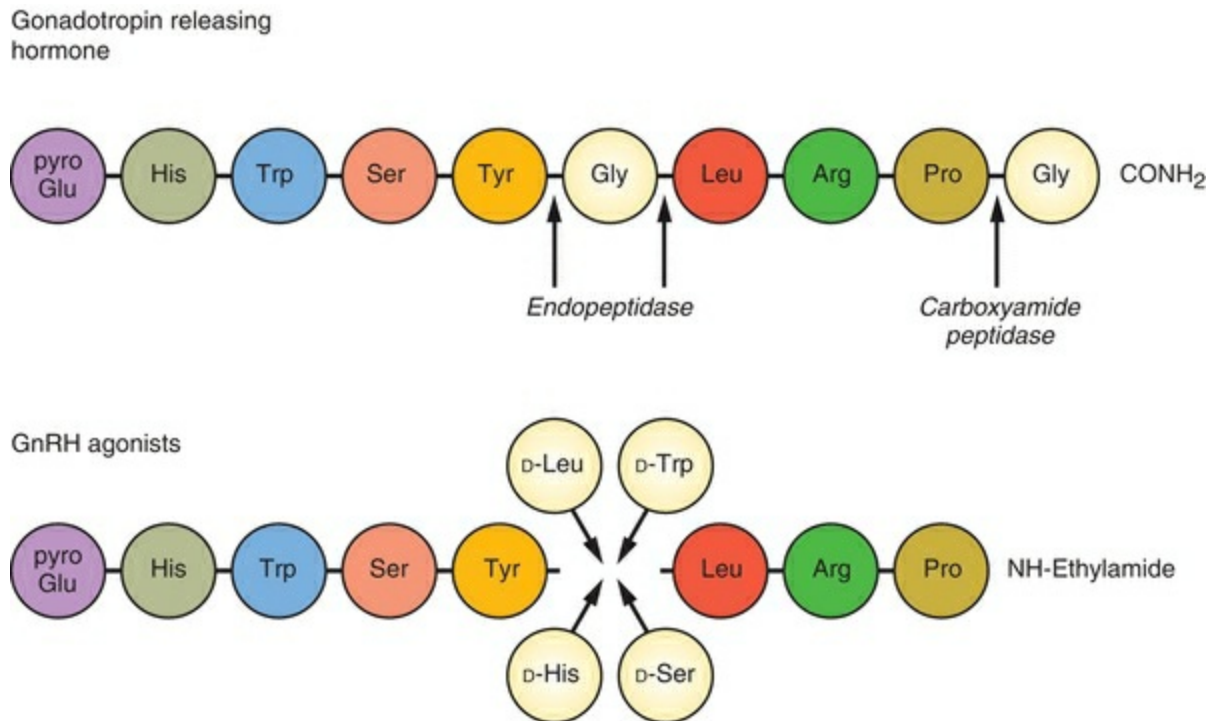

# GNRH AGONISTS AND ANTAGONISTS

---

The short half-life of GnRH is due to rapid cleavage of the bonds between amino acids 5–6, 6–7, and 9–10. By altering amino acids at these positions, analogues of GnRH can be synthesized with different properties. Substitution of amino acids at the 6 position or replacement of the C-terminal glycineamide (inhibiting degradation) produces analogues that act as GnRH agonists. In clinical practice, the GnRH agonists can be administered either intramuscularly or subcutaneously or by intranasal absorption. An initial agonistic action (the so-called flare effect) is associated with an increase in the circulating levels of FSH and LH. This response is greatest when the agonist is administered in the early follicular phase of menstrual cycle when GnRH and estradiol have combined to create a large reserve pool of gonadotropins ready for secretion. After 1–3 weeks of continuous presence of a GnRH agonist, desensitization and down-regulation of the pituitary occurs, resulting in a hypogonadotropic (low circulating FSH and LH levels), hypogonadal (low estradiol levels) state. The initial suppressive response is due to desensitization, whereas the sustained response is due to loss of receptors and the uncoupling of the receptor from its effector system. Furthermore, postreceptor mechanisms lead to secretion of biologically inactive gonadotropins, which, however, can still be detected by immunoassay.

Suppression of pituitary secretion of gonadotropins and resulting state of hypoestrogenism with the use of a GnRH agonist can be used for the treatment of estrogen dependent disorders such as endometriosis, uterine leiomyomas, precocious puberty, for the prevention of menstrual bleeding in special clinical situations (e.g., in thrombocytopenic patients), as well as for management of states of hormonal dysfunction such as premenstrual dysphoric disorder (PMDD).

GnRH antagonists are synthesized with multiple amino acid substitutions (positions 2, 3); by binding to the GnRH receptor, GnRH antagonists provide competitive inhibition of the naturally occurring GnRH. Thus, GnRH antagonists produce an immediate decline in gonadotropin levels with an immediate therapeutic effect within 24–72 hours. The early products either lacked potency or were associated with undesirable side effects due to histamine release. Products are now available for use in the treatment of endometriosis, prostate cancer, precocious puberty, and female infertility ([Figure 4.16](#)).

**FIGURE 4.16**

GnRH analogues (agonists and antagonists) have long been only available in non-oral forms due to susceptibility to destruction if administered orally. However, an oral GnRH antagonist formulation has recently been approved. Higher doses of GnRH analogues administered subcutaneously can achieve nearly equal effects as observed with intravenous and intramuscular treatment; however, the smaller blood peaks are slower to develop and take longer to return to baseline. Other forms of administration include nasal spray, sustained-release implants, and injections of biodegradable microspheres. With the nasal route, absorption enhancers have to be added to increase bioavailability; these agents produce considerable nasal irritation. The depot formulations of GnRH agonists are administered intramuscularly and are available as monthly and 3-monthly regimens. ([Table 4.2](#)).

## **TABLE 4.2 GnRH Agonists and Antagonists in Clinical Use**

Position	1	2	3	4	5	6	7	8	9	10	
Native GnRH-I	pGlu	His	Trp	Ser	Tyr	Gly		Leu	Arg	Pro	Gly-NH <sub>2</sub>
Native GnRH-II	pGlu	His	Trp	Ser	His	Gly		Trp	Tyr	Pro	Gly-NH <sub>2</sub>
Leuprolide						D-Leu					NH-ethylamide
Buserelin						D-Ser (tertiary butanol)					NH-ethylamide
Nafarelin						D-Naphthylalanine (2)					
Histrelin						D-His (tertiary benzyl)					NH-ethylamide
Goserelin						D-Ser (tertiary butanol)					Aza-Gly
Deslorelin						D-Trp					NH-ethylamide
Triptorelin						D-Trp					
Abarelix	D-Ala	D-Phe	D-Ala			D-Asp		Lys-(iPr)			D-Ala

Ganirelix	D-Nal	D-Phe	D-Pal			D-hArg		hArg			D-Ala

# TANYCYTES

A significant pathway for hypothalamic influence may be via the cerebrospinal fluid (CSF). Tanycytes are specialized ependymal cells whose ciliated cell bodies line the third ventricle over the median eminence. The cells terminate on portal vessels, and they can transport materials from ventricular CSF to the portal system, for example, substances from the pineal gland, or vasopressin, or oxytocin. Tanycytes change morphologically in response to steroids and exhibit morphologic changes during the ovarian cycle (Figure 4.17).

**FIGURE 4.17**

# THE POSTERIOR PITUITARY PATHWAY

The posterior pituitary is a direct prolongation of the hypothalamus via the pituitary stalk, whereas the anterior pituitary arises from pharyngeal epithelium that migrates into position with the posterior pituitary. Separate neurosecretory cells in both the supraoptic and paraventricular nuclei make vasopressin and oxytocin as parts of large precursor molecules that also contain the transport peptide, neurophysin.<sup>125</sup> Both oxytocin and vasopressin consist of nine amino acid residues, two of which are half cystines forming a bridge between positions 1 and 6 (Figure 4.18). In the human, vasopressin contains arginine, unlike animals that have lysine vasopressin. The neurophysins are polypeptides with a molecular weight of about 10,000. There are two distinct neurophysins, the estrogen-stimulated neurophysin known as neurophysin I and the nicotine-stimulated neurophysin known as neurophysin II.

**FIGURE 4.18**

The genes for oxytocin and vasopressin are closely linked on chromosome 20, derived from a common ancestor about 400 million years ago.<sup>126</sup> The transcriptional activity of these genes is regulated by endocrine factors, such as the sex steroids and thyroid

hormone, through hormone response elements located upstream. The neurons secrete two large protein molecules, a precursor called propressophysin, which contains vasopressin and its neurophysin, and a precursor called prooxyphysin, which contains oxytocin and its neurophysin.<sup>125</sup> Neurophysin I is specifically related to oxytocin, and neurophysin II accompanies vasopressin. Because of this unique packaging, the hormones and their neurophysins are stored together and released at the same time into the circulation. The neurophysins are cleaved from their associated neurohormones during axonal transport from the neuronal cell bodies in the supraoptic and paraventricular nuclei to the posterior pituitary. The only known function for the neurophysins is axonal transport of oxytocin and vasopressin. Mutations in the gene encoding the precursor prohormone protein produce an alteration in the neurophysin, preventing the conformational shape necessary for transport of vasopressin to the pituitary gland, resulting in diabetes insipidus.<sup>127,128</sup>

The posterior pathway is complex and not limited to the transmission of vasopressin and oxytocin to the posterior pituitary. The transportation of vasopressin and oxytocin to the posterior pituitary occurs via nerve tracts that emanate from the supraoptic and paraventricular nuclei and descend through the median eminence to terminate in the posterior pituitary. However, these hormones are also secreted into the CSF and directly into the portal system. Therefore, vasopressin and oxytocin can reach the anterior pituitary and influence ACTH secretion (in the case of vasopressin) and gonadotropin secretion (in the case of oxytocin). Vasopressin cooperates with CRH to cause an increased yield of ACTH. Vasopressin and oxytocin-like materials are also found in the ovary, the oviduct, the testis, and the adrenal gland, suggesting that these neurohypophyseal peptides have roles as paracrine or autocrine hormones.<sup>129</sup> The concentrations of these substances in the CSF exhibit a circadian rhythm (with peak levels occurring during the day), suggesting a different mechanism for CSF secretion compared with posterior pituitary release.<sup>130</sup>

Neurophysin II is called nicotine neurophysin because the administration of nicotine or hemorrhage increases the circulating levels. Neurophysin I is called estrogen neurophysin because estrogen administration increases the levels in the peripheral blood, and peak levels of both neurophysin I and oxytocin are found at the time of the LH surge.<sup>131</sup> Oxytocin neurons and vasopressin neurons have been demonstrated in the rat to contain the estrogen receptor- $\beta$ .<sup>132</sup> The rise in estrogen neurophysin begins 10 hours after the rise in estrogen and precedes that of the LH surge, and the elevation of neurophysin lasts longer than the LH surge. Because GnRH and oxytocin are competing substrates for hypothalamic degradation enzymes, it has been hypothesized that oxytocin in the portal blood at the midcycle can inhibit the metabolism of GnRH, thus increasing the amount of GnRH available. Furthermore, oxytocin may have direct actions on the

pituitary, ovary, uterus, and fallopian tube during ovulation.

Neurophysin-containing pathways have been traced from the hypothalamic nuclei to various centers in the brainstem and the spinal cord. In addition, behavioral studies suggest a role for vasopressin in learning and memory. Administration of vasopressin has been associated with improvement in memory in brain-damaged human subjects and enhanced cognitive responses (learning and memory) in both young, normal individuals and depressed patients.

Both oxytocin and vasopressin circulate as the free peptides with a rapid half-life (initial component less than 1 minute, second component of 2–3 minutes). Three major stimuli for vasopressin secretion are changes in osmolality of the blood, alterations in blood volume, and psychogenic stimuli such as pain and fear. The osmoreceptors are located in the hypothalamus; the volume receptors are in the left atrium, aortic arch, and carotid sinus. Angiotensin II also produces a release of vasopressin, suggesting another mechanism for the link between fluid balance and vasopressin. Cortisol may modify the osmotic threshold for the release of vasopressin.

The major functions of vasopressin mainly involve the regulation of osmolality and blood volume, but also the release of insulin and ACTH, and influences on behavioral responses such as memory.<sup>133</sup> Vasopressin is a powerful vasoconstrictor and antidiuretic hormone (ADH). Vasopressin release increases when plasma osmolality rises and is inhibited by water loading (resulting in diuresis). Diabetes insipidus is a condition marked by loss of water because of a lack of vasopressin action in the tubules of the kidney, secondary to a defect in synthesis or secretion of vasopressin. The opposite condition is the continuous and autonomous secretion of vasopressin, the syndrome of inappropriate ADH secretion. This syndrome, with its resultant retention of water, is associated with a variety of brain disorders and with the production of vasopressin and its precursor by malignant tumors.

Oxytocin stimulates muscular contractions in the uterus and myoepithelial contractions in the breast. Thus, it is involved in parturition and the reflex letdown of milk. The release of oxytocin is so episodic that it is described as spurts. Ordinarily, there are about three spurts every 10 minutes. Oxytocin is released during coitus, probably by the Ferguson reflex (vaginal and cervical stimulation) but also by olfactory, visual, and auditory pathways. Perhaps oxytocin has some role in muscle contractions during orgasm.<sup>134</sup> In the male, release of oxytocin during coitus may contribute to sperm transport during ejaculation. Oxytocin is also released in specific areas of the brain, especially the ventromedial hypothalamus where it can act to inhibit appetite and stimulate sexual behavior.<sup>135</sup>

Using sensitive assays, an increase in maternal levels of oxytocin can be detected prior to parturition, occurring at first only at night.<sup>136,137</sup> Once labor has begun, oxytocin

levels rise significantly, especially during the second stage. Thus, oxytocin may be important for developing the more intense uterine contractions. Extremely high concentrations of oxytocin can be measured in the cord blood at delivery, and release of oxytocin from the fetal pituitary may also be involved in the onset and/or establishment of labor. However, this is controversial, and studies in monkeys fail to indicate a role for fetal oxytocin in parturition.<sup>137</sup> Part of the contribution of oxytocin to parturition is the stimulation of prostaglandin synthesis in decidua and myometrium.<sup>138</sup> Cervical dilation appears to be dependent on oxytocin stimulation of prostaglandin production, probably in the decidua. The greater frequency of labor and delivery at night may be due to greater nocturnal oxytocin secretion.<sup>136</sup> In addition, oxytocin is synthesized in the amnion, in the chorion, and, significantly, in the decidua.<sup>136</sup> This locally produced oxytocin may be a significant stimulus for myometrial and membrane production of prostaglandins.

It is likely that oxytocin action during the initial stages of labor depends on myometrial sensitivity to oxytocin in addition to the circulating levels of oxytocin. The concentration of oxytocin receptors in the myometrium is low in the nonpregnant state; myometrial expression of oxytocin receptors increases steadily throughout gestation (an 80-fold increase), and during labor, the myometrial concentration of oxytocin receptors doubles. The mechanism/s for this increase in myometrial expression of oxytocin receptors is unknown but is likely due to a change in the prostaglandin and hormonal milieu of the uterus. This receptor concentration correlates with the uterine sensitivity to oxytocin.<sup>139</sup> The local production and effects of oxytocin, estrogen, and progesterone combine in a complicated process of autocrine, paracrine, and endocrine actions to result in parturition.

Oxytocin is released in response to suckling, mediated through impulses generated at the nipple and transmitted via the third, fourth, and fifth thoracic nerves to the spinal cord and to the hypothalamus. In addition to causing milk ejection, the reflex is responsible for the uterine contractions associated with breastfeeding. Opioid peptides inhibit oxytocin release, and this may be how stress, fear, and anger inhibit milk output in lactating women. Oxytocin is also expressed in many tissues where it exerts autocrine-paracrine actions.

# THE BRAIN AND OVULATION

---

Classic studies in a variety of rodents indicated the presence of feedback centers in the hypothalamus that responded to steroids with the release of GnRH. The release of GnRH was the result of the complex, but coordinated, relationships among the neurohormones, the pituitary gonadotropins, and the gonadal steroids designated by the time-honored terms positive and negative feedback.

FSH levels were thought to be largely regulated by a negative inhibitory feedback relationship with estradiol. For LH, both a negative inhibitory feedback relationship with estradiol and a positive stimulatory feedback with high levels of estradiol were demonstrated. The feedback centers were in the hypothalamus and were called the tonic and cyclic centers. The tonic center controlled the day-to-day basal level of gonadotropins and was responsive to the negative feedback effects of sex steroids. The cyclic center in the female brain was responsible for the midcycle surge of gonadotropins, a response mediated by the positive feedback of estrogen. Specifically, the midcycle surge of gonadotropins was thought to be due to an outpouring of GnRH in response to the positive feedback action of estradiol on the cyclic center of the hypothalamus.

**This classic concept was not inaccurate. The problem was that the concept accurately described events in the rodent, but the mechanism is different in the primate.** Neuroendocrine genetic expression studies based on rodents duplicate the earlier studies, and once again support a hypothalamic “center” as the primary locus for sex steroid actions, but the primate operates differently.

In the primate, the “center” for the midcycle surge of gonadotropins moved from the hypothalamus to the pituitary. Experiments in the monkey demonstrated that GnRH, originating in the hypothalamus, plays a permissive and supportive role. Its pulsatile secretion is an important prerequisite for normal pituitary function,<sup>124</sup> but the feedback responses regulating gonadotropin levels are controlled by ovarian steroid feedback on the anterior pituitary cells.

The present concept is derived from experiments in which the medial basal hypothalamus was either destroyed<sup>42</sup> or the hypothalamus was surgically separated from the pituitary.<sup>140</sup> In a typical (and now classic) experiment, lesion of the medial basal hypothalamus by radiofrequency waves was followed by loss of LH levels as the source of GnRH was eliminated.<sup>41</sup> Administration of GnRH in a pulsatile fashion by an intravenous pump restored LH secretion. The administration of estradiol was then able to produce both negative and positive feedback responses, actions that certainly must be directly on the anterior pituitary because the hypothalamus was absent and GnRH was being administered in a steady and unchanging frequency and dose (**Figure 4.19**).

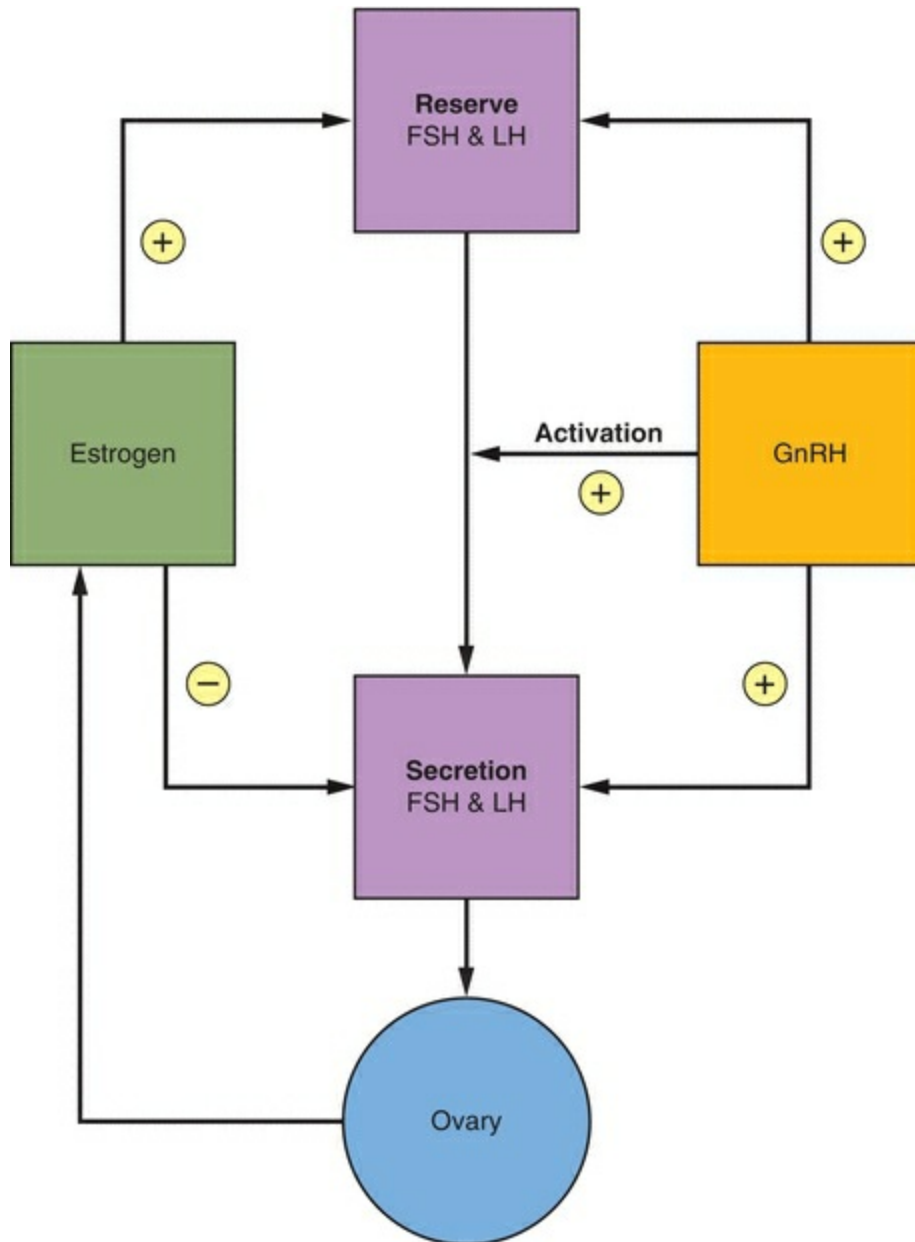

**FIGURE 4.19**

Administration of GnRH intravenously as a bolus produces an increase in blood levels of LH and FSH within 5 minutes, reaching a peak in about 20–25 minutes for LH and 45 minutes for FSH. Levels return to pretreatment values after several hours. When administered by constant infusion at submaximal doses, there is first a rapid rise with a peak at 30 minutes, followed by a plateau or fall between 45 and 90 minutes, and then a second and sustained increase at 225–240 minutes. This biphasic response suggests the presence of two functional pools of pituitary gonadotropins.<sup>141</sup> The readily releasable pool (secretion) produces the initial response, and the later response is dependent on a second, reserve pool of stored gonadotropins.

There are three principal positive actions of GnRH on gonadotropin elaboration:

1. **Synthesis and storage** (the reserve pool) of gonadotropins
2. **Activation**—movement of gonadotropins from the reserve pool to the releasable pool that is ready for direct secretion, a self-priming action
3. **Immediate release** (direct secretion) of gonadotropins

Gonadotropin secretion, synthesis, and storage change during the course of the menstrual cycle (**Figure 4.20**). At the beginning of the cycle, when estrogen levels are low, both secretion and storage levels are low. With increasing levels of estradiol, a greater increase occurs in storage, with little change in secretion. Thus, in the early follicular phase, estrogen has a positive effect on the synthesis and storage response, building up a supply of gonadotropins to meet the requirements of the impending midcycle surge. Premature release of gonadotropins is prevented by a negative (inhibitory) action of estradiol on the pituitary secretory response to GnRH.

**FIGURE 4.20**

As the midcycle approaches, subsequent responses to GnRH are greater than initial responses, indicating that each response not only induces release of gonadotropins but also activates the storage pool for the next response. This sensitizing or priming action of GnRH also involves an increase in the number of its own receptors and requires the presence of estrogen.<sup>142,143</sup> Estrogen itself is capable of increasing the number of GnRH receptors.<sup>80,144</sup> The rise in estrogen at midcycle prepares the gonadotropes to further respond to GnRH.

Because the midcycle surge of LH can be produced in the experimental monkey in the absence of a hypothalamus and in the face of unchanging GnRH, the ovulatory surge

of LH is believed to be a response to positive feedback action of estradiol on the anterior pituitary. When the estradiol level in the circulation reaches a critical concentration and this concentration is maintained for a critical time period, the inhibitory action on LH secretion changes to a stimulatory action. The exact mechanism of this steroid action is not known with certainty, but experimental evidence suggests that the positive feedback action of estradiol involves many mechanisms, including an increase in GnRH receptor concentration and an increase in pituitary sensitivity to GnRH. This action of estrogen is classically referred to as positive feedback, but it can also be viewed as an acute decrease in inhibitory influences.

The negative feedback of estrogen operates through different systems; at the pituitary level, estrogen inhibition of FSH secretion is associated with decreasing pituitary expression of activin.<sup>145,146,147,148</sup> In addition, estradiol directly inhibits the FSH  $\beta$  subunit gene by influencing corepressor proteins (adapter proteins) to bind to the gene and suppress transcription.<sup>149</sup>

**What a logical mechanism!** The midcycle surge must occur at the right time of the cycle to ovulate a ready and waiting mature follicle. What better way to achieve this extreme degree of coordination and timing than by the preovulatory follicle itself, through feedback effects of the sex steroids originating in the follicle that is destined to ovulate.

The presence of GnRH is certainly essential; the administration of a GnRH antagonist to women at midcycle prevents the LH surge.<sup>150</sup> GnRH is increased in the peripheral blood of women and the portal blood of monkeys at midcycle.<sup>151</sup> Although this increase may not be absolutely necessary (as demonstrated in the monkey experiments), studies do indicate that increased activity is occurring in both the hypothalamus and the pituitary.<sup>146,152,153,154</sup> Therefore, although the system can operate with only an unwavering, permissive action of GnRH, fine-tuning probably takes place by means of simultaneous effects on GnRH pulsatile secretion and pituitary response to GnRH. This is supported by gonadotropin gene expression studies, indicating steroid effects at both the hypothalamus and the pituitary.<sup>155</sup> The upstream region of the LH  $\beta$ -subunit gene binds the estrogen receptor, providing a means for direct steroid hormone modulation in the pituitary.<sup>156</sup>

The effect of estrogen on the hypothalamic release of GnRH was confusing at first because initial studies failed to detect the presence of estrogen receptors in GnRH neurons.<sup>157,158,159</sup> Later studies identified the more recently discovered estrogen receptor- $\beta$ , and experiments in knockout mice indicated that estrogen receptor- $\beta$  mediates estrogen effects on GnRH neurons.<sup>160,161,162</sup> Finally, more sophisticated methods and the knockout model demonstrated that both  $\alpha$  and  $\beta$  estrogen receptors are

present in GnRH neurons and are involved in cyclic changes in GnRH release.<sup>163,164,165</sup> The human GnRH gene contains a hormone-responsive element that binds estrogen and its receptor.<sup>166</sup> In molecular studies, estrogen decreased messenger RNA for GnRH-II but increased messenger RNA for GnRH-I.<sup>167</sup> In vivo studies in the sheep have demonstrated that estradiol has both negative and positive feedback effects on hypothalamic GnRH secretion and that a GnRH surge is involved in the preovulatory LH surge.<sup>168,169,170</sup> In monkeys, estrogen treatment decreases GnRH gene expression.<sup>171</sup> There no longer is any question that estrogen can regulate the activity of the hypothalamic GnRH neurons.<sup>172</sup>

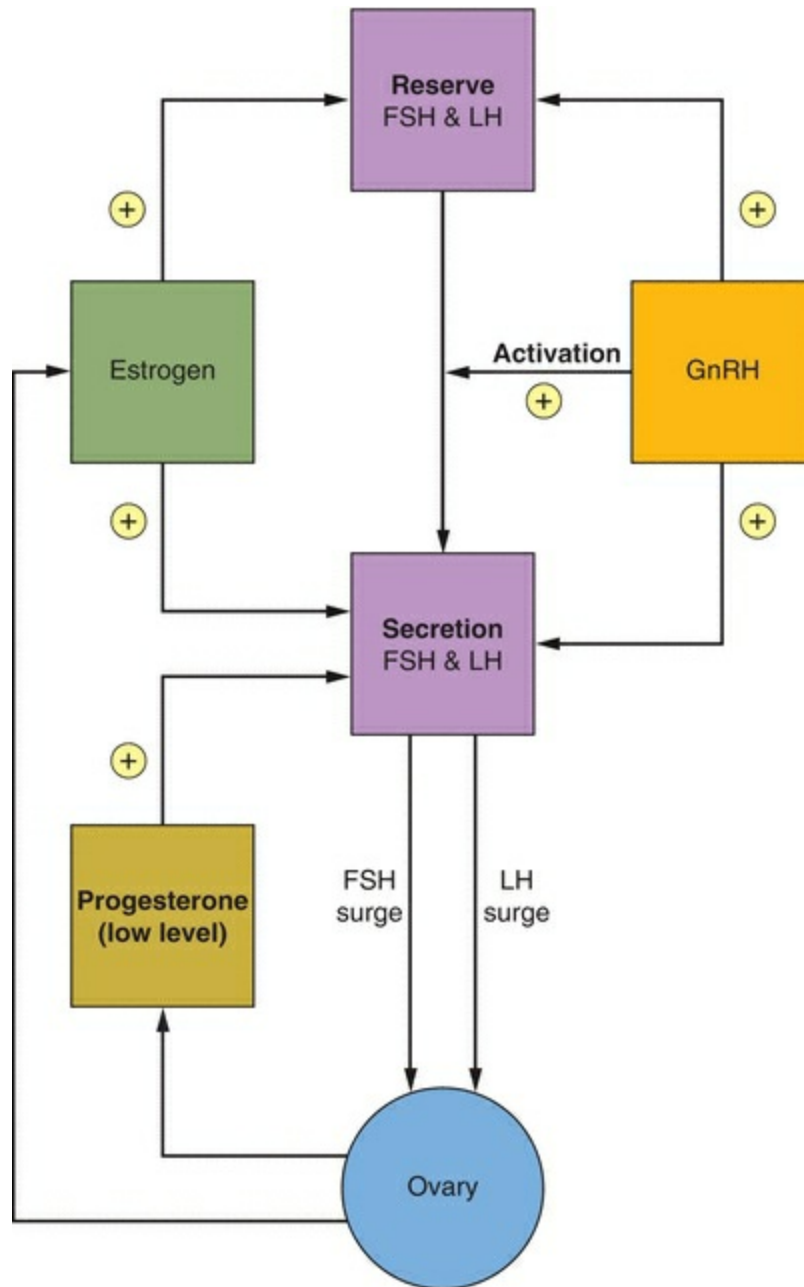

Influencing the hypothalamic frequency of GnRH secretion can in turn influence pituitary response to GnRH. Faster or slower frequencies of GnRH pulses result in lower GnRH receptor numbers in the pituitary.<sup>173</sup> Thus, a critical peak frequency is necessary for peak numbers of GnRH receptors and the peak midcycle response. Here is a method for the fine-tuning at both the hypothalamus (pulse frequency) and the pituitary (receptor number). Indeed, turning off the surge may involve down-regulation because of excessive GnRH. Studies in sheep indicate that a surge of GnRH at the time of the LH surge is associated with a switch from episodic secretion to continuous secretion into the portal circulation, producing the high exposure known to result in down-regulation.<sup>174</sup>

The differential response of FSH and LH, arising from the same pituitary cell, to the frequency of GnRH pulses is a consequence of the interplay among the regulating factors: the classic endocrine effects of estrogen, progesterone, and inhibin and the autocrine/paracrine actions of activin and follistatin.<sup>175</sup> The biphasic response of FSH, in particular, is modulated by the balance of activin and follistatin, created by the effects of estrogen and inhibin.

Another aspect of gonadotropin secretion is clinically important. A disparity exists between the quantity of gonadotropins measured during the midcycle surge as determined by immunoassay and bioassay. More FSH and LH are secreted at midcycle in a molecular form with greater biologic activity.<sup>176,177</sup> There is a well-established relationship between the activity and half-life of glycoprotein hormones and molecular composition (see [Chapter 2](#), under “Heterogeneity” of tropic hormones). The estrogen influence on gonadotropin synthesis is an additional method for maximizing the biologic effects of the midcycle surge. The bioactivity is also very dependent on pulsatile stimulation by GnRH. In addition to the change at midcycle that favors gonadotropin activity at the ovarian follicle, FSH isoforms with greater biologic activity also increase during the late luteal phase, a change that is appropriately geared toward propelling new ovarian follicle growth for the next cycle.<sup>178</sup>

The midcycle surge of FSH has an important clinical purpose. A normal corpus luteum requires the induction of an adequate number of LH receptors on granulosa cells, a specific action of FSH. In addition, FSH accomplishes important intrafollicular changes necessary for the physical expulsion of the ovum. The midcycle surge of FSH, therefore, plays a critical role in ensuring ovulation and a normal corpus luteum. Emerging progesterone secretion, just prior to ovulation, is the key.

Progesterone, at low levels and in the presence of estrogen, augments the pituitary secretion of LH and is responsible for the FSH surge in response to GnRH (**Figure 4.21**).<sup>179,180,181,182</sup> As the rising levels of LH produce the morphologic change of luteinization in the ovulating follicle, the granulosa layer begins to secrete progesterone directly into the bloodstream. The process of luteinization is inhibited by the presence of the oocyte; therefore, progesterone secretion is relatively suppressed, ensuring that only low levels of progesterone reach the brain.

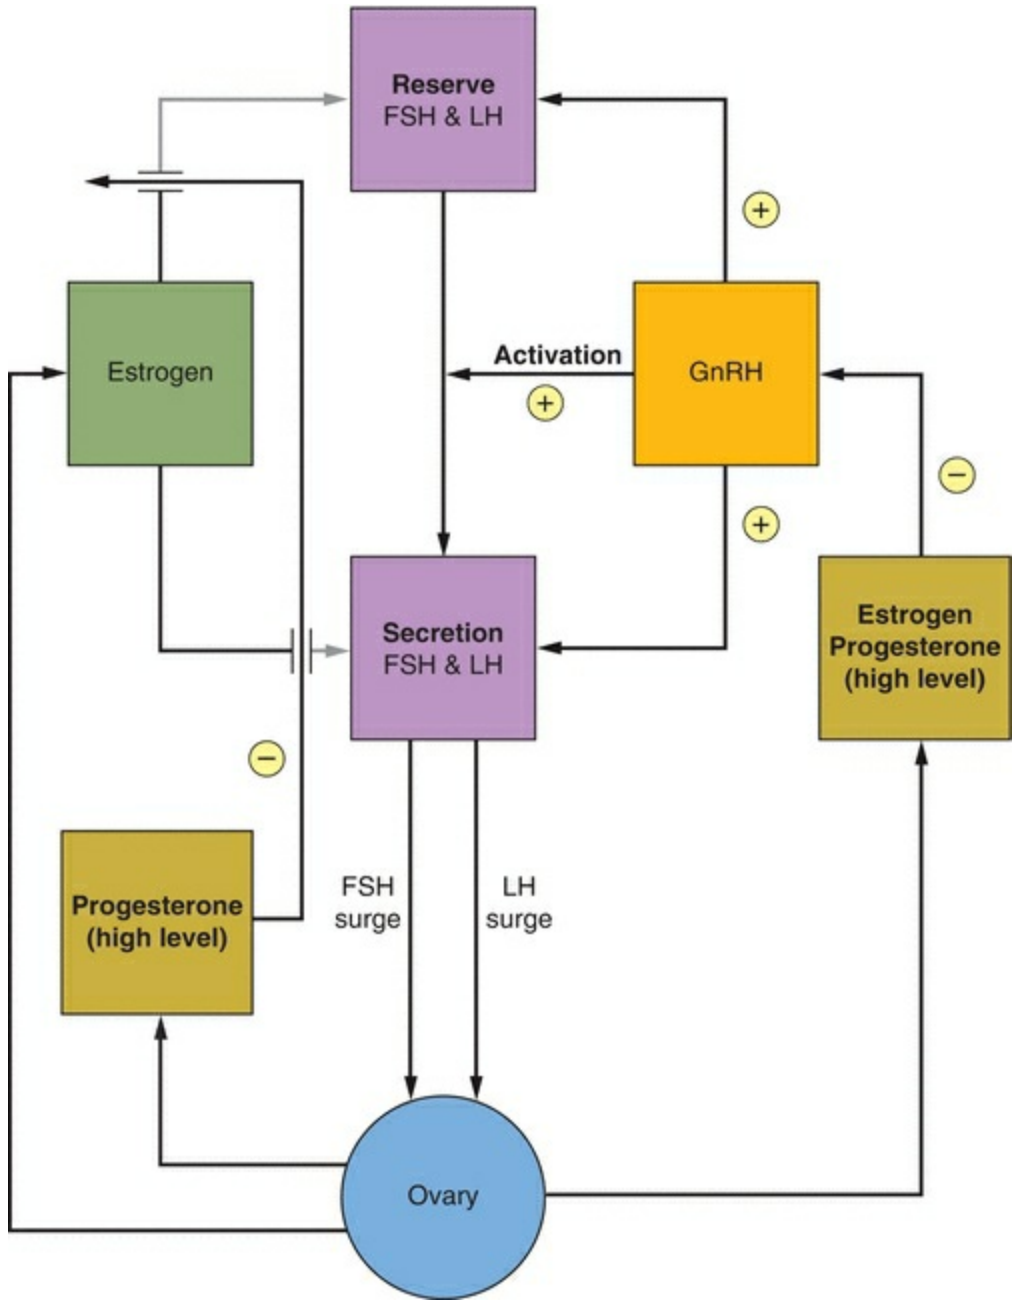

**FIGURE 4.21**

After ovulation, rapid and full luteinization is accompanied by a marked increase in progesterone levels, which, in the presence of estrogen, exercise a profound negative feedback action to suppress gonadotropin secretion (Figure 4.22). This action of progesterone takes place in two locations, the hypothalamus and the pituitary.<sup>183,184,185</sup> There definitely is a central action to decrease GnRH.<sup>186</sup> An important role for progesterone is to mediate the slowing of GnRH pulses in the late luteal phase, favoring the rise in FSH necessary to initiate the next cycle.<sup>51</sup> Progesterone fails to block estradiol-induced gonadotropin discharges in monkeys with hypothalamic lesions if

pulsatile GnRH replacement is provided. Therefore, high levels of progesterone inhibit ovulation at the hypothalamic level (Figure 4.21). In contrast, the facilitatory action of low levels of progesterone is exerted only at the pituitary on the response to GnRH (Figure 4.22).

**FIGURE 4.22**

## Key Points

- Pulsatile GnRH secretion must be within a critical range for both frequency and concentration (amplitude). This is absolutely necessary for normal reproductive function.
- GnRH has only positive actions on the anterior pituitary: synthesis and storage, activation, and secretion of gonadotropins. The gonadotropins are secreted in a pulsatile fashion in response to the similar pulsatile release of GnRH.
- Lower GnRH pulse frequencies, such as in the late luteal phase, favor FSH secretion, and higher GnRH pulse frequencies, as occur in the late follicular phase, favor LH secretion.
- Low levels of estrogen enhance FSH and LH synthesis and storage, have little effect on LH secretion, and inhibit FSH secretion.
- High levels of estrogen induce the LH surge at midcycle, and high steady levels of estrogen lead to sustained elevated LH secretion.
- Low levels of progesterone acting at the level of the pituitary gland enhance the LH response to GnRH and are responsible for the FSH surge at midcycle.
- High levels of progesterone inhibit pituitary secretion of gonadotropins by inhibiting GnRH pulses at the level of the hypothalamus. In addition, high levels of progesterone can antagonize pituitary response to GnRH by interfering with estrogen action.

# THE PINEAL GLAND

---

Although no physiologic role has been firmly established in the human, the reproductive functions of the hypothalamus may also be under inhibitory control of the brain via the pineal gland. The pineal arises as an outgrowth of the roof of the third ventricle, but soon after birth it loses all afferent and efferent neural connections with the brain. Instead, the parenchymal cells receive a new and unusual sympathetic innervation that allows the pineal gland to be an active neuroendocrine organ that responds to photic and hormonal stimuli and exhibits circadian rhythms.<sup>187,188,189</sup>

The neural pathway begins in the retina and passes through the suprachiasmatic and paraventricular nuclei in the hypothalamus to the inferior accessory optic tracts and the medial forebrain bundle to the upper spinal cord. Preganglionic fibers terminate at the superior cervical ganglion, and postganglionic sympathetic nerves terminate directly on pineal cells. Interruption of this pathway gives the same effect as darkness, which is an increase in pineal biosynthetic activity.

Hydroxyindole-O-methyltransferase (HIOMT), an enzyme essential for melatonin synthesis, is found mainly in pineal parenchymal cells, and its products are essentially unique to the pineal. Norepinephrine stimulates tryptophan entry into the pineal cell and also adenylate cyclase activity in the membrane. The resulting increase in cyclic AMP leads to N-acetyltransferase activity, the rate-limiting step in melatonin synthesis. Tryptophan is converted by the combined action of N-acetyltransferase and HIOMT into melatonin (N-acetyl-5-methoxytryptamine). Thus, melatonin synthesis is controlled by norepinephrine stimulation of adenylate cyclase, and the norepinephrine is liberated by sympathetic stimulation due to the absence of light. HIOMT is also found in the retina where melatonin may serve to regulate the pigment in retinal cells and in the intestine. However, pinealectomy completely eliminates detectable levels of melatonin in the circulation. Calcification of the pineal gland is common. It is frequently present in young children, and almost all elderly people have pineal calcification.

The association of hyperplastic pineal tumors with decreased gonadal function and of destructive tumors with precocious puberty suggested that the pineal is the source of gonadal inhibiting substances. However, pineal mechanisms cannot be essential for gonadal function. Normal reproductive function returns to the pinealectomized rat several weeks after pinealectomy; blind women have normal fertility, and pinealectomy in a primate did not affect pubertal development.<sup>190</sup>

## **DARKNESS → INCREASED MELATONIN → DECREASED GnRH**

A rat in constant light develops a small pineal gland with decreased HIOMT and melatonin, while the ovarian weight increases. A rat in constant dark has the opposite result, with increased pineal size, HIOMT, and melatonin, but with decreased ovarian

weight and pituitary function. A rhythm is established in pineal HIOMT activity by the presence or absence of light. Short days and long nights with increased melatonin secretion result in gonadal atrophy, and this is the major mechanism governing seasonal breeding.<sup>191,192</sup> In humans, melatonin secretion increases after darkness, peaks in the middle of the night, and then decreases. This rhythm is endogenous, originating in the suprachiasmatic nucleus. Light does not cause the rhythm, but influences its timing.

Possible roles of the pineal gland in humans may be to give circadian rhythmicity to other functions such as temperature and sleep. In all vertebrates tested so far, there is a daily and seasonal rhythm in melatonin secretion: high values during the dark and low during light, greater secretion in the winter compared with the summer. Desynchronization with travel across time zones may contribute to the symptom complex known as jet lag. Melatonin ingestion improves both the duration and quality of sleep, but the optimal timing of administration is unknown.<sup>189,193</sup>

The pineal, therefore, serves as an interface between the environment and hypothalamic-pituitary function. In order to correctly interpret day length, animals require a daily rhythm in melatonin secretion. This coordination of temporal, environmental information is especially important in seasonal breeders. This pineal rhythm appears to require the suprachiasmatic nucleus, perhaps the site at which pineal function and light changes are coordinated.

Melatonin is synthesized and secreted by the pineal gland and circulates in the blood like a classical hormone. It affects distant target organs, especially the neuroendocrine centers of the CNS. Whether melatonin is secreted primarily into the CSF or blood is still debated, but most evidence favors blood. Melatonin may reach the hypothalamus from the CSF by way of tanycyte transport.

The gonadal changes associated with melatonin are mediated via the hypothalamus and suggest a general suppressive effect on GnRH pulsatile secretion and reproductive function.<sup>194</sup> In humans, melatonin blood levels are highest in the first year of life (with highest levels at night), and then decrease with age, eventually releasing, some claim, the suppression of GnRH prior to puberty.<sup>191</sup> This hypothesis is challenged by the association of blindness in human females with an age of menarche that is earlier than normal.<sup>195</sup> Furthermore, pinealectomy in monkeys does not affect puberty.<sup>190</sup> Others have failed to find a decrease in melatonin levels with aging.<sup>196</sup>

Pineal activity can be viewed as the net balance between hormone- and neuron-mediated influences. The pineal contains receptors for the active sex hormones, estradiol, testosterone, dihydrotestosterone, progesterone, and prolactin. Furthermore, the pineal converts testosterone and progesterone to the active  $5\alpha$ -reduced metabolites, and androgens are aromatized to estrogens. The pineal also appears to be unique in that

a catechol amine neurotransmitter (norepinephrine), interacting with cell membrane receptors, stimulates cellular synthesis of estrogen and androgen receptors. In general, however, the sympathetic activity producing the circadian rhythm takes precedence over hormonal effects.

Despite a variety of suggestive leads, there is no definitive evidence for a role of the pineal in humans. Nevertheless, the important relationship between light exposure and circadian rhythms continues to focus attention on the pineal gland as a coordinator.<sup>197</sup> There is a seasonal distribution in human conception in northern countries with a decrease in ovarian activity and conception rates during the dark winter months.<sup>198,199</sup> In addition, the pineal can disrupt normal gonadal function. A male with delayed puberty due to hypogonadotropism has been described, who had an enlarged, hyperfunctional pineal gland.<sup>200</sup> Over time, his melatonin levels spontaneously decreased, and normal pituitary-gonadal function developed. Elevated nocturnal levels of melatonin have been reported in patients with hypothalamic amenorrhea and in women with anorexia nervosa, but this increase is probably a consequence of low estrogen levels, and not etiologic.<sup>194,201</sup>

A possible influence of the pineal gland may be the synchronization of menstrual cycles noted among women who spend time together. A significant increase in synchronization of cycles was first reported in 1971 among roommates and among closest friends in the first 4 months of residency in a dormitory of a women's college.<sup>32</sup> A similar increase in synchrony has been observed in women coworkers in occupations characterized by levels of interdependency that were equal to or greater than the levels of encountered job stress and in Bedouin families in which women live together for many years.<sup>33,35</sup> However, efforts to replicate these results have not always been successful.<sup>34,202</sup> There is also some evidence that the timing of ovulation can be affected by axillary human pheromones.<sup>31,203</sup>

Melatonin is available in 1- and 5-mg doses that produce blood levels that are 10–100 times higher than normal nighttime peaks.<sup>189,193</sup> The effects include increased sleepiness and decreased alertness. No data are available regarding long-term consequences on reproductive function.

A number of other indoles (also derivatives of tryptophan) have been identified in the pineal gland. Biologic roles for these indoles remain elusive, but one in particular has been extensively investigated. Arginine vasotocin differs from oxytocin by a single amino acid in position 8 and from vasopressin by a single amino acid in position 3. In general, arginine vasotocin has an inhibitory action on the gonads and pituitary secretion of prolactin and LH. Nevertheless a precise role continues to be evasive.

# GONADOTROPIN SECRETION THROUGH FETAL LIFE, CHILDHOOD, AND PUBERTY

---

We have often considered the endocrine events during puberty as an awakening, a beginning. However, endocrinologically, puberty is not a beginning but just another stage in a development that began at conception. The development of the anterior pituitary in the human starts between the 4th and 5th weeks of fetal life, and by the 12th week of gestation, the vascular connection between the hypothalamus and the pituitary is functional. Gonadotropin production has been documented throughout fetal life, during childhood, and into adult life.<sup>204</sup> Remarkable levels of FSH and LH, similar to postmenopausal levels, can be measured in the fetus. GnRH is detectable in the hypothalamus by 10 weeks of gestation, and by 10–13 weeks when the vascular connection is complete, FSH and LH are produced in the pituitary. The peak pituitary concentrations of FSH and LH occur at about 20–23 weeks, and peak circulating levels occur at 28 weeks of intrauterine life.

The increasing production rate of gonadotropins until midgestation reflects the growing ability of the hypothalamic-pituitary axis to perform at full capacity. Beginning at midgestation, there is an increasing sensitivity to inhibition by steroids and a resultant decrease in gonadotropin secretion. Full sensitivity to steroids is not reached until late in infancy. The rise in gonadotropins after birth reflects the loss of negative feedback that was exerted by the high in utero levels of placental steroids; this postnatal rise in gonadotropins is even greater in infants born prematurely. Thus, in the first year of life, there is considerable follicular activity in the ovaries in contrast to later in childhood when gonadotropin secretion is suppressed.

Testicular function in the fetus can be correlated with the fetal hormone patterns. Initial testosterone production and sexual differentiation are in response to the fetal levels of placental hCG, whereas further testosterone production and masculine differentiation are maintained by the fetal pituitary gonadotropins. Decreased testosterone levels in late gestation reflect the decrease in gonadotropin levels. The fetal generation of Leydig cells somehow avoids down-regulation and responds to high levels of hCG and LH by increased steroidogenesis and cell multiplication. This generation of cells is replaced by the adult generation that becomes functional at puberty and responds to high levels of hCG and LH with down-regulation and decreased steroidogenesis.

There is a sex difference in fetal gonadotropin levels. There are higher pituitary and circulating FSH and LH levels in female fetuses. The lower male levels are due to testicular testosterone and inhibin production. In infancy, the postnatal FSH rise is more marked and more sustained in females, whereas LH values are not as high. This early

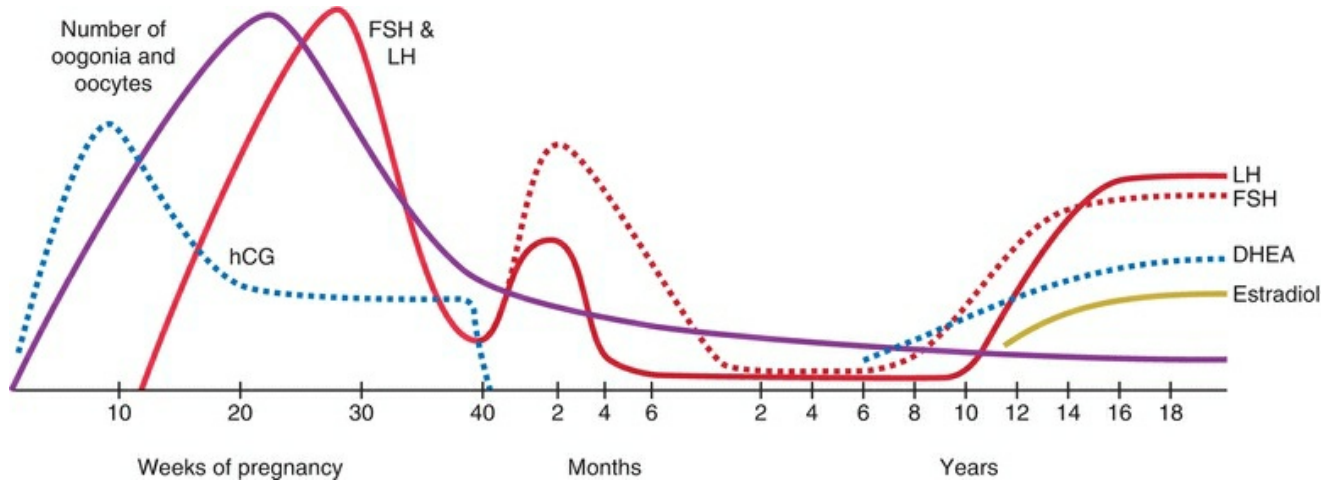

activity is accompanied by inhibin levels comparable to the low range observed during the follicular phase of the menstrual cycle.<sup>205</sup> After the postnatal rise, gonadotropin levels reach a nadir during early childhood (by about 6 months of age in males and 1–2 years in females) and then rise slightly between 4 and 10 years. The difference between males and females is notable; in the female, the suppression of gonadotropins begins later in childhood, is less intense than in the male, and the duration of suppression is shorter in females. The difference is believed to reflect the presence of testosterone in males.

This childhood period is characterized by low levels of gonadotropins in the pituitary and in the blood, little response of the pituitary to GnRH, and maximal hypothalamic suppression. This low level of activity is not maintained by the ovaries or testes because gonadal removal results in little change. Children without gonads experience this same low level of activity.<sup>206</sup> A central inhibitory force must be operating within the brain, awaiting a signal to initiate puberty.

The central inhibitory force restrains GnRH pulsatile secretion. The mechanism involves several neurotransmitters: GABA ( $\gamma$ -amino butyric acid), neuropeptide Y, and kisspeptin. GABA release in the hypothalamus declines as GnRH secretion increases at the onset of puberty, and blockade of GABA synthesis or activity can initiate puberty in monkeys.<sup>207,208</sup> Neuropeptide Y is recognized as an inhibitory neurotransmitter on GnRH pulsatility.<sup>209</sup> Kisspeptin is a newly appreciated neuroendocrine regulator of reproduction.<sup>210</sup> Kisspeptin expression is found in the arcuate nucleus of the hypothalamus and increases just prior to the resurgence of GnRH pulsatile secretion at puberty.<sup>211</sup> Mutations of the G-protein receptor for kisspeptin results in hypogonadotropic hypogonadism and a failure to enter puberty; these patients respond to either exogenous gonadotropins or GnRH. These are some of the signals involved, but the precise trigger that senses maturation and initiates the events of puberty remains elusive.

In girls, the first steroids to rise in the blood are dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) beginning at 6–8 years of age, shortly before FSH begins to increase. Estrogen levels, as well as LH, do not begin to rise until 9–12 years of age (**Figure 4.23**). If the onset of puberty is triggered by the first hormone to increase in the circulation, then a role for adrenal steroids must be considered. However, there is no evidence to suggest that the adrenal steroids are necessary for the proper timing of puberty, and adrenarche is independent; it is not controlled by the same mechanism that turns on the gonads.<sup>212</sup> Indeed, a longitudinal study concluded that increasing adrenal steroid activity reflects gradually increasing maturation with aging, without a sudden change associated with puberty.<sup>213</sup> Neither is there a definite relationship demonstrated between melatonin secretion and puberty. Because the studies have focused on the

amount of melatonin secreted rather than the rhythm of secretion, this question remains open. Nutritional status influences reproductive function, and the leptin system of communication probably contributes to the onset of puberty, but it is unlikely that it is the primary signal (discussed in [Chapter 19](#)). Leptin circulating levels can indicate readiness for puberty, in this case, an indication of an adequate amount of fat tissue in the body to support the metabolic requirements of reproduction.<sup>214</sup> Indeed, a more logical concept is to view puberty as the coming together of multiple systems and influences, including genetic, metabolic, and hormonal factors.

**FIGURE 4.23**

Prior to puberty, gonadotropin levels are low but still associated with pulses (although quite irregular).<sup>215</sup> This prepubertal restraint involves brain peptides, especially GABA and neuropeptide Y.<sup>208,209</sup> The clinical onset of puberty is preceded by an increase in pulse frequency, amplitude, and regularity, especially during the night.<sup>215,216,217,218,219</sup> At the time of appearance of secondary sex characteristics, the mean LH levels are 2–4 times higher during sleep than during wakefulness. This pattern is not present before or after puberty and is an early sign of changes taking place in the hypothalamus, where there is increasing coordination of GnRH neurons with increasing GnRH pulsatile secretion. This pattern can be detected in individuals who develop increasing and decreasing degrees of hypothalamic suppression (e.g., in individuals with worsening and improving anorexia nervosa). FSH levels plateau by mid-puberty, whereas LH and estradiol levels continue to rise until late puberty. Biologically active LH has been found to rise proportionately more than immunoreactive LH with the onset of puberty.

The rise of gonadotropins at puberty must be independent of the gonads because the same response can be observed in patients with gonadal dysgenesis (who lack functional steroid-producing gonadal tissue). Adolescent girls with Turner syndrome

(45,X) also demonstrate augmented gonadotropin secretion during sleep.<sup>220</sup> Thus, maturation at puberty must involve changes in the hypothalamus that are independent of ovarian steroids.

The maturational change in the hypothalamus is followed by an orderly and predictable sequence of events. Increased GnRH secretion leads to increased pituitary responsiveness to GnRH (a combination of steroid influence on the pituitary and a frequency effect of GnRH pulses on GnRH receptor numbers), leading to increasing production and secretion of gonadotropins. Increased gonadotropins are responsible for follicular growth and development in the ovary and increased sex steroid levels. The rising estrogen contributes to achieving an adult pattern of pulsatile GnRH secretion, finally leading to cyclic menstrual patterns.

The age of onset of puberty is variable and influenced by genetic factors, socioeconomic conditions, and general health. A trend toward lowering of the menarcheal age and the period of acceleration of growth is recognized. In a 10-year prospective study of middle class American girls in the 1970s, the mean age of menarche was 12.83.<sup>221</sup> Studies analyzing data from the National Health and Nutrition Examination Survey (NHANES) have observed a 2.3 month decrease in the average age of menarche between surveys for the years 1988–1994 (12.53 years) and 1999–2002 (12.34 years), and an overall 4.9 months decrease since 1960.<sup>222</sup> This lowering in age of menarche has been observed in all ethnic groups, declining from 12.57 to 12.52 years in non-Hispanic white girls, from 12.09 to 12.06 years for non-Hispanic black girls, and from 12.24 to 12.09 for Hispanic American girls (Table 4.3).

## **TABLE 4.3 Racial and Ethnic Differences in Age of Menarche**

<b>Ethnic Group</b>	<b>Mean Age of Menarche</b>
Black girls	12.06 y
Mexican-American girls	12.09 y
White girls	12.52 y

The earlier menarche today compared with the past is undoubtedly due to improved nutrition and better health. It has been suggested that initiation of growth and menarche occur at a particular body weight (48 kg) and percent of body fat (17%).<sup>223</sup> It is thought that this relationship reflects a required stage of metabolism. Although this hypothesis relating a critical weight threshold for timing of menarche is a helpful concept, the extreme variability in onset of menarche indicates that there is no particular age or size at which an individual girl should be expected to experience menarche.

In the female, the typical sequence of events is growth initiation, thelarche, pubarche, and finally menarche. This generally begins sometime between 8 and 14 years of age. The length of time involved in this evolution is usually 2–4 years. During this time span, puberty is said to occur. Individual variation in the order of appearance of this sequence is great. For example, growth of pubic hair and breast development are not always correlated.

Puberty is due to the reactivation of the hypothalamic-pituitary axis once fully active during the fetal life but suppressed during childhood. If the systems are potentially responsive, what holds function in check until puberty? The hypothalamic-pituitary-gonadal system is operative prior to puberty but is extremely sensitive to sex steroids and, therefore, suppressed. However, the typical “diphasic” pattern of gonadotropin secretion from infancy to puberty results primarily from changing levels of central inhibition of pulsatile GnRH secretion, and to a lesser extent, from a high sensitivity to low levels of gonadal steroid feedback. Negative feedback of steroids cannot be the sole explanation for the low gonadotropin levels in children because agonal children show the same decline in gonadotropins from age 2 to 6 as do normal children.<sup>224</sup> This indicates an intrinsic CNS inhibitory mechanism independent of gonadal steroids. Therefore, the restraint of puberty can be viewed as the result of two forces:

1. A CNS inhibitory force, a mechanism suppressing GnRH pulsatile secretion.
2. A very sensitive negative feedback of gonadal steroids (6–15 times more sensitive before puberty).

Because gonadal children show a rise in gonadotropins at pubertal age following suppression to a nadir during childhood, the dominant mechanism must be a CNS inhibitory force. The initial maturational change in the hypothalamus would then be a decrease in this inhibitory influence. A search for this inhibitory mechanism continues. Some have argued that, rather than a chronic state of inhibition prior to puberty, the GnRH neurons exist in an unrestrained but uncoordinated pattern of activity that prevents adequate secretion.

The pubertal changes result in increasing GnRH pulsatile secretion, leading to increasing gonadotropin production and ovarian stimulation, and finally to increasing estrogen levels. The reason that FSH is the first gonadotropin to rise at puberty is that arcuate activity begins with a low frequency of GnRH pulses. This is associated with a rise in FSH and little change in LH. With acceleration of frequency, FSH and LH reach adult levels. In addition, there is a qualitative change as a greater increase occurs in the bioactive forms of the gonadotropins.

The development of the positive feedback response to estrogen occurs later. This explains the well-known finding of anovulation in the first month (could be as long as 18 months) of menstruation following menarche. There are frequent exceptions, however, and ovulation can occur even at the time of menarche.

Don't think of puberty as being turned on by a controlling center in the brain but rather as a functional confluence of all factors. This is more a concept than an actual locus of action. The overall result of this change in the hypothalamus is the development of secondary sex characteristics, attainment of adult set-point levels, and the ability to reproduce. Neoplastic and vascular disorders that alter hypothalamic sensitivity can reverse the prepubertal threshold restraint and lead to precocious puberty.

# Regulation of the Menstrual Cycle

Many superstitious beliefs have surrounded menstruation throughout recorded history. Indeed, attitudes and ideas about this aspect of female physiology have changed slowly. Hopefully, the scientific progress of the last few decades, which has revealed the dynamic relationships between the hypothalamic, pituitary, and gonadal hormones and the cyclic nature of the normal reproductive process, will yield a better understanding. The hormone changes, correlated with the morphologic and autocrine-paracrine events in the ovary, make the coordination of this system one of the most remarkable events in biology.

The diagnosis and management of abnormal menstrual function must be based on an understanding of the physiologic mechanisms involved in the regulation of the normal cycle. To understand the normal menstrual cycle, it is helpful to divide the cycle into three distinct phases: the follicular phase, ovulation, and the luteal phase. We will examine each of these segments of the menstrual cycle, concentrating on the changes in ovarian and pituitary hormones, processes that govern the pattern of hormone changes, and the effects of these hormones on the ovary, pituitary, and hypothalamus in regulating the menstrual cycle.

# THE FOLLICULAR PHASE

---

In the human ovary, an orderly sequence of events in the follicular phase of the menstrual cycle results in the selection of a single follicle (dominant follicle) from within a group of immature follicles, and which is eventually ready for ovulation. This process, which occurs over the space of 10–14 days, features a series of sequential actions of hormones and autocrine-paracrine peptides on the follicle, leading the follicle destined to ovulate through a period of initial growth from a primordial follicle through the stages of the preantral, antral, and preovulatory follicle.

# The Primordial Follicle

The primordial germ cells originate in the endoderm of the yolk sac, allantois, and hindgut of the embryo, and by 5–6 weeks of gestation, they have migrated to the genital ridge. A rapid mitotic multiplication of germ cells begins at 6–8 weeks of pregnancy, and by 16–20 weeks, the maximum number of oocytes is reached: a total of 6–7 million in both ovaries.<sup>1</sup> The primordial follicle consists of an oocyte that is arrested in the diplotene stage of meiotic prophase, surrounded by a single layer of spindle-shaped granulosa cells.

Until their numbers are exhausted, follicles begin to grow and undergo atresia under all physiologic circumstances. Follicular growth and atresia are not interrupted by pregnancy, ovulation, or periods of anovulation. This dynamic process continues at all ages, including infancy and around the menopause. From the maximum number at 16–20 weeks of pregnancy, the number of oocytes will irretrievably decrease. The rate of decrease is proportional to the total number present; thus, the most rapid decrease occurs before birth, resulting in a decline from 6–7 to 2 million at birth and to 300,000 at puberty. From this large reservoir, about 400 follicles will ovulate during a woman's reproductive years.

The mechanism for determining which follicles and how many will start growing during any one cycle is unknown. The number of follicles that starts growing each cycle appears to be dependent upon the size of the residual pool of inactive primordial follicles.<sup>2,3</sup> Reducing the size of the pool (e.g., unilateral oophorectomy) causes the remaining follicles to redistribute their availability over time. It is possible that the follicle that is singled out to play the leading role in a particular cycle is the beneficiary of a timely match of follicle “readiness” (perhaps prepared by autocrine-paracrine actions in its microenvironment), and appropriate tropic hormone stimulation. The first follicle able to respond to stimulation may achieve an early lead that it never relinquishes. Nevertheless, each cohort of follicles that begins growth is engaged in a serious competition that ends, in humans, with only one of the cohort eventually succeeding to attain dominance.

## Rescue from Atresia (Apoptosis)

The early growth of follicles occurs over the time span of several menstrual cycles. The ovulatory follicle is one of a cohort that gets recruited at the time of the luteal-follicular transition in the preceding cycle.<sup>4,5,6</sup> The total duration of time to achieve preovulatory status is approximately 85 days. The majority of this time (until a late stage) involves responses that are independent of hormonal regulation.<sup>7</sup> Eventually, this cohort of follicles reaches a stage where, unless recruited (rescued) by follicle-stimulating

hormone (FSH), the next step is atresia. Thus, follicles are continuously available (2–5 mm in size) for a response to FSH. An increase in FSH is the critical feature in rescuing a cohort of follicles from atresia, the usual fate of most follicles, eventually allowing a dominant follicle to emerge and pursue a path to ovulation. In addition, maintenance of this increase in FSH for a critical duration of time is essential.<sup>8</sup> Without the appearance and persistence of an increase in the circulating FSH level, the cohort is doomed to the process of apoptosis, programmed physiologic cell death to eliminate superfluous cells.<sup>9</sup> “Apoptosis” is derived from Greek and means falling off, like leaves from a tree (Figure 5.1).

**FIGURE 5.1**

“Recruitment” has been traditionally used to describe the continuing growth of antral follicles in response to FSH. A more useful concept is that the cohort of follicles responding to FSH at the beginning of a cycle is rescued from apoptosis. Remember that the very early development of follicles begins continuously and independently from gonadotropin influence. The fate of almost all of these follicles is apoptosis; only those exposed to an increase in FSH stimulation, because of the juxtaposition of their readiness to respond and the increase in FSH during the luteal-follicular transition, have the good fortune to compete for selection as a dominant follicle.

The first visible signs of follicular development are an increase in the size of the oocyte and the granulosa cells becoming cuboidal rather than squamous in shape. These changes are better viewed as a process of maturation rather than growth. At this same

time, small gap junctions develop between the granulosa cells and the oocyte. Gap junctions are channels that when open permit the exchange of nutrients, ions, and regulatory molecules. Thus, the gap junctions serve as the pathway for nutritional, metabolite, and signal interchange between the granulosa cells and the oocyte, setting the stage for a bidirectional communication between the two cell types. In one direction, inhibition of the final maturation of the oocyte (until the luteinizing hormone [LH] surge) is maintained by factors derived from the granulosa cells. In the other direction, the process of follicular growth is influenced by regulatory factors that originate in the oocyte.

The molecular events that regulate primordial follicle formation involve a variety of factors, all locally produced and regulated, including members of the transforming growth factor beta (TGF- $\beta$ ) superfamily of proteins and another family of trophic factors called neurotrophins. Activins, inhibins, antimüllerian hormone (AMH), and bone morphogenetic proteins (BMPs) are members of the TGF- $\beta$  family of proteins. Activins promote and inhibins retard primordial follicle development, and their relative local concentrations in the fetal ovary during the time of follicle assembly may determine the size of the ovarian follicular pool.<sup>10</sup> AMH is an important inhibitor of primordial follicle growth, and BMPs exert the opposite effect.<sup>10</sup> Neurotrophins and their receptors are essential for the differentiation and survival of various neuronal populations in the central and peripheral nervous systems, but their presence in the developing ovary suggests that they also play a role in ovarian development. Four mammalian neurotrophins have been identified, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin 4/5 (NT-4/5), all of which exert their actions via binding to high-affinity transmembrane tyrosine kinase receptors encoded by members of the *trk* proto-oncogene family (NGF to TrkA, BDNF and NT-4/5 to TrkB, and NT-3 to TrkC).<sup>11</sup> Observations in NGF- and TrkA-null mice indicate that NGF stimulates the proliferation of ovarian mesenchymal cells during the early stages of follicular assembly and promotes differentiation and synthesis of FSH receptors in granulosa cells. Similar experiments with TrkB-null mice suggest that TrkB signaling is required for oocyte survival after follicular assembly and for preantral follicular development.<sup>11</sup> The specific signaling mechanisms that mediate the effects of activins, inhibins, BMPs, and neurotrophins remain to be established.

Other paracrine factors mediate a bidirectional communication between oocytes and their surrounding granulosa cells. Oocytes are linked to their investment of granulosa cells via gap junctions, which allow passage of small molecules such as ions (e.g., calcium), metabolites (e.g., pyruvate, nucleic acids, inositol), amino acids (e.g., L-alanine), cholesterol, and intracellular signaling molecules (e.g., cyclic adenosine monophosphate [cAMP]) between granulosa cells and oocytes. In mice, targeted deletions of gap junction proteins (known as connexins) disrupt follicular and oocyte

development.<sup>12</sup> Oocytes are unable to use glucose as an energy source to support meiotic maturation, cannot transport certain amino acids, and lack both the enzymes necessary for cholesterol synthesis and the receptors for its uptake from carrier-borne sources. Consequently, oocytes are dependent on adjacent granulosa cells to metabolize glucose into a usable energy substrate, such as pyruvate, for transport of essential amino acids, such as L-alanine, and for synthesis and transfer of cholesterol.<sup>13</sup> **To meet their energy needs, oocytes stimulate glycolysis, amino acid transport, and cholesterol synthesis in granulosa cells via paracrine and juxtacrine signals that promote expression of transcripts involved in these metabolic processes, at least in some species.**<sup>13</sup> Candidate signaling molecules include closely related members of the TGF- $\beta$  family, growth differentiation factor 9 (GDF9) and BMP15; both are expressed robustly in oocytes and appear crucial for normal ovarian follicle development in mammalian species.<sup>14</sup>

Mice that are genetically deficient in GDF-9, a peptide synthesized only in the oocyte after the primordial follicle becomes a preantral follicle, are infertile because follicular development cannot proceed beyond the primordial follicle stage.<sup>15,16</sup> Mutations in GDF-9 are rare causes of ovarian failure, but confirmed BMP-15 mutations have not been reported.<sup>17,18</sup>

Mutations in FOXL2, a gene encoding a transcription factor, cause blepharophimosis/ptosis/epicanthus inversus syndrome, a disorder affecting the eyelid and producing premature ovarian failure.<sup>19,20</sup> This transcription factor has been demonstrated to be essential for granulosa cell differentiation; indeed, mutations are associated with an absence of the very first sign of follicular development, the change in shape of granulosa cells from spindle to a cuboidal.<sup>21</sup>

The gap junction is composed of channels formed by an arrangement of proteins known as connexins, and more recently as GJAs. The connexin gap junctions are essential for growth and multiplication of the granulosa cells, and for the nutrition and regulation of oocyte development.<sup>22</sup> Connexin expression in ovarian follicles is up-regulated by FSH and down-regulated by LH.<sup>23</sup> In addition, FSH maintains an open channel in the gap junctions, a pathway that is closed by LH.<sup>24</sup> After ovulation, the gap junctions are important again in the corpus luteum, when their function is regulated by locally produced oxytocin.<sup>25</sup>

With multiplication of the cuboidal granulosa cells, the primordial follicle becomes a primary follicle. In early stages of primary follicle development, the granulosa cell arrangement around the oocyte appears pseudostratified. The granulosa layer is separated from the stromal cells by a basement membrane called the basal lamina. The surrounding stromal cells differentiate into concentric layers designated the theca

interna (closest to the basal lamina) and the theca externa (the outer portion). The theca layers appear when granulosa proliferation produces 3–6 layers of granulosa cells.<sup>6</sup>

The belief that the initiation of follicular growth from primordial stage is independent of gonadotropin stimulation is supported by the persistence of this initial growth in gonadotropin-deficient mutant mice and in anencephalic fetuses.<sup>26,27</sup> In the vast majority of instances, this growth is limited and rapidly followed by atresia. In studies of human ovarian follicles, expression of the gene for the FSH receptor could not be detected until after primordial follicles began to grow.<sup>28</sup> Furthermore, in a woman with an inactivating mutation in the  $\beta$  (beta) subunit FSH gene, antral follicular activity was present, although successful growth and ovulation were impossible.<sup>29</sup> Treatment of FSH-deficient women with exogenous FSH results in follicular growth, ovulation, and pregnancy, demonstrating that oocytes and growth of follicles until the appearance of FSH are normal.<sup>29,30</sup>

The general pattern of limited growth and quick atresia is interrupted at the beginning of the menstrual cycle when a group of follicles (after approximately 70 days of development) responds to hormonal changes and is propelled to grow. In young women, this cohort numbers 3–11 follicles per ovary.<sup>31</sup> The decline in luteal phase steroidogenesis and inhibin-A secretion in the preceding cycle allows for a progressive late luteal rise in FSH, beginning a few days before menses.<sup>32,33</sup> The timing of this important event was based on data derived from the immunoassay of FSH. Using a sensitive measurement of FSH bioactivity, it has been suggested that increasing bioactivity of FSH begins in the mid- to late luteal phase.<sup>34</sup>

## The Preantral Follicle

Once growth is accelerated, the follicle progresses to the preantral stage as the oocyte enlarges and is surrounded by a membrane, the zona pellucida. The granulosa cells undergo a multilayer proliferation as the theca layer continues to organize from the surrounding stroma. This growth is dependent upon gonadotropins and is correlated with increasing ovarian production of estrogen. Molecular studies indicate that the granulosa cells in mature follicles are all derived from as few as three precursor cells.<sup>35</sup>

The granulosa cells of the preantral follicle have the ability to synthesize all three classes of steroids; however, significantly more estrogens than either androgens or progestins are produced. An aromatase enzyme system acts to convert androgens to estrogens and is a factor limiting ovarian estrogen production. Aromatization is induced or activated through the action of FSH. The binding of FSH to its receptor and activation of the adenylate cyclase-mediated signal is followed by expression of

multiple mRNAs, which encode proteins responsible for cell proliferation, differentiation, and function. Thus, FSH both initiates steroidogenesis (estrogen production) in granulosa cells and stimulates granulosa cell growth.<sup>36</sup>

Specific receptors for FSH are not detected on granulosa cells until the preantral stage,<sup>28</sup> and the preantral follicle requires the presence of FSH in order to aromatize androgens and generate its own estrogenic microenvironment.<sup>37</sup> Cellular estrogen production is, therefore, limited by its FSH receptor content. Administration of FSH will alter the concentration of its own receptor on granulosa cells (both up- and down-regulation), in vivo and in vitro.<sup>38</sup> This action of FSH is modulated by growth factors.<sup>39</sup> FSH receptors quickly reach a concentration of approximately 1,500 receptors per granulosa cell.<sup>40</sup>

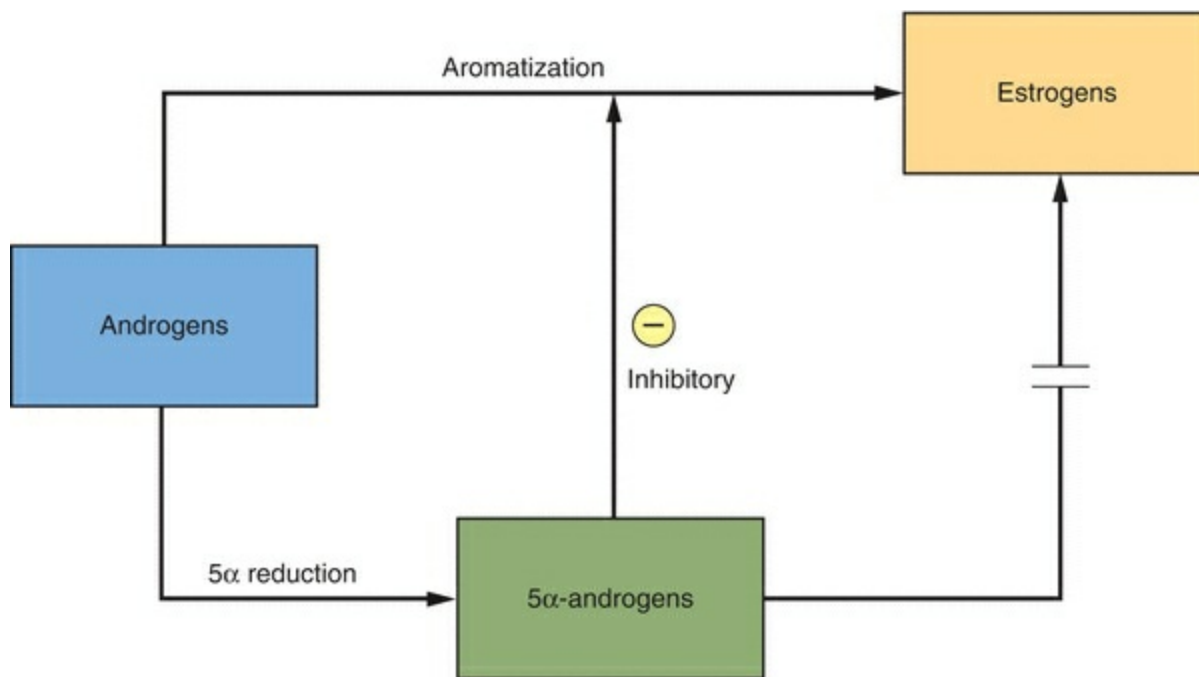

FSH operates through the G protein, adenylate cyclase system (described in [Chapter 1](#)), which is subject to down-regulation and modulation by many factors, including a calcium-calmodulin intermediary. Although steroidogenesis in the ovarian follicle is mainly regulated by the gonadotropins, multiple signaling pathways are involved that respond to many factors besides the gonadotropins. Besides the adenylate cyclase enzyme system, these pathways include ion gate channels, tyrosine kinase receptors, and the phospholipase system of second messengers. These pathways are regulated by a multitude of factors, including growth factors, nitric oxide, prostaglandins, and peptides such as gonadotropin-releasing hormone (GnRH), angiotensin II, tissue necrosis factor- $\alpha$  (alpha), and vasoactive intestinal peptide (VIP). The binding of LH to its receptor in the ovary is also followed by activation of the adenylate cyclase–cyclic AMP pathway via the G protein mechanism.

FSH combines synergistically with estrogen to exert (at least in the nonprimate) a mitogenic action on granulosa cells to stimulate their proliferation. Together, FSH and estrogen promote a rapid accumulation of FSH receptors, reflecting in part the increase in the number of granulosa cells in the dominant follicle. The early appearance of estrogen within the selected follicle allows the follicle to respond to relatively low concentrations of FSH, an autocrine function for estrogen within the follicle. As growth proceeds, the granulosa cells differentiate into several subgroups of different cell populations. This appears to be determined by the position of the cells relative to the oocyte.

There is a system of communication that exists within follicles. Not every cell has to contain receptors for the gonadotropins. Cells with receptors can transfer a signal (by gap junctions), which causes protein kinase activation in cells that lack the receptors.<sup>41</sup> Thus, hormone-initiated action can be transmitted throughout the follicle even though only a subpopulation of cells binds the hormone. This system of communication promotes a coordinated and synchronous performance throughout the follicle, a system

that continues to operate in the corpus luteum.

The role of androgens in early follicular development is complex. Specific androgen receptors are present in the granulosa cells.<sup>42</sup> The androgens serve not only as a substrate for FSH-induced aromatization but, in low concentrations, can further enhance aromatase activity. When exposed to an androgen-rich environment, preantral granulosa cells favor the conversion of androgens to more potent  $5\alpha$ -reduced androgens rather than to estrogens (Figure 5.2).<sup>43</sup> These androgens cannot be converted to estrogen and, in fact, inhibit aromatase activity.<sup>44</sup> They also inhibit FSH induction of LH receptor formation, another essential step in follicular development.<sup>45</sup>

**FIGURE 5.2**

**The fate of the preantral follicle is in delicate balance.** At low concentrations, androgens enhance their own aromatization and contribute to estrogen production. At higher levels, the limited capacity of aromatization is overwhelmed, and the follicle becomes androgenic and ultimately atretic.<sup>46</sup> The FSH to LH ratio is important for follicular recruitment and development. Follicles will progress in development only if emerging when FSH is elevated and LH is low. Those follicles arising at the end of the luteal phase or early in the subsequent cycle would be favored by an environment in which aromatization in the granulosa cell can prevail. **The success of a follicle depends upon its ability to convert an androgen-dominated microenvironment to an estrogen-dominated microenvironment.**<sup>47,48</sup>

## Key Points: Preantral Follicle

- Initial follicular development occurs independently of hormone influence.
- FSH stimulation propels follicles to the preantral stage.
- FSH-induced aromatization of androgen in the granulosa results in the production of estrogen.
- Together, FSH and estrogen increase the FSH receptor content of the follicle.

# The Antral Follicle

Under the synergistic influence of estrogen and FSH, there is an increase in the production of follicular fluid that accumulates in the intercellular spaces of the granulosa, eventually coalescing to form a cavity, as the follicle makes its gradual transition to the antral stage. The accumulation of follicular fluid provides a means whereby the oocyte and surrounding granulosa cells can be nurtured in a specific endocrine environment. The granulosa cells surrounding the oocyte are now designated the **cumulus oophorus**. The differentiation of the cumulus cells is believed to be a response to signals originating in the oocyte.<sup>49</sup> The follicular fluid, rich in hormones, growth factors, and cytokines, provides the milieu that is required for the orderly maturation and development of the oocyte and its surrounding cells.

In the presence of FSH, estrogen becomes the dominant substance in the follicular fluid. Conversely, in the absence of FSH, androgens predominate.<sup>50,51</sup> LH is not normally present in follicular fluid until the midcycle. If LH is prematurely elevated in the plasma and antral fluid, mitotic activity in the granulosa decreases, degenerative changes ensue, and intrafollicular androgen levels rise. Therefore, the dominance of estrogen and FSH is essential for sustained accumulation of granulosa cells and continued follicular growth. Antral follicles with the greatest rates of granulosa proliferation contain the highest estrogen concentrations and the lowest androgen/estrogen ratios, and are the most likely to house a healthy oocyte.<sup>52</sup> An androgenic milieu antagonizes estrogen-induced granulosa proliferation and, if sustained, promotes degenerative changes in the oocyte.

The steroids present in follicular fluid can be found in concentrations several orders of magnitude higher than those in plasma and reflect the functional capacity of the surrounding granulosa and theca cells. The synthesis of steroid hormones is functionally compartmentalized within the follicle: the two-cell system.<sup>40,46,51,53,54</sup>

## The Two-Cell, Two-Gonadotropin System

The aromatase activity of the granulosa far exceeds that observed in the theca. In human preantral and antral follicles, LH receptors are present only on the theca cells and FSH receptors only on the granulosa cells.<sup>55,56</sup> Theca interstitial cells, located in the theca interna, have approximately 20,000 LH receptors in their cell membranes. In response to LH, theca tissue is stimulated to produce androgens that can then be converted, through FSH-induced aromatization, to estrogens in the granulosa cells.

The interaction between the granulosa and theca compartments, with resulting accelerated estrogen production, is not fully functional until later in antral development. Like preantral granulosa cells, the granulosa of small antral follicles exhibits an in vitro

tendency to convert significant amounts of androgen to the more potent  $5\alpha$ -reduced form. In contrast, granulosa cells isolated from large antral follicles readily and preferentially metabolize androgens to estrogens. The conversion from an androgen microenvironment to an estrogen microenvironment (a change that is essential for further growth and development) is dependent upon a growing sensitivity to FSH brought about by the action of FSH and the enhancing influence of estrogen.

As the follicle develops, theca cells begin to express the genes for LH receptors, P450<sub>scc</sub>, and  $3\beta$ -hydroxysteroid dehydrogenase.<sup>57</sup> The separately regulated (by LH) entry of cholesterol into the mitochondria, utilizing internalization of low-density lipoprotein (LDL) cholesterol, is essential for steroidogenesis. **Therefore, ovarian steroidogenesis is LH dependent to a significant degree.** Human ovarian granulosa cells, after luteinization and vascularization that occur following ovulation, can use high-density lipoprotein (HDL) cholesterol in a system that differs from the LDL-cholesterol pathway. The HDL lipoproteins are not internalized, but rather, the cholesteryl esters are extracted from the lipoproteins at the cell surface and then transferred into the cell.<sup>58</sup>

As the follicle matures, the theca cells are characterized by their expression of P450<sub>c17</sub>, the enzyme step, which is rate limiting for the conversion of 21-carbon substrate to androgens.<sup>59</sup> Granulosa cells do not express P450<sub>c17</sub> and thus are dependent upon androgens from the theca in order to make estrogen. Increasing expression of the aromatization system (P450<sub>arom</sub>) is a marker of increasing maturity of granulosa cells. The presence of P450<sub>c17</sub> only in theca cells and P450<sub>arom</sub> only in granulosa cells is impressive evidence confirming the two-cell, two-gonadotropin explanation for estrogen production.<sup>60</sup>

The importance of the two-cell, two-gonadotropin system in the primate (**Figure 5.3**) is supported by the response of women with a deficiency in gonadotropins to treatment with recombinant (pure) FSH.<sup>61,62,63</sup> Follicles developed in these women (confirming the essential role of FSH, and the lesser role for LH, in recruitment and initial growth), but estradiol production was limited. Some aromatization occurred, perhaps using androgens originating in the adrenal glands, producing early follicular phase estradiol levels, but the usual robust steroidogenesis was impossible without the presence of LH to provide theca production of androgen substrate. This same response has been observed in experiments that use a GnRH antagonist to produce LH-deficient monkeys, followed by the administration of recombinant, pure human FSH.<sup>64,65</sup> **These results indicate that only FSH is required for folliculogenesis, and that in the primate, autocrine-paracrine peptides have assumed the important intraovarian role of modulating gonadotropin response. However, the final stages of maturation are optimized by LH, increasing the amount of androgen substrate for estrogen**

production and promoting the growth of the dominant follicle while simultaneously hastening the regression of smaller follicles.<sup>66</sup>

**FIGURE 5.3**

## Selection of the Dominant Follicle

The successful conversion to an estrogen-dominant follicle marks the “selection” of a follicle destined to ovulate, the process whereby, with rare exception in humans, only a single follicle succeeds in each cycle.<sup>67</sup> This selection process is to a significant degree the result of two estrogen actions: (1) a local interaction between estrogen and FSH

within the follicle and (2) the effect of estrogen on pituitary secretion of FSH. While estrogen exerts a positive influence on FSH action within the maturing follicle, its negative feedback relationship with FSH at the hypothalamic-pituitary level serves to withdraw gonadotropin support from the other less-developed follicles. The fall in FSH leads to a decline in FSH-dependent aromatase activity, limiting estrogen production in the less mature follicles. Even if a lesser follicle succeeds in achieving an estrogen microenvironment, decreasing FSH support would interrupt granulosa proliferation and function, promote a conversion to an androgenic microenvironment, and thereby induce irreversible atretic change. Indeed, the first event in the process of atresia is a reduction in FSH receptors in the granulosa layer.

The loss of oocytes (and follicles) through atresia is a response to changes in many factors. Certainly gonadotropin stimulation and withdrawal are important, but ovarian steroids and autocrine-paracrine factors are also involved. The consequence of these unfavorable changes, atresia, in the process called **apoptosis**, programmed cell death, is heralded by alterations in mRNAs required for cell proteins that maintain follicle integrity.<sup>68</sup> This type of “natural death” is a physiologic process, in contrast to the pathologic cell death of necrosis.

Once cells have entered the process of apoptosis, their response to FSH is modulated by local growth factors. Tumor necrosis factor (TNF), produced in the granulosa cells, inhibits FSH stimulation of estradiol secretion, except in the dominant follicle.<sup>69</sup> An inverse relationship exists between TNF expression and gonadotropin stimulation of granulosa cells. Thus, as the successful follicle increases its response to gonadotropins, its TNF production decreases. Those follicles with a failing response to gonadotropins increase their TNF production, hastening their own demise.

Although the principal function of AMH is to cause müllerian duct regression during male embryonic sexual differentiation, AMH is detected in the granulosa cells of early primordial follicles and reaches peak concentrations in the small antral follicles.<sup>70</sup> Its secretion appears to be regulated by the mature oocyte, and AMH decreases when FSH-stimulated follicular growth and estrogen production occur.<sup>71,72</sup> Studies with knockout model mice have indicated that AMH inhibits the recruitment of primordial follicles.<sup>73</sup> The paracrine activity of AMH inhibits FSH-stimulated follicle growth, thus suppressing the growth of lesser follicles and allowing the dominant follicle to emerge. Because of these activities, the circulating level of AMH reflects the number of growing follicles, and the blood concentration of AMH is a recognized measure of ovarian aging and as a prognostic marker for ovarian response during fertility treatment.<sup>74</sup> AMH levels are relatively unaffected by gonadotropins or the sex steroids. Measurement of AMH is reliable on any day in an individual’s menstrual cycle,<sup>75</sup> although prolonged periods of ovarian suppression, such as with use of hormonal contraceptives, can result

in spuriously lower circulating AMH levels.<sup>76</sup>

An asymmetry in ovarian estrogen production, an expression of the emerging dominant follicle, can be detected in ovarian venous effluent as early as 5th day of the cycle, corresponding with the gradual fall of FSH levels observed at the mid-follicular phase and preceding the increase in diameter that marks the physical emergence of the dominant follicle.<sup>77</sup> This is a crucial time in the cycle. Exogenous estrogen, administered even after selection of the dominant follicle, disrupts preovulatory development and induces atresia by reducing FSH levels below the sustaining level. Because the lesser follicles have entered the process of atresia, loss of the dominant follicle during this period requires beginning over, with recruitment of another set of preantral follicles.<sup>78</sup>

The negative feedback of estrogen on FSH serves to inhibit the development of all but the dominant follicle. The selected follicle remains dependent upon FSH and must complete its preovulatory development in the face of declining plasma levels of FSH. The dominant follicle, therefore, must escape the consequences of declining FSH induced by its own accelerating estrogen production. **The dominant follicle has two significant advantages, a greater content of FSH receptors acquired because of a rate of granulosa proliferation that surpasses that of its cohorts and enhancement of FSH action because of its high intrafollicular estrogen concentration, a consequence of local autocrine-paracrine molecules.** Thus, the dominant follicle is more sensitive to FSH, and as long as a critical duration of FSH exposure was initially present, the dominant follicle continues to develop.<sup>8</sup> As a result, the stimulus for aromatization, FSH, can be maintained, while at the same time, it is being withdrawn from among the less-developed follicles. A wave of atresia among the lesser follicles, therefore, is seen to parallel the rise in estrogen.

The accumulation of a greater mass of granulosa cells is accompanied by advanced development of the theca vasculature. By day 9, theca vascularity in the dominant follicle is twice that of other antral follicles.<sup>79</sup> This allows a preferential delivery of gonadotropins to the follicle, permitting the dominant follicle to retain FSH responsiveness and sustain continued development and function despite waning gonadotropin levels. The monkey ovary expresses a potent growth factor (vascular endothelial growth factor [VEGF]) that induces angiogenesis, and this expression is observed at the two development points when proliferation of capillaries is important: the emerging dominant follicle and the early corpus luteum (**Figure 5.4**).<sup>80,81</sup>

**FIGURE 5.4**

In order to respond to the ovulatory LH surge and to become a successful corpus luteum, the granulosa cells must acquire LH receptors. FSH induces LH receptor development on the granulosa cells of the large antral follicles. Here again estrogen and local autocrine-paracrine peptides (primate), serve as the chief coordinators. With increasing concentrations of estrogen within the follicle, FSH changes its focus of action, from up-regulating its own receptor to the generation of LH receptors.<sup>82</sup> The combination of a capacity for continued response despite declining levels of FSH and a high local estrogen environment in the dominant follicle provides optimal conditions for LH receptor development. LH can induce the formation of its own receptor in FSH-primed granulosa cells, but the primary mechanism utilizes FSH stimulation and estrogen enhancement.<sup>83,84</sup> The role for estrogen goes beyond synergism and enhancement; it is obligatory.

Evidence from ovarian stimulation for in vitro fertilization indicates that LH plays a

critical role in the late stages of follicle development, providing support for the final maturation and function of the dominant follicle.<sup>66,85</sup> At least one LH contribution in the late follicular phase is the LH-mediated stimulation of androgen production in the theca to provide for the large amounts of estrogen required at this point in the cycle. In addition, the theca androgens may have a direct beneficial effect on essential growth factors within the follicle. LH presence in the follicle prior to ovulation, therefore, is an important contributor to optimal follicular development that ultimately provides a healthy oocyte.<sup>86,87</sup>

The local action of estrogen within the ovarian follicle was questioned when initial studies failed to detect estrogen receptors in any of the significant ovarian compartments.<sup>88</sup> Subsequently, it was discovered that human granulosa cells and primate oocytes contain only mRNA for estrogen receptor- $\beta$ .<sup>89,90,91,92</sup> The dynamic expression of estrogen receptor- $\beta$  is consistent with an important local role for estrogen in ovarian follicle and corpus luteum growth and function.

Although prolactin is always present in follicular fluid, there is no evidence to suggest that prolactin is important during normal ovulatory cycles in the primate.

## The Feedback System

Through its own estrogen and peptide production, the dominant follicle assumes control of its own destiny. By altering gonadotropin secretion through feedback mechanisms, it optimizes its own environment to the detriment of the lesser follicles.

As reviewed in [Chapter 4](#), GnRH plays an obligatory role in the control of gonadotropin secretion, but the pattern of gonadotropin secretion observed in the menstrual cycle is the result of feedback modulation of steroids and peptides originating in the dominant follicle, acting directly on the hypothalamus and anterior pituitary.<sup>4</sup> An increase in GnRH accompanying the LH surge, indicating that positive feedback of estrogen operates at both pituitary and hypothalamic sites, has been reported in monkeys, but not in women.<sup>93,94</sup> Interestingly, positron emission tomography (PET) studies in women have indicated that the positive feedback effects of estrogen on LH occur at the level of the pituitary.<sup>95</sup>

Estrogen exerts its inhibitory effects in both the hypothalamus and the anterior pituitary, decreasing both GnRH pulsatile secretion and the pituitary gonadotropin response to GnRH.<sup>96</sup> Progesterone also operates at these two sites. Its inhibitory action is at the hypothalamic level, and its positive action is directly on the pituitary.<sup>97</sup> As determined by PET studies, the primary site of estrogen-negative feedback on LH is the hypothalamus.<sup>95</sup>

The secretion of FSH is very sensitive to the negative inhibitory effects of estrogen even at low levels. At higher levels, estrogen combines with inhibin for a suppression of FSH that is profound and sustained. In contrast, the influence of estrogen on LH release varies with concentration and duration of exposure. At low levels, estrogen imposes a negative feedback relationship with LH. At higher levels, however, estrogen is capable of exerting a positive stimulatory feedback effect on LH release.

The transition from estrogen-mediated suppression to stimulation of LH release occurs as estradiol levels rise during the midfollicular phase. There are two critical features in this mechanism: (1) the concentration of estradiol and (2) the length of time during which the estradiol elevation is sustained. In women, the estradiol concentration necessary to achieve a positive feedback effect on LH release is more than 200 pg/mL, and this concentration must be sustained for approximately 50 hours.<sup>98</sup> In spontaneous cycles, this level of circulating estrogen is achieved approximately when the dominant follicle has reached a diameter of 15 mm.<sup>99</sup> The estrogen stimulus must be sustained beyond the initiation of the LH surge until after the surge actually begins. Otherwise, the LH surge is abbreviated or fails to occur at all.

Within the well-established monthly pattern, the gonadotropins are secreted in a pulsatile fashion with a frequency and magnitude that vary with the phase of the cycle. While the pulsatile pattern of gonadotropins is directly due to a similar pulsatile secretion of GnRH, the amplitude and frequency modulations are the consequence of steroid feedback on both the hypothalamus and the anterior pituitary.<sup>100,101,102</sup> **Pulsatile secretion is more frequent but smaller in amplitude during the follicular phase compared to the luteal phase, with a slight increase in frequency observed as the follicular phase progresses to ovulation.**

The pulsatile pattern of FSH is not easily discerned because of its relatively longer half-life compared to LH, but the experimental data indicate that FSH and LH are secreted simultaneously and that GnRH stimulates the secretion of both gonadotropins. Even as late as only 36–48 hours before menses, gonadotropin secretion is still characterized by infrequent LH pulses and low FSH levels typical of the late luteal phase.<sup>100</sup> During the transition from the previous luteal phase to the next follicular phase, GnRH and the gonadotropins are released from the inhibitory effects of estradiol, progesterone, and inhibin. A progressive and fairly rapid increase in GnRH pulse secretion is associated with a preferential secretion of FSH compared to LH. The frequency of GnRH and LH pulses increases 4.5-fold during this period and is accompanied by a 3.5-fold increase in the circulating levels of FSH and a lesser 2-fold increase in LH levels.<sup>103</sup>

The GnRH pulse frequency changes in the luteal phase correlate with duration of exposure to progesterone, while pulse amplitude changes appear to be influenced by

changes in progesterone levels.<sup>100</sup> Both estradiol and progesterone are required to achieve the low, suppressed secretory pattern of GnRH during the luteal phase.<sup>104</sup> Evidence supports that the circulating steroids influence changes in both frequency and amplitude of gonadotropin pulses in the different phases of the cycle; the frequency of gonadotropin pulses is modulated through effects on frequency of GnRH release at the level of the hypothalamus, whereas the amplitude of gonadotropin pulses is mediated by actions of steroids at the level of the pituitary. The inhibitory action of luteal phase steroids on gonadotropin release appears to be mediated by an increase in hypothalamic endogenous opioid peptides. Both estrogen and progesterone can increase endogenous opiates. Estrogen appears to enhance the stimulatory action of progesterone in the luteal phase on endogenous opioid peptides, creating relatively high levels of endogenous opiates during the luteal phase. Administration of clomiphene (an estrogen receptor antagonist) during the luteal phase increases the LH pulse frequency with no effect on amplitude.<sup>105</sup>

Plasma endorphin begins to rise in the 2 days before the LH peak, coinciding with the midcycle gonadotropin surge.<sup>106</sup> The maximal level is reached just after the LH peak, coinciding with ovulation. Levels then gradually decline until the nadir is reached during menses and the early follicular phase. Monkeys have their highest beta-endorphin levels in the hypophyseal portal blood at midcycle.<sup>106,107</sup> **Normal cyclicality requires sequential periods of high (midcycle and luteal phase) and low (during menses) hypothalamic opioid activity.**

There is another important action of estrogen. A disparity exists between the patterns of FSH and LH secretion as determined by immunoassay and bioassay, indicating that more biologically active gonadotropins are secreted at midcycle than at other times in the cycle.<sup>108</sup> This quality, bioactivity versus immunoreactivity, is determined by the molecular structure of the gonadotropin molecule, a concept referred to in [Chapter 1](#) as heterogeneity of the tropic hormones. There is a well-established relationship between the activity and half-life of glycoprotein hormones and their sialic acid content. The feedback effects of estrogen include modulation of sialylation and the size and activity of the gonadotropins subsequently released, as well as an augmentation of GnRH-stimulated secretory release of biologically active gonadotropin. It certainly makes sense to intensify the gonadotropin effect at midcycle. The positive feedback actions of estrogen, therefore, increase both the quantity and the quality (the bioactivity) of FSH and LH. In addition to the change at midcycle that favors gonadotropin activity at the ovarian follicle, FSH isoforms with greater biologic activity also increase during the late luteal phase, a change that is appropriately geared toward propelling new ovarian follicle growth for the next cycle.<sup>109,110</sup>

There is a diurnal rhythm in FSH and LH secretion.<sup>111</sup> In contrast to the nocturnal

rise seen with other anterior pituitary hormones such as ACTH, thyroid-stimulating hormone (TSH), growth hormone, and prolactin, FSH and LH exhibit nocturnal decline, probably mediated by the endogenous opiates. This diurnal rhythm for LH is present only in the early follicular phase, while FSH maintains a circadian rhythm throughout the menstrual cycle (and thus it is not influenced by steroid hormone feedback) and even in the postmenopausal period of life.

## **Inhibin, Activin, Follistatin**

This family of peptides is synthesized by the granulosa cells in response to FSH and secreted into the follicular fluid and ovarian venous effluent.<sup>112,113,114,115</sup> Expression of these peptides is not limited to the ovary; they are present in many tissues throughout the body, serving as autocrine-paracrine regulators. Inhibin is an important inhibitor of FSH secretion. Activin stimulates FSH release in the pituitary and augments FSH action in the ovary. Follistatin suppresses FSH activity, by binding activin.

Inhibin consists of two dissimilar peptides (known as alpha- and beta-subunits) linked by disulfide bonds. Two forms of inhibin (inhibin A and inhibin B) have been purified, each containing an identical alpha-subunit and distinct but related beta-subunits. Thus, there are three subunits for inhibins: alpha, beta-A, and alpha, beta-B. Each subunit is a product of a different messenger RNA, each derived from its own precursor molecule.

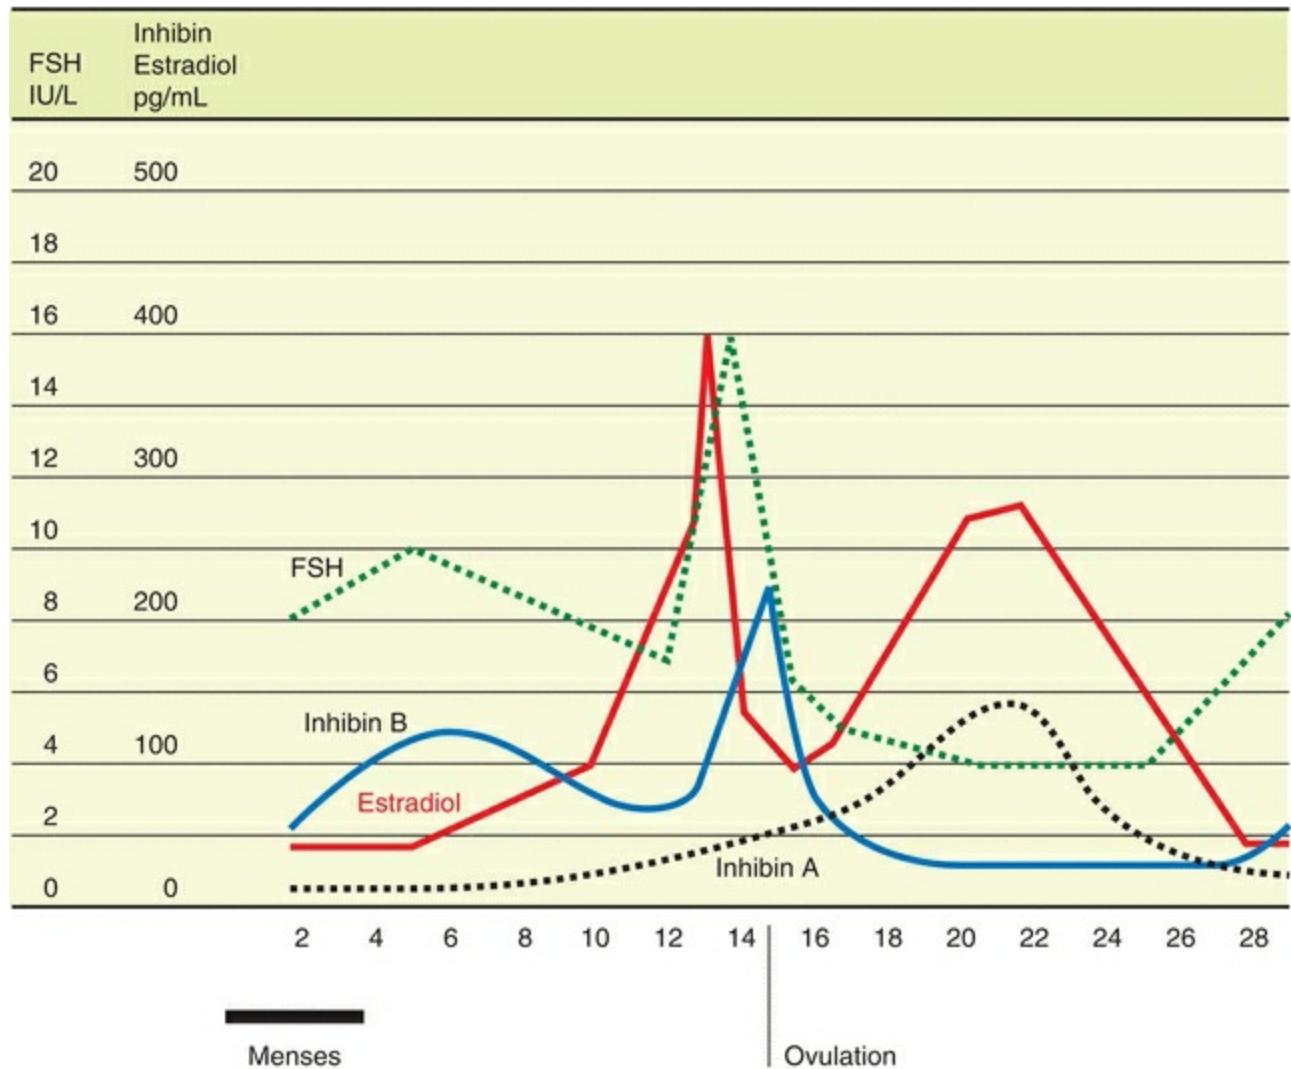

### **The Two Forms of Inhibin:**

- 1. Inhibin A: Alpha-BetaA**
- 2. Inhibin B: Alpha-BetaB**

FSH stimulates the secretion of inhibin from granulosa cells and, in turn, is suppressed by inhibin—a reciprocal relationship.<sup>116,117</sup> Refinements in assay techniques have revealed that inhibin B is the form of inhibin predominantly secreted by granulosa cells in the follicular phase of the cycle.<sup>118,119</sup> The secretion of inhibin is further regulated by local autocrine-paracrine control. GnRH and the epidermal growth factor (EGF) diminish FSH stimulation of inhibin secretion, whereas insulin-like growth factor-I (IGF-I) enhances inhibin production. The inhibitory effects of GnRH and EGF are consistent with their known ability to decrease FSH-stimulated estrogen production and LH receptor formation. The two forms of GnRH (GnRH-I and GnRH-II) along with their receptor are expressed in granulosa cells.<sup>120,121</sup>

**The secretion of inhibin B into the circulation further amplifies the withdrawal of FSH from other follicles, another mechanism by which an emerging follicle secures dominance.** Inhibin B rises slowly but steadily, in a pulsatile fashion (60–70

minute periodicity) reaching peak levels in the early and midfollicular phases, and then decreasing in the late follicular phase before ovulation to reach a nadir in the midluteal phase (**Figure 5.5**).<sup>33,118,122,123</sup> An inhibin-B peak the day after ovulation is probably the result of release from the ruptured follicle. This relationship of inhibin B and FSH is supported by the demonstration that inhibin-B levels are lower and FSH levels are higher in the follicular phase in women 45–49 years old compared to younger women.<sup>122,124</sup> An ovarian fibrothecoma secreting inhibin B predictably was associated with secondary amenorrhea and infertility due to suppression of FSH secretion.<sup>125</sup>

**FIGURE 5.5**

With the appearance of LH receptors on the granulosa cells of the dominant follicle and the subsequent development of the follicle into a corpus luteum, inhibin expression comes under the control of LH, and expression changes from inhibin B to inhibin A.<sup>126</sup>

The circulating levels of inhibin A rise in the late follicular phase to reach a peak level at the midluteal phase.<sup>33,127</sup> Inhibin A, therefore, contributes to the suppression of FSH to nadir levels during the luteal phase and to the changes at the luteal-follicular transition.

Inhibin has multiple, diverse inhibitory effects on gonadotropin secretion. Inhibin can block the synthesis and secretion of FSH, prevent the up-regulation of GnRH receptors by GnRH, reduce the number of GnRH receptors present, and, at high concentrations, promote the intracellular degradation of gonadotropins.

Activin, derived from granulosa cells but also present in the pituitary gonadotropes, contains two subunits that are identical to the beta subunits of inhibin A and B. In addition, activins have been identified with variants of the beta subunits, designated as beta-C, beta-D, and beta-E.<sup>128</sup> The activin beta-C and beta-E genes have been demonstrated to be nonessential in mouse knockout models.<sup>129</sup> Activin augments the secretion of FSH and inhibits prolactin, ACTH, and growth hormone responses.<sup>130,131,132,133</sup> Activin increases pituitary response to GnRH by enhancing GnRH receptor formation.<sup>134,135</sup> The effects of activin are blocked by inhibin and follistatin.<sup>136</sup> The structure of the activin genes is homologous to that of TGF- $\beta$ , indicating that these products all come from the same gene family.<sup>137</sup> Another important member of the TGF- $\beta$  family is the AMH, as well as a protein active during insect embryogenesis and a protein active in frog embryos.

### **The Three Forms of Activin:**

- 1. Activin A: BetaA-BetaA**
- 2. Activin AB: BetaA-BetaB**
- 3. Activin B: BetaB-BetaB**

Activin is present in many cell types, regulating growth and differentiation. In the ovarian follicle, activin increases FSH binding in granulosa cells (by regulating receptor numbers) and augments FSH stimulation of aromatization and inhibin production.<sup>114</sup> Considerable evidence derived from human cells exists to indicate that inhibin and activin act directly on theca cells to regulate androgen synthesis.<sup>138,139,140</sup> Inhibin enhances the stimulatory action of LH and/or IGF-I, while activin suppresses this action. Inhibin in increasing doses can overcome the inhibitory action of activin. Prior to ovulation, activin suppresses progesterone production by granulosa cells, perhaps preventing premature luteinization. There is a repertoire of cell transmembrane kinase receptors for activin, with differing binding affinities and domain structures.<sup>141</sup> This receptor heterogeneity allows the many different responses elicited by a single peptide. Both activin A and inhibin A have been demonstrated to be very potent in

stimulating in vitro maturation of oocytes that subsequently yield a high rate of fertilization.<sup>142</sup>

In the male, activin inhibits and inhibin facilitates LH stimulation of androgen biosynthesis in the testicular Leydig cells. In addition, activin stimulates and inhibin decreases spermatogonial proliferation; inhibin is produced in the Sertoli cell, the locus that has the principal role in modulating spermatogenesis. Thus, activin and inhibin play similar autocrine-paracrine roles in both the male and female gonads.

The anterior pituitary expresses the inhibin-activin subunits, and locally produced activin B augments FSH secretion. Activin A has been demonstrated to directly stimulate the synthesis of GnRH receptors in pituitary cells.<sup>143</sup> Follistatin is a glycopeptide secreted by a variety of pituitary cells, including the gonadotropes.<sup>144</sup> This peptide has also been called FSH-suppressing protein because of its main action: inhibition of FSH synthesis and secretion and the FSH response to GnRH by binding to activin and in that fashion decreasing the activity of activin.<sup>145,146</sup> Activin stimulates follistatin production, and inhibin prevents this response. Follistatin is also expressed by granulosa cells in response to FSH, and, therefore, follistatin, like inhibin and activin, functions locally in the follicle and in the pituitary.<sup>147</sup> Circulating levels of activin increase in the late luteal phase to peak at menses; however, activin A is highly bound in the circulation, and it is not certain it has an endocrine role.<sup>148</sup> Nevertheless, the timing is right for activin to contribute to the rise in FSH during the luteal-follicular transition.

**In summary, the pituitary secretion of FSH can be significantly regulated by the balance of activin and inhibin, with follistatin playing a role by inhibiting activin and enhancing inhibin activity. Within the ovarian follicle, activin and inhibin influence growth and development by modulating theca and granulosa responses to the gonadotropins.**

The inhibin-activin family of peptides (which also includes AMH and TGF- $\beta$ ) inhibits cell growth and can be considered as a class of tumor-suppressor proteins. Mice have been generated that are deficient in the inhibin-alpha-subunit gene.<sup>115</sup> The mice that are homozygous and lack inhibin are susceptible to the development of gonadal stromal tumors that appear after normal sexual differentiation and development. Thus, the alpha-inhibin gene is a specific tumor-suppressor gene for the gonads. A contributing factor to this tumor development could be the high FSH levels associated with the deficiency in inhibin.

## Growth Factors

Growth factors are polypeptides that modulate cell proliferation and differentiation,

operating through binding to specific cell membrane receptors. They are not classic endocrine substances; they act locally and function in paracrine and autocrine modes. There are multiple growth factors, and most cells contain multiple receptors for the various growth factors.

## **Insulin-Like Growth Factors**

The insulin-like growth factors (IGFs) (also called somatomedins) are peptides that have structural and functional similarity to insulin and mediate growth hormone action.<sup>149</sup> IGF-I and IGF-II are single chain polypeptides containing three disulfide bonds. IGF-I is encoded on the long arm of chromosome 12 and IGF-II on the short arm of chromosome 11 (which also contains the insulin gene). The genes are subject to a variety of promoters, and thus differential regulation can govern ultimate actions.

IGF-I mediates the growth-promoting actions of growth hormone. The majority of circulating IGF-I is derived from growth hormone-dependent synthesis in the liver. However, IGF-I is also synthesized in many tissues where production can be regulated in conjunction with growth hormone or **independently** by other factors.

IGF-II has little growth hormone dependence. It is believed to be important in fetal growth and development. Both IGFs induce the expression of cellular genes responsible for cellular proliferation and differentiation.

## **Insulin-like Growth Factor–Binding Proteins**

There are six known nonglycosylated peptides that function as IGF-binding proteins (IGFBPs), IGFBP-1 to IGFBP-6.<sup>150</sup> These binding proteins serve to carry the IGFs in serum, prolong half-lives and regulate tissue effects of the IGFs. The regulating action appears to be due to binding and sequestering of the IGFs, preventing their access to the cell membrane surface receptors, and, thus, not permitting the synergistic actions that result when gonadotropins and growth factors are combined. The IGFBPs may also exert direct actions on cellular functions, independently of growth factor functions. IGFBP-1 is the principal binding protein in the amniotic fluid, whereas IGFBP-3 is the main binding protein in serum, and its synthesis, which occurs primarily in the liver, is dependent on growth hormone. Circulating levels of IGFBP-3 reflect the total IGF concentration (IGF-I plus IGF-II) and carry at least 90% of the circulating IGFs. The IGFBPs change with age (decreasing levels of IGFBP-3) and during pregnancy (decreasing IGFBP-3 due to a circulating protease unique to pregnancy). IGFBPs do not bind insulin.

## **Insulin-like Growth Factor Receptors**

The Type I receptor preferentially binds IGF-I and can be called the IGF-I receptor. The

Type II receptor in a similar fashion can be called the IGF-II receptor. IGF-I also binds to the insulin receptor but with low affinity. Insulin binds to the IGF-I receptor with moderate affinity. The IGF-I receptor and the insulin receptor are similar in structure: tetramers composed of two alpha-subunits and two beta-subunits linked by disulfide bonds. The intracellular component of the beta-subunit is a tyrosine kinase that is activated by autophosphorylation. The IGF-II receptor does not bind insulin. It is a single chain glycoprotein, with 90% of its structure extending extracellularly. This receptor functions as a receptor coupled to a G protein. The physiologic effects of IGF-I are mediated by its own receptor, but IGF-II can exert its actions via both receptors. Indeed, the IGF-I receptor binds IGF-I and IGF-II with equal affinity. In human cells, the IGF-I receptor and IGF-II receptor are present in theca and granulosa cells and in luteinized granulosa cells. Ovarian stromal tissue contains IGF-I receptors.

### The Ovarian Actions of IGFs

IGF signaling is recognized to play critical roles in processes of follicular development, growth and for steroidogenesis (**Figures 5.6, 5.7, 5.8**). IGF-I has been demonstrated to stimulate the following events in ovarian theca and granulosa cells: DNA synthesis, steroidogenesis, aromatase activity, LH receptor synthesis, and inhibin secretion. IGF-II stimulates granulosa mitosis. In human ovarian cells, IGF-I, in synergy with FSH, stimulates protein synthesis and steroidogenesis. After LH receptors appear, IGF-I enhances LH-induced progesterone synthesis and stimulates proliferation of granulosa-luteal cells. IGF-I, in synergy with FSH, is very active in stimulating aromatase activity in the preovulatory follicles. Thus, IGF-I can be involved in both estradiol and progesterone synthesis.

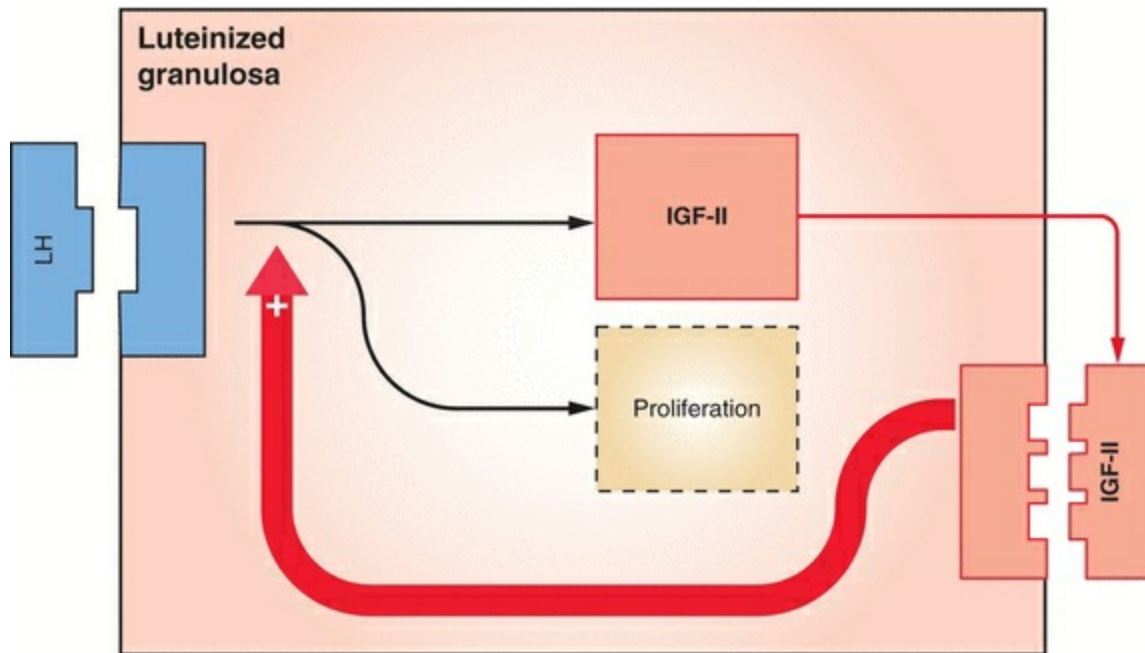

**FIGURE 5.6**

**FIGURE 5.7**

**FIGURE 5.8**

In animal experiments, synthesis of IGF-I by the granulosa cells is dependent upon FSH but enhanced by estradiol. Growth hormone also acts synergistically with FSH and estradiol to increase IGF synthesis. The story becomes confused when the many growth factors and regulators are studied, because of their various stimulating and inhibiting effects. In the rat, the granulosa cell is the major site for IGF-I gene expression, which is active only prior to ovulation. It is not detected in atretic follicles or in corpora lutea. IGF-II gene expression appears to be limited to the theca and interstitial cells in the rat. However, the site of IGF expression is different in primates.

In studies with human ovarian tissue, IGF-II is highly expressed in both theca cells and granulosa cells; however, the level is highest in the granulosa and increases with growth of the follicle.<sup>151,152</sup> IGF-II is also synthesized by luteinized granulosa and appears to function locally in an autocrine fashion.<sup>153</sup> These findings indicate that IGF-II is the primary IGF in the human ovary. Nevertheless, IGF-I is still a significant product of human theca cells.<sup>154</sup>

Human theca cells express mRNA transcripts that encode receptors for both IGF-I and insulin.<sup>155</sup> Because insulin and IGF-II can both activate the receptor for IGF-I, this pathway provides a method for exertion of paracrine influences on granulosa cells and autocrine activity in the theca (augmenting LH stimulation of androgen production). In vitro studies confirm that IGF-II is capable of stimulating steroidogenesis and proliferation in human theca and granulosa cells.<sup>156,157,158</sup> These actions are augmented by growth hormone, which increases IGF production and, thus, indirectly enhances

gonadotropin stimulation of ovarian follicles.<sup>159</sup>

This primate scenario is supported by finding higher levels of IGF-II, but not IGF-I, in the follicular fluid of developing follicles, with the highest levels present in dominant follicles.<sup>160</sup> The IGF levels in follicular fluid correlate with estradiol levels and undergo a further transient increase after the LH surge. There are no menstrual cycle changes in the circulating levels of IGF-I, IGF-II, IGFBP-1, or IGFBP-3; high levels in the dominant follicle are not associated with an increase in circulating levels.<sup>161</sup>

In studies with human tissue, IGFBP-1 inhibits IGF-I-mediated steroidogenesis and proliferation of the luteinized granulosa cells. Synthesis of IGFBPs by human granulosa is inhibited by FSH, IGF-I, and IGF-II.<sup>162,163</sup> These findings fit with the overall idea that the binding proteins counteract the synergism between gonadotropins and growth factors. In general, IGFBP-1 expression is found in granulosa cells of the growing follicles, IGFBP-3 in theca cells and the granulosa of the dominant follicle, and IGFBP-2, -4, and -5 in theca and granulosa of antral and atretic follicles; however, IGFBP-6 has not been found in the ovary.<sup>151</sup> The predominant binding protein in the preovulatory follicles is IGFBP-2 in the granulosa and IGFBP-3 in the theca; these increase progressively in the follicle that gains dominance and then decrease in the late follicular phase.<sup>152,164,165</sup> These patterns suggest that IGFBPs -1, -2, and -3 play a role in the growing follicles, whereas IGFBPs -2, -4, and -5 are relevant in the atretic and failing follicles. IGFBP expression in polycystic ovaries is like that seen in atretic follicles. The decrease in IGFBP-3 that occurs in dominant follicles should allow an increase in IGF levels and activity. The increase in IGFBP-2 in the failing follicles probably correlates with sequestering of IGF, depriving the follicle of an important force in gonadotropin augmentation.

Circulating levels of IGFBP-1 decrease in response to insulin, and thus circulating levels are decreased in women with anovulation and polycystic ovary syndrome who have elevated levels of insulin.<sup>166</sup> These patients also have increased circulating levels of IGF-I, probably a consequence of LH-stimulated synthesis and secretion in the theca cells. The level of IGFBP-1 in the follicular fluid from polycystic ovaries is decreased; thus, this binding protein is not playing a role inhibiting the action of IGF-I in the polycystic ovaries. The levels of IGFBPs -2 and -4 in the follicular fluid from follicles in anovulatory patients are increased (as in atretic follicles).<sup>151,167</sup> Even though these changes may play a role in anovulatory pathophysiology, they are consistent with failure in development and thus may not be etiologic factors.

IGF activity may also be modulated by the proteases that regulate the activity of the IGF-binding proteins.<sup>168</sup> Estrogen-dominant follicular fluid contains very low levels of IGFBP-4, in contrast to the high levels present in androgen-dominant follicular fluid.

The low level of IGFBP-4 in estrogen-dominant follicular fluid is associated with the presence of an IGFBP-4 specific protease. This protease would decrease IGFBP activity and enhance IGF activity, another mechanism for ensuring the success of the dominant follicle.

The IGF story is at once complex, fascinating, and compelling. However, its contribution may be facilitatory, but not essential. Laron-type dwarfism is characterized by a deficiency in IGF-I due to an abnormality in the growth hormone receptor. Despite low levels of IGF-I and high levels of IGFBP, a woman with Laron-type dwarfism responded to exogenous gonadotropin stimulation with the production of multiple, mature follicles with good estrogen production and fertilizable oocytes.<sup>169</sup> Another explanation for this observation is that IGF-II, rather than IGF-I, is the important factor in the human-dominant follicle. This possibility is supported by evidence indicating that IGF-II is the most abundant IGF in human ovarian follicles.<sup>151,152</sup> Another possibility is that the Laron-type dwarf is deficient only in growth hormone–dependent IGF-I and that ovarian IGFs are not totally dependent on growth hormone.

## Key Points: Insulin-Like Growth Factor Action in the Ovary

- IGF-II stimulates granulosa cell proliferation, aromatase activity, and progesterone synthesis.
- IGF-II is produced in theca cells, granulosa cells, and luteinized granulosa cells.
- Gonadotropins stimulate IGF production, and in animal experiments, this stimulation is enhanced by estradiol and growth hormone.
- IGF-I receptors are present in theca and granulosa cells, and only IGF-II receptors are present in luteinized granulosa.
- IGF-II activates both IGF-I and IGF-II receptors.
- The most abundant IGF in human follicles is IGF-II. In the pig and rat, the primary IGF is IGF-I.
- FSH inhibits binding protein synthesis and thus maximizes growth factor availability.

## Epidermal Growth Factor

EGF is a mitogen for a variety of cells, and its action is potentiated by other growth factors. Granulosa cells in particular respond to this growth factor in a variety of ways related to gonadotropin stimulation, including proliferation. EGF suppresses the up-

regulatory effects of FSH on its own receptor.<sup>39</sup> Amphiregulin and epiregulin, ligands that are similar to EGF, are produced in luteinized granulosa cells in response to LH and induce progesterone synthesis in the corpus luteum.<sup>170</sup>

## **Transforming Growth Factor**

TGF-alpha ( $\alpha$ ) is a structural analog of EGF and can bind to the EGF receptor. TGF-beta ( $\beta$ ) utilizes a receptor that is distinct from the EGF receptor. These factors are thought to be autocrine growth regulators. Inhibin and activin are derived from the same gene family. TGF- $\beta$ , secreted by theca cells, enhances FSH induction of LH receptors on granulosa cells, an action that is opposite that of EGF.<sup>171</sup> While this action can be viewed as a positive impact on granulosa cells, in the theca, TGF- $\beta$  has a negative action, inhibiting androgen production.<sup>172</sup> GDF-9 is a member of the TGF- $\beta$  family that originates in the oocyte and is essential for normal growth and development of the ovarian follicle.<sup>16</sup>

## **Fibroblast Growth Factor (FGF)**

This factor is a mitogen for a variety of cells and is present in all steroid-producing tissues. Important roles in the ovarian follicle include stimulation of mitosis in granulosa cells, stimulation of angiogenesis, stimulation of plasminogen activator, inhibition of FSH up-regulation of its own receptor, and inhibition of FSH-induced LH receptor expression and estrogen production.<sup>39,173</sup> These actions are opposite to those of TGF- $\beta$ .

## **Platelet-Derived Growth Factor**

This growth factor modifies cyclic AMP pathways responding to FSH, especially those involved in granulosa cell differentiation. Both platelet-derived growth factor (PDGF) and EGF may also modify prostaglandin production within the follicle.

## **Angiogenic Growth Factors**

Vascularization of the follicle is influenced by peptides in the follicular fluid, especially VEGF, a cytokine produced in granulosa cells in response to LH.<sup>174,175</sup> Luteal cells respond to human chorionic gonadotropin (hCG) with greater VEGF output, a probable mechanism contributing to the increased vascular permeability associated with ovarian hyperstimulation syndrome that can occur with exogenous gonadotropin administration (Chapter 28).<sup>176</sup> Angiopoietins bind to an endothelial receptor (Tie-2) and provide an inhibitory influence on angiogenesis. Angiopoietin-1 is the active agent, opposed by angiopoietin-2, which competes for the Tie-2 receptor on endothelial cells. Differential

expression of these angiogenic factors is involved in the coordinated growth and regression of follicles and the corpus luteum.<sup>177,178,179</sup> Injection of VEGF and angiopoietin antagonists directly into dominant follicles in the monkey interferes with both the physical process of ovulation and the subsequent function of the corpus luteum.<sup>180</sup>

## The Interleukin-1 (IL-1) System

Leukocytes are a prominent component of the ovarian follicle and a major source of interleukins. IL-1 is a member of the cytokine family of immunomediators. The human ovary contains the complete IL-1 system (ligand and receptor). In the rat, IL-1 stimulates ovarian prostaglandin synthesis and perhaps plays a role in ovulation.<sup>181</sup>

## Tumor Necrosis Factor-alpha

Tumor necrosis factor-alpha (TNF- $\alpha$ ) is also a product of leukocytes (macrophages). It very likely is a key player in the process of apoptosis, a feature of follicular atresia as well as luteolysis of the corpus luteum.

## Other Peptides

The follicular fluid is a veritable protein soup! It is composed of exudates from plasma and secretions from follicular granulosa cells. A variety of hormones can be found in the follicular fluid, as well as enzymes and peptides, which play important roles in follicular growth and development, ovulation, and modulation of hormonal responses.

Follicular fluid contains **prorenin**, the inactive precursor of renin, in a concentration that is about 12 times higher than in the plasma.<sup>182</sup> LH stimulates its synthesis in the follicle, and there is a midcycle peak in prorenin plasma levels. The circulating levels of prorenin also increase (10-fold) during the early stages of pregnancy—the result of ovarian stimulation by the rise in hCG. These increases in prorenin from the ovary are not responsible for any significant changes in the plasma levels of the active form, renin. Possible roles for this ovarian prorenin-renin-angiotensin system include stimulation of steroidogenesis to provide androgen substrate for estrogen production, regulation of calcium and prostaglandin metabolism, and stimulation of angiogenesis. This system may affect vascular and tissue functions both within and outside the ovary.

Members of the proopiomelanocortin family are found in human follicular fluid.<sup>183</sup> Follicular levels of **ACTH** and  **$\beta$ -lipotropin** remain constant throughout the cycle, but  **$\beta$ -endorphin** levels peak just before ovulation. In addition, enkephalin is present in relatively unchanging concentrations. The complete **corticotropin-releasing hormone**

(**CRH**) system, including CRH, the CRH receptor, and CRH-binding protein, is present in the theca but not in granulosa cells.<sup>184</sup> CRH inhibits LH-stimulated androgen production in theca cells, apparently by suppressing P450c17 gene expression.<sup>185</sup>

## Antimüllerian hormone

A member of the TGF- $\beta$  family, like inhibin and activin, AMH is produced by granulosa cells and may play a role in oocyte maturation (it inhibits oocyte meiosis) and follicular development.<sup>186,187</sup> AMH directly inhibits proliferation of granulosa and luteal cells, as well as EGF-stimulated proliferation. Its paracrine function may be to suppress growth of all but the dominant follicle in each cycle.<sup>70</sup> Circulating level of AMH is highest in the late follicular phase, peaking simultaneously with inhibin A just before ovulation.<sup>188</sup> Experimental evidence suggests that the source of the AMH is the entire cohort of growing follicles except for the dominant follicle, and thus, the circulating level correlates with follicle number and potential for fertility.<sup>189,190</sup> With aging and a decrease in the number of follicles, AMH levels decline. AMH can be measured on any day in an individual's menstrual cycle, as there is minimal variability across the different phases of the menstrual cycle. While previously believed that AMH levels remain unaffected by use of steroid contraception, recent evidence demonstrates that circulating AMH levels may be falsely suppressed in long-term users of hormonal contraceptives.<sup>75,76</sup>

Follicular fluid prevents resumption of meiosis until the preovulatory LH surge either overcomes or removes this inhibition. This action is attributed to **oocyte maturation inhibitor (OMI)**. **Pregnancy-associated plasma protein A**, found in the placenta, is also present in follicular fluid. It may inhibit proteolytic activity within the follicle before ovulation. **Endothelin-1** is a peptide, produced in vascular endothelial cells, which may be the substance previously known as luteinization inhibitor; endothelin gene expression is induced by the hypoxia associated with the avascular granulosa, and it inhibits LH-induced progesterone production.<sup>191</sup> It is uncertain whether **GnRH-like peptides** have a follicular role or represent sequestered GnRH. **Oxytocin** is found in preovulatory follicles and the corpus luteum. Growth hormone-binding protein is present in follicular fluid and is similar in characteristics to the same binding protein in serum.

## Key Points: Antral Follicle

- Follicular phase estrogen production is explained by the two-cell, two-gonadotropin mechanism.

- Selection of the dominant follicle is established during cycle days 5–7, and consequently, peripheral levels of estradiol begin to rise significantly by cycle day 7.
- Estradiol levels, derived from the dominant follicle, increase steadily and, through negative feedback effects, exert a progressively greater suppressive influence on FSH release.
- While directing a decline in FSH levels, the midfollicular rise in estradiol exerts a positive feedback influence on LH secretion.
- The positive action of estrogen also includes modification of the gonadotropin molecule, increasing the quality (the bioactivity) as well as the quantity of FSH and LH at midcycle.
- LH levels rise steadily during the late follicular phase, stimulating androgen production in the theca.
- A unique responsiveness to FSH allows the dominant follicle to utilize the androgen as substrate and further accelerate estrogen production through aromatization.
- FSH induces the appearance of LH receptors on granulosa cells.
- Follicular response to the gonadotropins is modulated by a variety of growth factors and autocrine-paracrine peptides.
- Inhibin B, secreted by the granulosa cells in response to FSH, directly suppresses pituitary FSH secretion.
- Activin, originating in both pituitary and granulosa, augments FSH secretion and action.

# Follicular Growth and Development in the Primate Ovary

Evidence strongly indicates that autocrine-paracrine peptides, and not estrogen, play the major role in regulating ovarian follicle growth and development in the primate. In monkey experiments, no reduction in total number or size of follicles resulted when estradiol production was effectively suppressed by treatment with an inhibitor of the aromatase enzyme system or with an inhibitor of the  $3\beta$ -hydroxysteroid dehydrogenase enzyme.<sup>192,193,194</sup> Oocyte development was not altered, although the subsequent fertilization rate was reduced by this treatment. Another argument against a major role for estrogen in follicular growth and development is the successful stimulation with gonadotropins of normal follicular growth and development in women with  $17\alpha$ -hydroxylase deficiency (an inherited disorder that prevents the production of androgens and estrogens).<sup>195,196</sup>

A nonessential role for estrogen in follicular growth and development is further supported by the response of women with a deficiency in gonadotropins to treatment with recombinant (pure) FSH.<sup>61,62,63</sup> Some aromatization occurred, perhaps using androgens originating in the adrenal glands, producing early follicular phase estradiol levels, but the usual robust steroidogenesis was impossible without the presence of LH to provide theca production of androgen substrate. Nevertheless, oocytes were retrieved, and with in vitro fertilization, pregnancy was achieved. This same response was observed in experiments that used a GnRH antagonist to produce LH-deficient monkeys and then the administration of recombinant, pure human FSH.<sup>64,65</sup>

These results indicate that only FSH is required for early folliculogenesis and that in the primate, autocrine-paracrine peptides have replaced estrogen in the important role of modulating gonadotropin response. Consider the following actions that have been documented in primate ovaries:

1. Inhibin and activin regulate androgen synthesis in human theca cells. Inhibin enhances and activin suppresses the stimulatory action of LH and/or IGF-I, and inhibin can overcome the inhibitory action of activin on theca cells.<sup>138,139,140</sup>
2. In immature granulosa cells, activin augments all FSH activities, especially aromatase activity (estrogen production).<sup>114,197</sup>
3. In luteinizing granulosa cells, activin has direct mitogenic activity and suppresses steroidogenesis in response to LH, while inhibin has no effect on LH-dependent aromatase in mature granulosa cells.<sup>197,198</sup>
4. In the follicular phase, granulosa production of inhibin is under the control of FSH, but during the late follicular phase a change occurs, culminating in LH control of

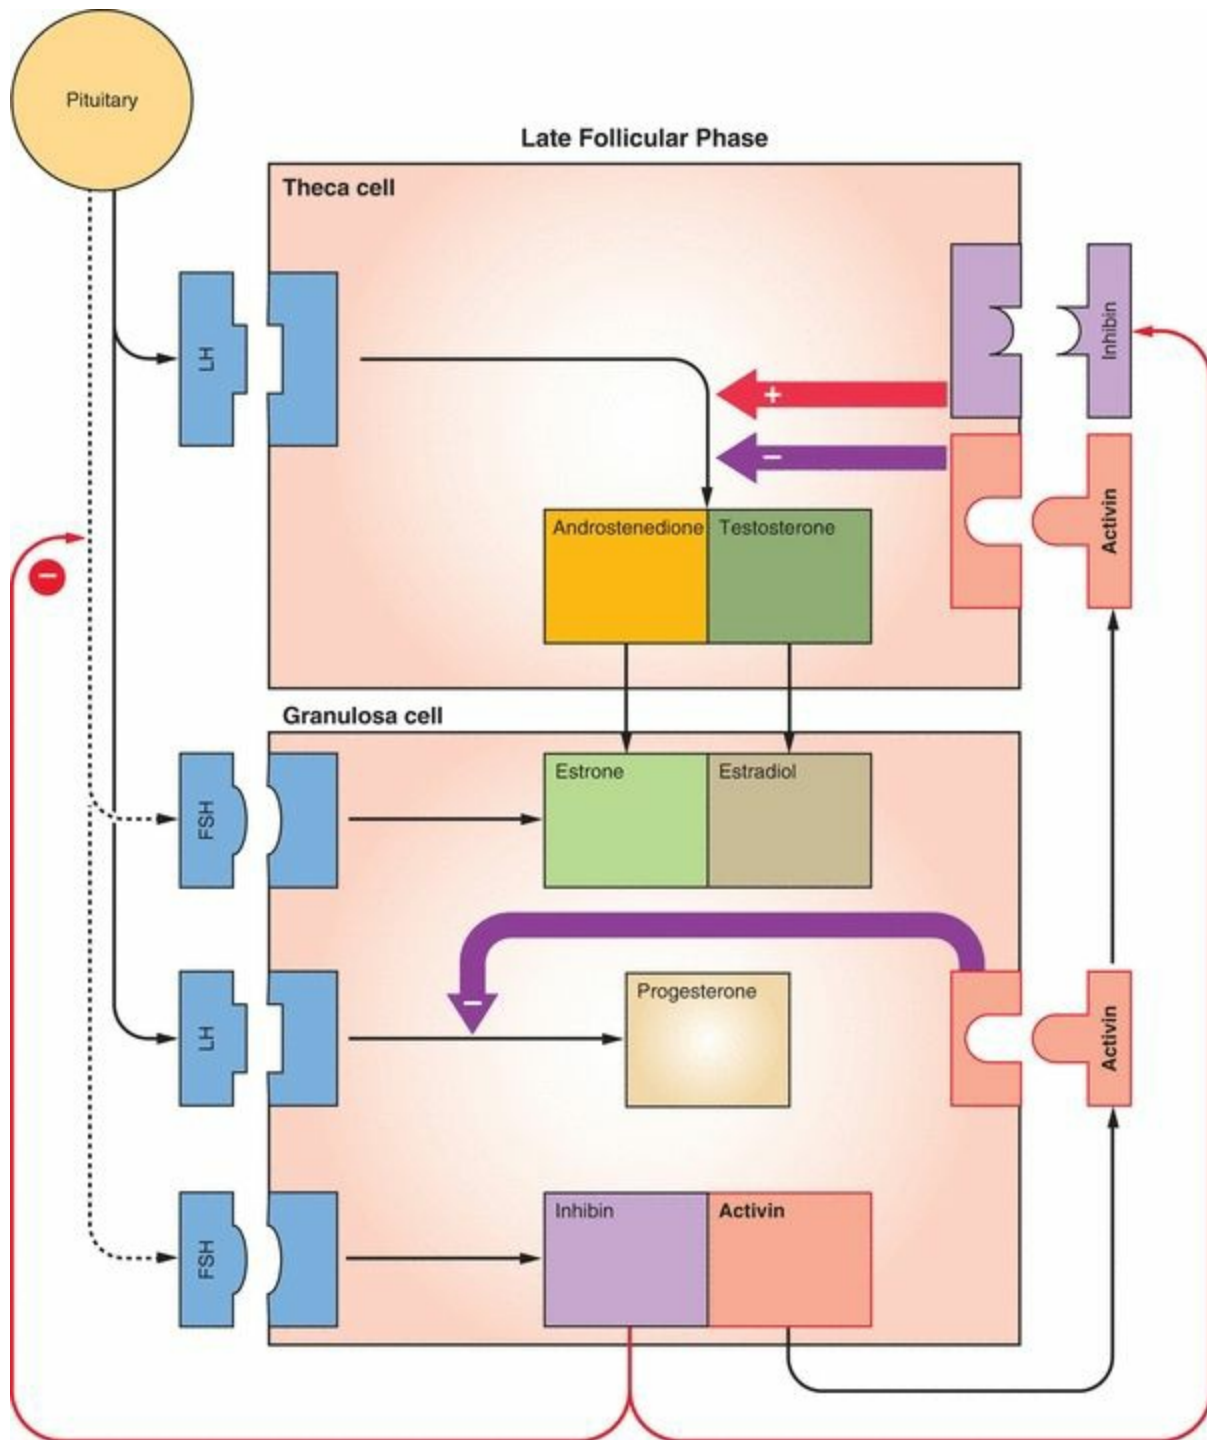

luteal synthesis of inhibin.<sup>199,200</sup>

5. As the follicle grows, activin production decreases, and inhibin production increases.<sup>201,202</sup> In addition, follistatin levels increase in the follicular fluid with increasing growth of the follicle, a mechanism for decreasing activin activity.<sup>203</sup> In the early follicular phase, FSH and estradiol enhance inhibin-B secretion, probably indirectly by increasing granulosa cell numbers, whereas late in the follicular phase, when LH levels increase, inhibin-A secretion is favored.<sup>204</sup>

These actions come together as follows. In the early follicular phase, activin produced by granulosa in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation, while simultaneously suppressing theca androgen synthesis (**Figure 5.9**). In the late follicular phase, increased production of inhibin (specifically inhibin B) by the granulosa (and decreased activin) promotes androgen synthesis in the theca in response to LH and IGF-II to provide substrate for even greater estrogen production in the granulosa (**Figure 5.10**). In the mature granulosa of the dominant preovulatory follicle, activin serves to prevent premature luteinization and progesterone production.

**FIGURE 5.9**

**FIGURE 5.10**

The successful follicle is the one that acquires the highest level of aromatase activity and LH receptors in response to FSH and is characterized by the highest estrogen (for central feedback action) and the greatest inhibin production (for both local and central actions). This accomplishment occurs in synchrony with the appropriate activin expression. The highest level of gene activity encoding activin is found in immature

antral follicles and the lowest level in the preovulatory follicles. Thus, activin proteins (which enhance FSH activity) are produced in greatest amounts early in follicular development to enhance follicle receptivity to FSH. As with circulating levels of inhibin, inhibin B is the predominant inhibin in the follicular fluid of preantral follicles, and inhibin A increases when follicles become large and mature.<sup>205,206,207</sup> Inhibin synthesis and secretion during the follicular phase are regulated by FSH and growth factors.<sup>208</sup>

The right concentration of androgens in granulosa cells promotes aromatase activity and inhibin production and, in turn, inhibin promotes LH stimulation of theca androgen synthesis. With development of the follicle, inhibin expression (specifically inhibin A) comes under the control of LH. A key to successful ovulation and luteal function is the conversion of inhibin production to LH responsiveness to maintain FSH suppression centrally (**Figure 5.11**) and enhancement of LH action locally.

**FIGURE 5.11**

Responses of ovarian follicles to exogenous FSH and LH stimulation for in vitro fertilization indicate that the final maturation and function of the dominant follicle prior to ovulation are significantly influenced by LH.<sup>84</sup> Final maturation of the dominant follicle and the health of the oocyte are optimized by the required presence of a threshold level of LH.<sup>66,86,87,209</sup>

A lesser role is assigned to the insulin-like growth factors in view of the successful production of multiple, estrogen-producing follicles, which yielded fertilizable oocytes in a woman with IGF-I deficiency treated with gonadotropins.<sup>169</sup> The growth factors assume an important, but perhaps not essential, role as facilitating agents. However,

successful pregnancy in a woman with IGF-I deficiency may indicate the greater importance of IGF-II.

## Key Points: Primate Ovarian Follicle

- FSH has multiple activities in the granulosa cell: stimulating aromatization of androgens to estrogens, increasing granulosa cell content of FSH and LH receptors, stimulating proliferation of granulosa cells, and producing autocrine-paracrine factors, especially activin and inhibin.
- In the granulosa of the early follicular phase, activin augments FSH activities: FSH receptor expression, aromatization, inhibin/activin production, and LH receptor expression. In the theca, activin suppresses androgen production, allowing the emergence of an estrogen-dominant microenvironment.
- Later in the follicular phase, inhibin enhances LH stimulation of androgen synthesis in the theca to provide substrate for aromatization to estrogen in the granulosa, making available the large amount of estrogen necessary for local follicular actions and to trigger the LH surge.
- Inhibin B is secreted by the granulosa cells into the circulation, where it acts in a classic endocrine fashion to suppress FSH secretion by the pituitary gland, an important method to ensure the dominance of a single follicle.
- With the appearance of LH receptors, inhibin production by the granulosa is maintained as it comes under the control of LH.
- Late in the follicular phase, final follicular maturation to yield the most favorable level of steroidogenesis and an oocyte with the best viability requires the presence of a threshold level of LH.
- All functions are modulated by an army of growth factors, and IGF-II may be especially important.

# The Preovulatory Follicle

Granulosa cells in the preovulatory follicle enlarge and acquire lipid inclusions while the theca becomes vacuolated and richly vascular, giving the preovulatory follicle a hyperemic appearance. The oocyte proceeds in meiosis, approaching completion of its reduction division.

Approaching maturity, the preovulatory follicle produces increasing amounts of estrogen. During the late follicular phase, estrogens rise slowly at first, then rapidly, reaching a peak approximately 24–36 hours prior to ovulation.<sup>210</sup> The onset of the LH surge occurs when the peak levels of estradiol are achieved.<sup>211</sup> In providing the ovulatory stimulus to the selected follicle, the LH surge seals the fate of the remaining follicles, with their lower estrogen and FSH content, by further increasing androgen superiority.

Acting through its own receptors, LH promotes luteinization of the granulosa in the dominant follicle, resulting in the production of progesterone. The LH receptor, once expressed, inhibits further cell growth and focuses the cell's energy on steroidogenesis (these actions are enhanced by IGF).<sup>212</sup> An increase in progesterone can be detected in the venous effluent of the ovary bearing the preovulatory follicle as early as day 10 of the cycle.<sup>77</sup> This small but significant increase in the production of progesterone in the preovulatory period has immense physiologic importance. Prior to the emergence of this follicular progesterone, the circulating levels of progesterone are of adrenal origin.<sup>213</sup>

Progesterone receptors begin to appear in the granulosa cells of the dominant follicle in the periovulatory period.<sup>88</sup> The traditional view has been that progesterone receptors are expressed in response to estrogen through an estrogen-receptor-mediated mechanism; however, this is not the case. Experimental data in the monkey provide excellent evidence that LH stimulates progesterone receptor expression in the granulosa cells.<sup>214</sup> In vitro data with human cells suggest that the preovulatory progesterone and progesterone receptor expression directly inhibit granulosa cell mitosis, probably explaining the limitation of granulosa cell proliferation as these cells gain LH receptors.<sup>215</sup>

Progesterone affects the positive feedback response to estrogen in both a time- and dose-dependent manner. When introduced after adequate estrogen priming, progesterone facilitates the positive feedback response of estrogen by direct action at the level of the pituitary, and in the presence of subthreshold levels of estradiol, it can induce a characteristic LH surge.<sup>216,217</sup> This ability of progesterone to induce an LH surge can explain the surprising onset of ovulation occasionally observed in an anovulatory, amenorrheic woman following administration of a progestin challenge. However, when

administered before the estrogen stimulus, or in high doses (achieving a blood level >2 ng/mL), progesterone blocks the midcycle LH surge.

Thus, appropriately low levels of progesterone derived from the maturing follicle contribute to the precise synchronization of the midcycle surge. In addition to its facilitator action on LH, progesterone at midcycle is also responsible for the FSH surge.<sup>217</sup> This action of progesterone can be viewed as a further step in ensuring completion of FSH action on the preovulatory follicle, especially making sure that a full complement of LH receptors is in place in the granulosa layer. In certain experimental situations, incremental estradiol alone can elicit simultaneous surges of LH and FSH, suggesting that progesterone certainly enhances the effect of estradiol but may not be obligatory for the occurrence of the midcycle gonadotropin surge.<sup>218</sup> Nevertheless, blockade of midcycle progesterone synthesis or activity in the monkey impaired the processes of ovulation and luteinization.<sup>219</sup> These actions of estrogen and progesterone in modulating gonadotropin release require the presence and action of GnRH.

The preovulatory period is associated with a rise in plasma levels of 17-hydroxyprogesterone (17-OHP). This steroid precursor does not appear to have a role in cycle regulation, and its appearance in the blood simply represents the secretion of an intermediate product. The preovulatory rise in 17-OHP reflects LH stimulation of the P450<sub>scc</sub> and P450<sub>c17</sub> enzymes that are critical for the production of androgens by the theca, which then get aromatized to estrogen by the granulosa. After ovulation, some of the theca cells become luteinized as part of the corpus luteum and lose the ability to express P450<sub>c17</sub>. Other luteinized theca cells retain P450<sub>c17</sub> activity and are believed to continue to produce androgens for aromatization to estrogens.

For the lesser follicles that fail to achieve full maturity and undergo atresia, the adjoining theca returns to its original role as a component of the ovarian stromal tissue, retaining, however, an ability to respond to LH with P450 activity and steroid production. Because the hormonal products of theca tissue are androgens, the increase in stromal tissue in the late follicular phase is associated with a rise in circulating androgen levels at midcycle, when a 15% increase in androstenedione and a 20% increase in testosterone levels can occur.<sup>220</sup> This response is enhanced by the late follicular phase rise in inhibin, known to augment LH stimulation of androgen production in theca cells.

Increasing androgen production in the preovulatory stage in the cycle may serve two purposes: (1) a local role within the ovary to enhance the process of atresia of the lesser follicles and (2) a systemic effect to stimulate libido nearing the time of ovulation.

Intraovarian androgens accelerate granulosa cell death and follicular atresia. The specific mechanism for this action is unclear, although it is attractive to suspect an

interference with estrogen and the autocrine-paracrine factors in enhancing FSH activity. Therefore, androgens may play a regulatory role in ensuring that only a dominant follicle reaches the point of ovulation.

It is well known that libido can be stimulated by androgens. If the midcycle rise in androgens affects libido, then an increase in sexual activity should coincide with this rise. Early studies failed to demonstrate a consistent pattern in coital frequency in women because of the effect of male partner initiation. If only sexual behavior initiated by women is studied, a peak in female-initiated sexual activity is seen during the ovulatory phase of the cycle.<sup>221</sup> The coital frequency of married couples has also been noted to increase at the time of ovulation.<sup>222</sup> Therefore, the midcycle rise in androgens may serve to increase sexual activity at the time most likely to achieve pregnancy.

## Key Points: Preovulatory Follicle

- Estrogen production becomes sufficient to achieve and maintain peripheral threshold concentrations of estradiol that are required to induce the LH surge.
- Acting through its receptors, LH initiates luteinization and progesterone production in the granulosa layer.
- The preovulatory rise in progesterone facilitates the positive feedback action of estrogen at the level of pituitary, which results in the LH surge. Preovulatory rise in progesterone may also be required to induce the midcycle FSH peak.
- A midcycle increase in local and peripheral androgens occurs, derived from the theca tissue of the lesser, unsuccessful follicles.

# OVULATION

The preovulatory follicle, through the elaboration of estradiol, provides its own ovulatory stimulus. Considerable variation in timing exists from cycle to cycle, even in the same woman. A reasonable and accurate estimate places ovulation approximately 10–12 hours after the LH peak and 24–36 hours after peak estradiol levels are attained (**Figure 5.12**).<sup>210,223</sup> The onset of the LH surge appears to be the most reliable indicator of impending ovulation, occurring 34–36 hours prior to follicle rupture.<sup>224</sup> A threshold of LH concentration must be maintained for 14–27 hours in order for full maturation of the oocyte to occur.<sup>225</sup> Usually, the LH surge lasts 48–50 hours.<sup>224</sup>

**FIGURE 5.12**

Over recent decades, increasing utilization of in vitro fertilization in infertility

management has allowed clarity in our understanding of the timeline of ovarian events following an induced LH surge. Spontaneous LH surge tends to occur at approximately 3 A.M., beginning between midnight and 8:00 A.M. in over two-thirds of women.<sup>98</sup> Seasonal variation in timing of LH surge is recognized.<sup>226</sup> Ovulation occurs primarily in the morning during spring, and primarily in the evening during autumn and winter. From July to February in the Northern Hemisphere, about 90% of women ovulate between 4 and 7 P.M.; during Spring, 50% of women ovulate between midnight and 11 A.M.

Most of the studies have concluded that ovulation occurs more frequently (about 55% of the time) from the right ovary compared to the left. Furthermore, oocytes from the right ovary are suggested to have a higher potential for pregnancy compared to those from the left side.<sup>227</sup> The side of ovulation does not affect cycle characteristics, but cycles with short follicular phases tend to be followed by contralateral ovulation, and ovulation occurs randomly following cycles with a long follicular phase.<sup>228,229</sup> Ovulation alternating between the two ovaries predominates in younger women, but after 30 years of age, ovulations occur more frequently from the same ovary; however, throughout the reproductive years, more ovulations occur from the right ovary.<sup>229</sup> Contralateral ovulation favors pregnancy more than ipsilateral ovulation, and ipsilateral ovulation increases with increasing age and decreasing fertility.<sup>230</sup>

The gonadotropin surge initiates a cascade of events that ultimately lead to ovulation, the physical release of the oocyte, and its cumulus mass of granulosa cells.<sup>231</sup> Ovulation is not an explosive event; therefore, a complex series of changes must occur, which cause the final maturation of the oocyte and the decomposition of the collagenous layer of the follicular wall with its subsequent breakdown followed by release of the follicular contents.<sup>232</sup>

The LH surge initiates the resumption of meiosis in the oocyte (meiosis is not completed until after the sperm has entered and the second polar body is released), luteinization of granulosa cells and progesterone production, expansion of the cumulus, and the synthesis of prostaglandins and other eicosanoids essential for follicle rupture. Premature oocyte maturation and luteinization are prevented by local factors.

An LH-induced increase in cyclic AMP occurs within the follicle just prior to ovulation. Cyclic AMP is transferred from the granulosa cells to the oocyte via the gap junction network, and thus a reduction in cyclic AMP occurs when LH causes a breakdown of the gap junctions. This results in a decrease in the local inhibitory action of OMI and luteinization inhibitor (LI). The OMI originates from granulosa cells, and its activity depends upon an intact cumulus oophorus. LI may be endothelin-1, a product of vascular endothelial cells.<sup>190</sup> Locally produced activin suppresses progesterone production by the luteal cells, providing yet another means of preventing premature

luteinization.<sup>233,234</sup> The propagation of LH-induced changes throughout the follicle depends on growth factors and their receptors, especially members of the EGF-like family, specifically LH-induced factors named amphiregulin, epiregulin, and betacellulin.<sup>235</sup> Disruption of this pathway interferes with oocyte resumption of meiosis and ovulation.

There is abundant evidence that the oocyte exerts control over granulosa functions, affecting both metabolism and proliferation through the secretion of proteins in the TGF- $\beta$  family.<sup>49,236,237,238,239</sup> These proteins include inhibin, activin, AMH, BMPs, and GDF9, which must be secreted in their active forms after processing of precursor proteins by proteases. The production of the active proteins is regulated by an interaction of the signaling proteins from the oocyte and the granulosa cells, determined by changing responsiveness to FSH as the components of the ovarian follicle develop and differentiate.<sup>240</sup> The differentiation and maintenance of the cumulus cells from the preantral granulosa cells are under the direction of the oocyte.<sup>241,242</sup>

The cumulus oophorus differs from other granulosa cells, lacking in LH receptors and progesterone production; FSH-induced LH receptor expression is suppressed in the contiguous granulosa cells by the oocyte. The oocyte enables cumulus cells to respond to the gonadotropin-induced physical and biochemical changes just before ovulation. The local factors that prevent premature oocyte maturation and luteinization are probably under control of the oocyte. One mediator of this control system is nitric oxide, which maintains the gap junction system of communication.<sup>243</sup> Nitric oxide resists LH-induced resumption of oocyte meiosis and breakdown of the gap junction network until the massive LH surge overcomes this resistance and communication between the oocyte and the follicular cells is interrupted.

With the LH surge, levels of progesterone in the follicle continue to rise, up until the time of ovulation. The progressive rise in progesterone may act to terminate the LH surge as a negative feedback effect is exerted at higher concentrations. In addition to its central effects, progesterone increases the distensibility of the follicle wall. A change in the elastic properties of the follicular wall is necessary to accommodate the rapid increase in follicular fluid volume, which occurs just prior to ovulation, unaccompanied by any significant change in intrafollicular pressure. FSH, LH, and progesterone stimulate the activity of proteolytic enzymes, resulting in digestion of collagen in the follicular wall and increasing its distensibility. The escape of the ovum is associated with degenerative changes of the collagen in the follicular wall so that just prior to ovulation the follicular wall becomes thin and stretched. The gonadotropin surge also releases histamine, and histamine alone can induce ovulation in some experimental models.

The proteolytic enzymes are activated in an orderly sequence.<sup>244</sup> The granulosa and

theca cells produce plasminogen activator in response to the gonadotropin surge. Plasminogen is activated by either of two plasminogen activators: tissue-type plasminogen activator and urokinase-type plasminogen activator. These activators are encoded by separate genes and are also regulated by inhibitors.

Plasminogen activators produced by granulosa cells activate plasminogen in the follicular fluid to produce plasmin. Plasmin, in turn, generates active collagenase to disrupt the follicular wall. In rat models, plasminogen activator synthesis is triggered by LH stimulation (as well as growth factors and FSH), while plasminogen inhibitor synthesis is decreased.<sup>245</sup> Thus, before and after ovulation, the inhibitor activity is high, while just at ovulation, activator activity dominates and the inhibitors are at a nadir. A coordinated molecular regulation of these factors is necessary for the complex sequence of events result in ovulation. Plasminogen activator synthesis in granulosa cells is expressed only at a precise preovulatory stage in response to LH. The inhibitor system, which is very active in the theca and interstitial cells, prevents inappropriate activation of plasminogen and disruption of growing follicles. The inhibitor system has been demonstrated to be present in human granulosa cells and preovulatory follicular fluid and to be responsive to paracrine substances, EGF and interleukin-1 $\beta$ .<sup>246,247,248</sup> Physical migration of the preovulatory follicle to the surface of the ovary is an important step in that the exposed surface of the follicle is now prone to rupture because it is now separated from cells rich in the plasminogen inhibitor system. Ovulation is the result of proteolytic digestion of the follicular apex, a site called the stigma. The matrix metalloproteinase (MMP) enzymes and their endogenous inhibitors, tissue inhibitors of metalloproteinases (TIMPs), are increased in response to LH and progesterone and are also involved in this event.<sup>249</sup>

In the rat, the gene that encodes for plasminogen activator contains a promoter region, which has several sequences for known transcription factors, such as the cyclic AMP-responsive element (CRE). The activation of this CRE (which involves a CRE-binding protein) requires FSH stimulation. Thus, both gonadotropins appear to be involved in this process. Studies in the monkey indicate that the activation of plasminogen activator is mediated by prostaglandin E<sub>2</sub>.<sup>250</sup>

Prostaglandins E<sub>2</sub> and F<sub>2 $\alpha$</sub> , but mainly prostaglandin E<sub>2</sub>, and other eicosanoids (especially HETEs, hydroxyeicosatetraenoic acids) increase markedly in the preovulatory follicular fluid in response to the LH surge, reaching a peak concentration at ovulation.<sup>251,252,253</sup> Prostaglandin synthesis is stimulated by interleukin-1 $\beta$ , implicating this cytokine in ovulation.<sup>254</sup> Inhibition of cyclooxygenase-2 (COX-2)-mediated synthesis of these products from arachidonic acid blocks follicle rupture without affecting the other LH-induced processes of luteinization and oocyte maturation.<sup>255,256,257</sup>

Prostaglandins act to free proteolytic enzymes within the follicular wall; HETEs may promote angiogenesis and hyperemia (an inflammatory-like response).<sup>250,252,258</sup> LH and PGE<sub>2</sub> both activate the EGF-like signaling pathway that leads to cumulus expansion and resumption of oocyte meiosis.<sup>259</sup> Prostaglandins may also contract smooth muscle cells that have been identified in the ovary, thereby aiding the extrusion of the oocyte-cumulus cell mass from the ruptured follicle (**Figure 5.13**). **This ovulatory role of prostaglandins is so well demonstrated that infertility patients should be advised to avoid the use of drugs that inhibit prostaglandin synthesis.**<sup>257,260,261</sup>

**FIGURE 5.13**

A large number of leukocytes enter the follicle prior to ovulation. Neutrophils are a prominent feature in the theca compartment of both healthy and atretic antral follicles.<sup>262</sup> The accumulation of leukocytes is mediated by chemotactic mechanisms of the interleukin system.<sup>263</sup> However, ovulation does not depend on these invading immune cells for the expression of the inflammatory-like response associated with ovulation. Ovarian follicular cells themselves in response to LH express the genes involved with immune responses, resulting in the release of the host of products that affect the cellular reactions associated with ovulation and the remodeling process that leads to the corpus luteum.<sup>264</sup>

Estradiol levels plunge as LH reaches its peak. This may be a consequence of LH-mediated down-regulation of its own receptors on the periovulatory follicle. Theca tissue derived from healthy antral follicles exhibits marked suppression of steroidogenesis when exposed to high levels of LH, whereas exposure over a low range

stimulates steroid production. The low midcycle levels of progesterone exert an inhibitory action on further granulosa cell multiplication, and the drop in estrogen may also reflect this local follicular role for progesterone. Finally, estrogen can exert an inhibitory effect on P450c17, a direct action on the gene that is not receptor mediated.

The granulosa cells that are attached to the basement membrane and enclose the follicle become luteal cells. The cumulus granulosa cells are in immediate proximity and are attached to the oocyte. In the mouse, the cumulus cells are metabolically linked to the oocyte and respond to the FSH surge by secreting hyaluronic acid that disperses the cumulus cells prior to ovulation. This hyaluronic acid response depends upon maintenance of the link with the oocyte, indicating the secretion of a supporting factor. The oocyte further secretes factors that promote granulosa cell proliferation and maintain the structural organization of the follicle.<sup>265</sup> While FSH stimulates mural granulosa cell proliferation, its effect on the cumulus cells is the opposite; proliferation of the cumulus cells is suppressed by FSH.

The FSH peak, partially and perhaps totally dependent on the preovulatory rise of progesterone, has several functions. Plasminogen activator production is sensitive to FSH as well as LH. Expansion and dispersion of the cumulus cells allows the oocyte-cumulus cell mass to become free-floating in the antral fluid just before follicle rupture. The process involves the deposition of a hyaluronic acid matrix, the synthesis of which is stimulated by FSH. Finally, an adequate FSH peak ensures an adequate complement of LH receptors on the granulosa layer. It should be noted that a shortened or inadequate luteal phase is observed in cycles when FSH levels are low or selectively suppressed at any point during the follicular phase.

The mechanism that shuts off the LH surge is unknown. Within hours after the rise in LH, there is a precipitous drop in the plasma estrogens. The decrease in LH may be due to a loss of the positive stimulating action of estradiol or to an increasing negative feedback of progesterone. The abrupt fall in LH levels may also reflect a depletion in pituitary LH content due to down-regulation of GnRH receptors, either by alterations in GnRH pulse frequency or by changes in steroid levels.<sup>266,267</sup> LH may further be controlled by “short” negative feedback of LH upon the hypothalamus. Direct LH suppression of hypothalamic-releasing hormone production has been demonstrated. However, in the sheep, the LH surge ends before the GnRH signal begins to decline.<sup>268</sup> Another possibility has been suggested: a so-called gonadotropin surge-inhibiting factor (GnSIF) originating in the ovary.<sup>269,270</sup> GnSIF is produced in granulosa cells under the control of FSH and reaches a peak level in the circulation in the midfollicular phase. Its major role is believed to be prevention of premature luteinization. It is likely that a combination of all these influences causes the rapid decline in gonadotropin secretion.

The many contributions of progesterone to ovulation are highlighted by the results of

experiments in the monkey. Suppression of steroidogenesis at midcycle prevented ovulation, but not the resumption of oocyte meiosis.<sup>219</sup> Administration of a progestin agonist to this experimental model restored ovulation. In experimental models of mice, knockout of progesterone receptor gene results in failure to ovulate, although oocyte maturation and luteinization are not impeded.<sup>271,272</sup> These experiments indicate that progesterone receptor-A is the critical isoform necessary for normal ovulation.

An adequate gonadotropin surge does not ensure ovulation. The follicle must be at the appropriate stage of maturity for it to respond to the ovulating stimulus. In the normal cycle, gonadotropin release and final maturation of the follicle coincide because the timing of the gonadotropin surge is controlled by the level of estradiol, which in turn is a function of follicular growth and maturation. Therefore, gonadotropin release and morphologic maturity of the follicle are usually coordinated and coupled in time. In the majority of spontaneous cycles in humans, the requisite feedback relationships in this system allow only a single follicle to reach the point of ovulation. Nonidentical multiple births may, in part, reflect the random statistical chance of more than one follicle fulfilling all the requirements for simultaneous ovulation.

## Key Points: Ovulatory Events

- The LH surge initiates the continuation of meiosis in the oocyte, luteinization of the granulosa, and synthesis of progesterone and prostaglandins within the follicle.
- Progesterone enhances the activity of proteolytic enzymes responsible, together with prostaglandins, for digestion and rupture of the follicular wall.
- The progesterone-influenced midcycle rise in FSH serves to free the oocyte from follicular attachments, to convert plasminogen to the proteolytic enzyme, plasmin, and to ensure that sufficient LH receptors are present to allow an adequate normal luteal phase.

# THE LUTEAL PHASE

---

Before rupture of the follicle and release of the ovum, the granulosa cells begin to increase in size and assume a characteristic vacuolated appearance associated with the accumulation of a yellow pigment, lutein, which lends its name to the process of luteinization and the anatomical subunit, the corpus luteum. During the first 3 days after ovulation, the granulosa cells continue to enlarge. In addition, theca lutein cells may differentiate from the surrounding theca and stroma to become part of the corpus luteum. Dissolution of the basal lamina and rapid vascularization and luteinization make it difficult to distinguish the origin of specific cells.

Capillaries begin to penetrate into the granulosa layer after the cessation of the LH surge, reach the central cavity, and often fill it with blood; the corpus luteum at this stage has also been referred to as corpus hemorrhagicum.<sup>273</sup> Angiogenesis is an important feature of the luteinization process, a response to LH that is mediated by factors such as VEGF and angiopoietins produced in luteinized granulosa cells.<sup>174,175,274</sup> In the early luteal phase, angiogenesis accompanies an increased expression of VEGF, with stabilization of vessel growth maintained by angiopoietin-1 binding to the endothelial Tie-2 receptor.<sup>178,275</sup> With regression of the corpus luteum, VEGF and angiopoietin-1 expressions decrease allowing greater occupancy of the Tie-2 receptor by angiopoietin-2, leading to the vascular breakdown that accompanies luteolysis.

By day 8 or 9 after ovulation, a peak of vascularization of the corpus luteum is reached, associated with peak circulating levels of progesterone and estradiol. The corpus luteum has one of the highest blood flows per unit mass in the body. On occasion, this ingrowth of vessels and bleeding will result in unchecked hemorrhage and an acute surgical emergency that can present at any time during the luteal phase. Indeed, excessive bleeding following ovulation can be a real risk for women who are anticoagulated; medical suppression of ovulation, such as through use of a hormonal contraceptive (pill or patch or injection or vaginal ring) should be considered for premenopausal women who are prescribed blood thinners in an effort to minimize the risk of uncontrolled hemorrhage consequent to an otherwise innocuous event of ovulation.

Normal luteal function requires optimal preovulatory follicular development. Suppression of FSH during the follicular phase is associated with lower preovulatory estradiol levels, depressed midluteal progesterone production, and a decrease in luteal cell mass.<sup>276</sup>

Experimental evidence supports the contention that the accumulation of LH receptors during the follicular phase predetermines the extent of luteinization and the subsequent functional capacity of the corpus luteum. Successful conversion of the

avasascular granulosa of follicular phase to the vascularized luteal tissue is also of importance. Because steroid production is dependent upon LDL transport of cholesterol, vascularization of the granulosa layer is essential to allow circulating LDL cholesterol to reach the luteal cells to provide sufficient substrate for progesterone production. One of the important jobs for LH is to regulate LDL receptor binding, internalization, and postreceptor processing; the induction of LDL receptor expression occurs in granulosa cells during the early stages of luteinization in response to the midcycle LH surge.<sup>277,278</sup> This mechanism supplies cholesterol to the mitochondria for utilization as the basic building block in steroidogenesis (**Figure 5.14**).

**FIGURE 5.14**

The life span and steroidogenic capacity of the corpus luteum are dependent on continued tonic LH secretion. Studies in hypophysectomized women have demonstrated that normal corpus luteum function requires the continuous presence of small amounts of LH.<sup>279</sup> This dependence of the corpus luteum on LH is further supported by the prompt luteolysis that follows the administration of GnRH agonists or antagonists or withdrawal of GnRH when ovulation has been induced by the administration of pulsatile GnRH.<sup>280,281</sup> There is no evidence that other luteotropic hormones, such as prolactin, play a role in primates during the menstrual cycle.<sup>282</sup>

The corpus luteum is a complex and heterogeneous structure. Besides the luteal cells, also present are endothelial cells, leukocytes, and fibroblasts. These nonsteroidogenic cells form the bulk, about 70%, of the total cell population of the corpus luteum. The leukocyte population of the corpus luteum contributes several

cytokines, including IL1- $\beta$  and TNF- $\alpha$ .<sup>283</sup> The many different leukocytes in the corpus luteum are also a rich resource for cytolytic enzymes, prostaglandins, and growth factors involved in processes of angiogenesis, steroidogenesis, and luteolysis.

The corpus luteum is one of the best examples of communication and cross talk in biology. For example, endothelial cells contribute vasoactive compounds, and, in turn, steroidogenic cells contribute factors that influence angiogenesis. The harmonious function of this system is in inverse proportion to its complexity.

Endothelial cells constitute about 35% of the cells in a mature corpus luteum.<sup>284</sup> As elsewhere in the body, endothelial cells participate in immune reactions and endocrine functions. The endothelial cells are a source of endothelin-1, expressed in response to changes in blood flow, blood pressure, and oxygen tension. Studies have indicated that endothelin-1 may be a mediator of luteolysis.<sup>285,286</sup> Inhibition of VEGF prevents luteal angiogenesis.<sup>287</sup>

Even the luteal cell population is not homogeneous, being composed of at least two morphologically and functionally distinct cell types, large and small cells.<sup>288</sup> Some believe that the large cells are derived from granulosa cells and the small cells from theca cells. The small cells are the most abundant. Despite the fact that greater steroidogenesis takes place in the large cells, it is the small cells that contain LH and hCG receptors.<sup>289,290</sup> The absence of LH/hCG receptors on the large cells, presumably derived from granulosa cells that acquire LH receptors in the late follicular phase, requires explanation. Perhaps large cells are functioning at a maximal level with receptors totally occupied and functional, or because of intercellular communication through gap junctions, the large cells do not require direct gonadotropin support. Thus, the large cells can be functioning at a high level, under the control of regulating factors that originate in the small cells in response to gonadotropins. In addition, the overall function is influenced by autocrine-paracrine signals from the endothelial and immune cells.

Large luteal cells produce peptides (oxytocin, relaxin, inhibin, GnRH, growth factors, and prostaglandins) and are more active in steroidogenesis, with greater aromatase activity and more progesterone synthesis than the small cells.<sup>291,292</sup> Human granulosa cells (already luteinizing, when recovered from patients undergoing in vitro fertilization) contain minimal amounts of P450c17 mRNA. This is consistent with the two-cell explanation, which assigns androgen production (and P450c17) to the cells derived from theca. With luteinization, expression of StAR, P450scc, and 3- $\beta$  hydroxysteroid dehydrogenase markedly increases to account for the increasing production of progesterone; continued expression of these essential factors requires LH.<sup>293,294,295</sup> The aromatase system (P450arom), of course, continues to be active in the luteinized granulosa cells.

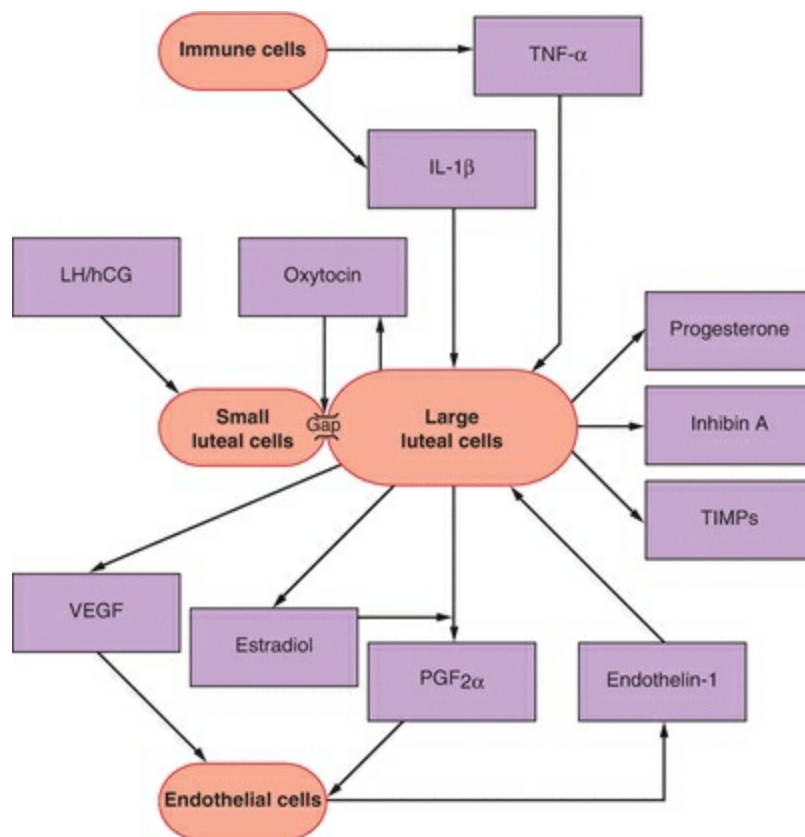

Progesterone levels normally rise sharply after ovulation, reaching a peak approximately 8 days after the LH surge. Initiation of new follicular growth during the luteal phase is further inhibited by the low levels of gonadotropins due to the negative feedback actions of estrogen, progesterone, and inhibin A. With the appearance of LH receptors on the granulosa cells of the dominant follicle and the subsequent transformation of the ovulatory follicle into a corpus luteum, inhibin expression comes under the control of LH, and expression changes from inhibin B to inhibin A.<sup>126,289,296</sup> The circulating levels of inhibin A rise in the late follicular phase to reach a peak level at the midluteal phase.<sup>33,127,188</sup> Inhibin A, therefore, contributes to the suppression of FSH to nadir levels during the luteal phase, and to the changes at the luteal-follicular transition. There is a wave of small follicle growth during the luteal phase, probably in response to the FSH surge at midcycle; however, the luteal phase FSH suppression ensures that a mature, large follicle will not emerge.<sup>297,298</sup>

The secretion of progesterone and estradiol during the luteal phase is episodic, and the changes correlate closely with LH pulses.<sup>100,299</sup> Because of this episodic secretion, relatively low midluteal progesterone levels, which some inappropriately believe are indicative of an inadequate luteal phase, can be found in the course of totally normal luteal phases. The corpus luteum of the primate is unique in its production of estrogen; however, unlike the follicular phase, luteal estrogen synthesis is dependent on LH. Within the corpus luteum, progesterone acts locally to enhance the LH-induced luteinization of granulosa cells, to support its own LH-stimulated synthesis, and to inhibit apoptosis.<sup>300,301,302</sup>

In the normal cycle, the time period from the LH midcycle surge to menses is consistently close to 14 days. For practical purposes, luteal phases lasting between 11 and 17 days can be considered normal.<sup>303</sup> The incidence of short luteal phases is about 5–6%. It is well known that significant variability in cycle length among women is due to the varying number of days required for follicular growth and maturation in the follicular phase. The luteal phase cannot be extended indefinitely even with progressively increasing LH exposure, indicating that the demise of the corpus luteum is due to an active luteolytic mechanism.

The corpus luteum rapidly declines 9–11 days after ovulation, and the mechanism of the degeneration remains unknown. In certain nonprimate mammalian species, a luteolytic factor originating in the uterus and stimulated by estrogen (prostaglandin  $F_{2\alpha}$ ) regulates the life span of the corpus luteum. No definite luteolytic factor has been identified in the primate menstrual cycle, and removal of the uterus in the primate does not affect the ovarian cycle. The morphologic regression of luteal cells may be induced by the estradiol produced by the corpus luteum.<sup>304</sup> A premature elevation of circulating

estradiol levels in the early luteal phase results in a prompt fall in progesterone concentrations, and direct injections of estradiol into the ovary bearing the corpus luteum induce luteolysis, while similar treatment of the contralateral ovary produces no effect.<sup>305</sup> This action of estrogen may be mediated by nitric oxide. Nitric oxide stimulates luteal prostaglandin synthesis and decreases progesterone production.<sup>306</sup> Nitric oxide and hCG have opposing actions in the human corpus luteum; nitric oxide is associated with apoptosis of luteal cells.<sup>307</sup> The final signal for luteolysis, however, is prostaglandin  $F_{2\alpha}$  that is produced within the ovary in response to the locally synthesized luteal estrogen (**Figure 5.15**).<sup>305,308</sup> These relationships are supported by genome studies delineating prostaglandin  $F_{2\alpha}$  and hCG effects on gene expression.<sup>309</sup> The early luteal phase in primates is dominated by intraluteal synthesis of the luteotropic prostaglandin,  $PGE_2$ ; late in the luteal phase, intraluteal prostaglandin synthesis shifts to  $PGF_{2\alpha}$ .<sup>292</sup>

**FIGURE 5.15**

There is another possible role for the estrogen produced by the corpus luteum. In view of the known estrogen requirement for the synthesis of progesterone receptors in the

endometrium, luteal phase estrogen may be necessary to allow the progesterone-induced changes in the endometrium after ovulation. Inadequate progesterone receptor content due to inadequate estrogen priming of the endometrium is an additional possible mechanism for subfertility; similarly, some early miscarriages (biochemical losses) may represent a form of luteal phase deficiency.

Experimental evidence indicates that the luteolytic effect of prostaglandin  $F_{2\alpha}$  is partially mediated by endothelin-1.<sup>285,286</sup> Prostaglandin  $F_{2\alpha}$  stimulates the synthesis of endothelin-1; endothelin-1 inhibits luteal steroidogenesis, and in turn, endothelin-1 stimulates prostaglandin production in luteal cells.<sup>310</sup> In addition, endothelin-1 stimulates the release of TNF- $\alpha$ , a growth factor known to induce apoptosis; members of the TNF family, including their receptors, are expressed in the corpus luteum and their expression peaks at the time of luteolysis.<sup>311,312</sup>

The corpus luteum involves cellular interactions that require cell-to-cell contact. Gap junctions are a prominent feature of luteal cells, just as they are in the follicle before ovulation. When the various cell types of the corpus luteum are studied together, the performance is different compared with studies of single-cell types, greater steroidogenesis more closely approximating the total function of the corpus luteum.<sup>313</sup> It is believed that communication and exchange of signals takes place through the gap junction structures, explaining how the small cells respond to LH and hCG, but the large cells are the main site of steroidogenesis. Regulation of the gap junction system is influenced by oxytocin, a paracrine role for oxytocin in the corpus luteum.<sup>25</sup>

When ovulation is induced by the administration of GnRH, normal luteal phase demise occurs despite no change in treatment, arguing against a change in LH as the dominant luteolytic mechanism. In addition, LH receptor-binding affinity does not change throughout the luteal phase. Thus, the decline in steroidogenesis must reflect deactivation of the system (producing a refractoriness of the corpus luteum to LH), perhaps through the uncoupling of the G protein adenylate cyclase system. This is supported by studies in the monkey in which alteration in LH pulse frequency or amplitude did not provoke luteolysis.<sup>314</sup>

The process of luteolysis involves proteolytic enzymes, especially the MMPs. These enzymes are held under inhibitory control by TIMPs secreted by the steroidogenic luteal cells, and because TIMP levels do not change in luteal tissue, luteolysis is believed to involve a direct increase in MMP expression. An important part of the rescue mission for hCG is to prevent this increase in MMP expression.<sup>315</sup> hCG can increase TIMP production, and this, too, would inhibit MMP activity and luteolysis.<sup>316</sup> The source of MMPs is the fibroblast cell, and because luteal fibroblasts do not contain LH/hCG receptors, the release of MMPs in the regressing corpus luteum

must depend on another signal. One such signal can be locally produced activin-A that acts upon the fibroblasts to synthesize and release MMPs.<sup>317</sup> Emerging hCG from a pregnancy can inhibit this activin-A system by increasing follistatin, the glycopeptide that binds the activin. In addition, human ovary contains the complete IL-1 system, providing another source of cytolytic enzymes.

The survival of the corpus luteum is prolonged by the emergence of a new stimulus of rapidly increasing intensity, the hCG. Blastocysts grown in culture produce and secrete hCG, beginning days 7–8 after fertilization.<sup>318</sup> Messenger RNA for hCG can be found in 6- to 8-cell human embryos.<sup>319</sup> Because the 8- to 12-cell stage is achieved about 3 days after fertilization, it is believed that the human embryo begins to produce hCG before implantation when it can be detected in the mother as early as 6–7 days after ovulation. The embryo is capable, therefore, of preimplantation signaling, and higher levels of estradiol and progesterone can be measured in the maternal circulation even before maternal hCG is detectable, presumably because of stimulation of the corpus luteum by hCG delivered directly from the uterine cavity to the ovary (**Figure 5.16**).<sup>320</sup> Function of the corpus luteum is crucial during the first 7–9 weeks of pregnancy, and luteectomy early in pregnancy can precipitate miscarriage.<sup>321</sup> Similarly, early pregnancy loss in primates can be induced by injections of anti-hCG serum.<sup>322</sup> Rescue of the corpus luteum by rising hCG levels from an early pregnancy is associated with maintenance of the corpus luteal vascular system (not new vessel growth), a process that is dependent on the angiogenic factors VEGF and angiopoietin-2.<sup>177,178,275,323</sup>

**FIGURE 5.16**

Unlike the biphasic luteal pattern of circulating progesterone levels (a decrease after ovulation and then a new higher peak at the midluteal phase), mRNA levels for the two major enzymes involved in progesterone synthesis (cholesterol side-chain cleavage and 3 $\beta$ -hydroxysteroid dehydrogenase) are maximal at ovulation and decline throughout the luteal phase.<sup>323</sup> This suggests that the life span of the corpus luteum is established at the time of ovulation, and luteal regression is inevitable unless the corpus luteum is rescued by the hCG of pregnancy. **Therefore, primates have developed a system that requires rescue of the corpus luteum in contrast to lower animals that use a mechanism that actively causes the demise of the corpus luteum (luteolysis).**

## Key Points: Luteal Phase

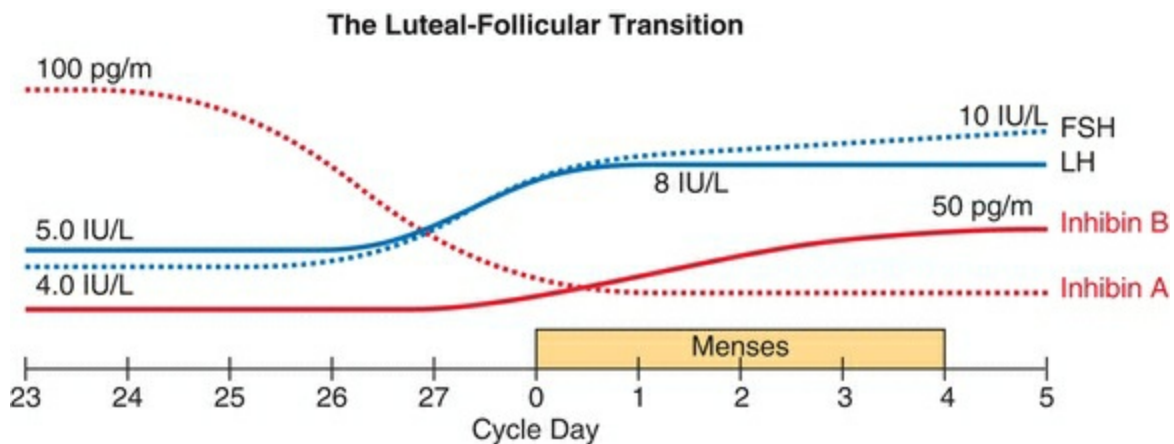

- Normal luteal function requires optimal preovulatory follicular development (especially adequate FSH stimulation) and continued tonic LH support.
- The early luteal phase is marked by active angiogenesis mediated by VEGF. New vessel growth is held in check by angiopoietin-1 working through its receptor Tie-2 on endothelial cells.
- Progesterone, estradiol, and inhibin A act centrally to suppress gonadotropins and new follicular growth during the luteal phase.
- Regression of the corpus luteum is associated with a decrease in VEGF and angiopoietin-1 expression and an increase in angiopoietin-2 activity and may involve the luteolytic action of its own estrogen production, mediated by an alteration in local prostaglandin and involving nitric oxide, endothelin, and other factors.
- In early pregnancy, hCG rescues the corpus luteum, maintaining luteal function until placental steroidogenesis is well established.

# THE LUTEAL-FOLLICULAR TRANSITION

The interval extending from the late luteal decline of estradiol and progesterone production to the selection of the dominant follicle for the ensuing cycle is a critical and decisive time, marked by the appearance of menses; equally important but less apparent are the hormone changes that initiate the next cycle. The critical factors include GnRH, FSH, LH, estradiol, progesterone, and inhibin.

Given the important role for FSH-mediated actions on the granulosa cells, it is appropriate that the recruitment of a new ovulating follicle is directed by a selective increase in FSH that begins approximately 2 days before the onset of menses (**Figure 5.17**).<sup>324,325,326,327</sup> Using a sensitive FSH bioassay, an increase in FSH bioactivity can be measured beginning as early as the midluteal phase.<sup>34</sup> There are at least two influential changes that result in this important increase in FSH: a decrease in the luteal steroids and inhibin and a change in GnRH pulsatile secretion.

**FIGURE 5.17**

Inhibin B, originating in the granulosa cells of the corpus luteum and now under the regulation of LH, reaches a nadir in the circulation at the midluteal period.<sup>188</sup> Inhibin A reaches a peak in the luteal phase, and, thus, may help to suppress FSH secretion by the pituitary to the lowest levels reached during a menstrual cycle.<sup>33,188</sup> The process of luteolysis, whatever the mechanism/s, with resulting demise of the corpus luteum, affects inhibin-A secretion as well as steroidogenesis. Administration of inhibin A to monkeys effectively suppresses circulating FSH.<sup>328</sup> Thus, an important suppressing influence on FSH secretion is removed from the anterior pituitary during the last days of the luteal phase. This selective action of inhibin on FSH (and not LH) is partly responsible for the greater rise in FSH seen during the luteal-follicular transition,

compared to the change in LH. Administration of recombinant (pure) FSH to gonadotropin-deficient women has demonstrated that the early growth of follicles requires FSH, and that LH is not essential during this period of the cycle.<sup>61,62</sup>

Inhibin-B levels begin to rise shortly after the increase in FSH (a consequence of FSH stimulation of granulosa cell secretion of inhibin) and reach peak levels about 4 days after the maximal increase in FSH.<sup>33,118,188</sup> Thus, suppression of FSH secretion during the follicular phase is an action exerted by inhibin B, whereas escape of FSH inhibition during the luteal-follicular transition is partly a response to decreasing inhibin A secretion by the regressing corpus luteum.

Circulating levels of activin increase before ovulation to a peak in the luteal phase; however, activin A is highly bound in the circulation, and it is not certain if it has an endocrine role.<sup>148,188</sup> Nevertheless, the timing is right for activin to contribute to the rise in FSH during the luteal-follicular transition. Activin enhances and follistatin suppresses GnRH activity. Evidence in vivo and in vitro indicates that gonadotropin response to GnRH requires activin activity.<sup>329</sup> Activin specifically acts synergistically with GnRH to stimulate gene expression in the pituitary for the FSH beta-subunit.<sup>330</sup>

The selective rise in FSH is also significantly influenced by a change in GnRH pulsatile secretion, previously strongly suppressed by the high estradiol and progesterone levels of the luteal phase exerting a negative feedback effect at the hypothalamus.<sup>104,331</sup> A progressive and rapid increase in GnRH pulses (as assessed by the measurement of LH pulses) occurs during the luteal-follicular transition.<sup>103</sup> From the midluteal peak to menses, there is a 4.5-fold increase in LH pulse frequency (and presumably GnRH) from approximately 3 pulses/24 hours to 14 pulses/24 hours.<sup>103</sup> During this time period, the mean level of LH increases approximately 2-fold, from approximately a mean of 4.8–8 IU/L. The increase in FSH is, as noted, greater than that of LH. FSH pulse frequency increases 3.5-fold from the midluteal period to the time of menses, and FSH levels increase from a mean of approximately 4 IU/L to as much as 15 IU/L.

An increase in GnRH pulse frequency has been associated with an initial selective increase in FSH in several experimental models, including the ovariectomized monkey with destruction of the hypothalamus. Treatment of hypogonadal women with pulsatile GnRH results first in predominance of FSH secretion (over LH). This experimental response and the changes during the luteal-follicular transition are similar to changes observed during puberty with a predominance of FSH as GnRH pulsatile secretion begins to increase.

The pituitary response to GnRH is also relevant in the luteal follicular transition period. Estradiol suppresses FSH secretion by its classic negative feedback

relationship at the pituitary level. The decrease in estradiol in the late luteal phase restores the capability of the pituitary to respond with an increase in FSH secretion.<sup>332</sup>

## Key Points: Luteal-Follicular Transition

- The demise of the corpus luteum results in a nadir in the circulating levels of estradiol, progesterone, and inhibin.
- The decrease in inhibin A removes a suppressing influence on FSH secretion in the pituitary.
- The decrease in estradiol and progesterone allows a progressive and rapid increase in the frequency of GnRH pulsatile secretion and removal of the pituitary from negative feedback suppression.
- The removal of inhibin A and estradiol and increasing GnRH pulses combine to allow greater secretion of FSH compared with LH, with an increase in the frequency of the episodic secretion.
- The rising FSH is instrumental in rescuing approximately a 70-day-old group of ready follicles from atresia, initiating a new wave of follicular recruitment, growth that is destined for attainment of dominance of a single follicle in the ensuing cycle.

# THE NORMAL MENSTRUAL CYCLE

Menstrual cycle length (duration between day 1 of menses to the 1st day of subsequent menses) is determined by the rate and the quality of follicular growth and development, and it is normal for the cycle length to vary in individual women.<sup>333,334</sup> Subtle alterations in cycle length are appreciated with advancing age, and cycle lengths are the shortest (with the least variability) in the late 30s, a time when subtle but real increases in FSH and decreases in inhibin are occurring (**Figure 5.18**).<sup>124,303,335,336,337,338</sup> This can be pictured as accelerated follicular growth (because of the changes in FSH and inhibin B). At the same time, fewer follicles grow per cycle as a woman ages.<sup>339</sup> Approximately 2–4 years prior to the final menstrual period (marking the end of reproductive phase and the onset of menopause), the cycles lengthen again. In the last 10–15 years before menopause, there is an acceleration of follicular loss.<sup>3</sup> This accelerated loss begins when the total number of follicles reaches approximately 25,000, a number reached in normal women at age 37–38. Eventually menopause occurs because the supply of follicles is near depleted.<sup>340</sup>

**FIGURE 5.18**

The changes in the later reproductive years reflect either lesser follicular competence as the better primordial follicles respond early in life, leaving the lesser follicles for later, or the fact that the total follicular pool is reduced in number (or both factors).<sup>341</sup> Arguing in favor of a role for a reduced follicular pool is the observation that follicular fluid obtained from preovulatory follicles of older women contains amounts of inhibins

A and B that are similar to that measured in follicular fluid from young women.<sup>342</sup>

Variations in menstrual flow and cycle length are common at the extremes of reproductive age, during the early teenage years and in the years preceding the menopause. The prevalence of anovulatory cycles is highest in women under age 20 and over age 40.<sup>343,344</sup> Menarche is typically followed by approximately 5–7 years of relatively long cycles that gradually decrease in length and become more regular. Although menstrual cycle characteristics generally do not change appreciably during the reproductive years,<sup>344</sup> overall cycle length and variability slowly decrease. On average, mean cycle length and variability reach their lows at about age 40–42.<sup>334,345</sup> Over the subsequent 8–10 years before the menopause, the trend is reversed; both average cycle length and variability steadily increase as ovulations become less regular and more infrequent.<sup>333,334,346,347</sup> Mean cycle length is greater in women at the extremes of body mass and composition; both high and low body mass index are associated with an increased mean cycle length.<sup>348,349</sup>

In general, variations in cycle length reflect differences in the length of the follicular phase of the ovarian cycle. Women who have a 25-day cycle ovulate on or about cycle day 10–12, and those with a 35-day cycle ovulate approximately 10 days later. Within a few years after menarche, the luteal phase becomes extremely consistent (13–15 days) and remains so until the perimenopause.<sup>332,333</sup> At age 25, over 40% of cycles are between 25 and 28 days in length; from age 25 to 35, over 60% are. Although it is the most often reported intermenstrual interval, only approximately 15% of cycles in reproductive-aged women are actually 28 days in length. Less than 1% of women have a regular cycle lasting less than 21 days or more than 35 days.<sup>350</sup> Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles.<sup>345</sup>

# Conception - Sperm and Egg Transport, Fertilization, Implantation and Early Embryogenesis

Among his many accomplishments, Galileo Galilei gave to science, in 1609, two important instruments, the telescope and the microscope.<sup>1</sup> Anton van Leeuwenhoek of Delft, Holland, was fascinated by Galileo's microscope. Leeuwenhoek was a draper and had no medical or scientific training, yet he became a fellow of the Royal Society of London to which he submitted 375 scientific papers. In 1677, Leeuwenhoek described (fairly accurately) the "little animals of the sperm." It was another 198 years before Wilhelm August Oscar Hertwig, in Germany, demonstrated the union of sperm and egg, fertilization, in the sea urchin.

The coming together of sperm and egg is one of the essentials of reproduction; however, the remote site of this event and the enclosed origins of the participants made fertilization a difficult subject for study. This changed with the advent of in vitro fertilization. Greater understanding of sperm and egg development and union is one of the major benefits of the clinical application of the assisted reproductive technologies. This chapter examines the mechanisms involved in sperm and egg transport, fertilization, and implantation.

# SPERM TRANSPORT

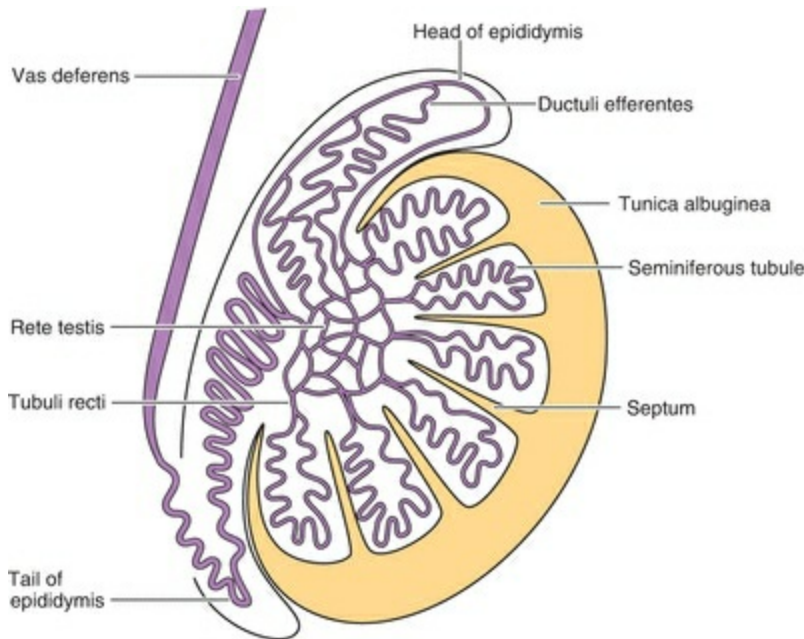

The evolution of scrotal mammals and the adoption of internal fertilization are associated with sperm maturation that occurs outside of the testes. This includes epididymal maturation in the male and capacitation in the female before fertilization. The need for capacitation (the final step required to acquire the ability to fertilize) may be an evolutionary consequence of the development of a storage system for inactive sperm in the caudal epididymis<sup>2</sup> (Figure 6.1).

**FIGURE 6.1**

The epididymis is over 6 m long in men, approximately 80 m in stallions, and over one hundred times the body length in a mouse; however, there are few functions known aside from sperm storage and nutrition. The epididymis is divided into three segments, the caput (head) where the sperm begin their process of maturation, the corpus (body) where maturation continues, and the cauda (tail), the site of final maturation and storage.<sup>3</sup> The sperm reach the caudal epididymis approximately 72 days after the initiation of spermatogenesis. At this time, the head of the sperm contains a membrane-bound nucleus capped by the acrosome, a large vesicle of proteolytic enzymes. The inner acrosomal membrane is closely apposed to the nuclear membrane, and the outer acrosomal membrane is next to the surface plasma membrane. The flagellum is a complex structure of microtubules and fibers, surrounded at the proximal end by mitochondria. Motility and the ability to fertilize are acquired gradually as the sperm pass into the epididymis (Figure 6.2).

**FIGURE 6.2**

The caudal epididymis stores sperm available for ejaculation. The ability to store functional sperm provides a capacity for repetitive fertile ejaculations. Preservation of optimal sperm function during this period of storage requires adequate testosterone levels in the circulation and maintenance of the normal scrotal temperature.<sup>4</sup> The importance of temperature is emphasized by the correlation of reduced numbers of sperm associated with episodes of body fever. The evolution of the scrotum served the purpose of achieving the cooler temperatures required for effective sperm storage.

In all mammalian species that have been studied except humans, it is necessary for spermatozoa to pass through the epididymis in order to develop two characteristics, which are essential to achieve fertilization: the capacity for motility and the ability to bind to the zona pellucida and penetrate the oocyte. There is evidence that the maturation process occurring in the epididymis involves modification of the sperm surface by epididymal proteins that are synthesized and secreted under the control of androgens.<sup>5</sup> Most of the maturational changes occur in the proximal epididymis, where surface proteins that must be removed in the process of capacitation, discussed later, are acquired by the sperm. It can be argued that in humans, the epididymis is not necessary for posttesticular sperm maturation and that its role is limited to storage because sperm that have never passed through the epididymis and that have been obtained from the vasa efferentia in men with a congenital absence of the vas deferens can fertilize the human oocyte in vitro and result in pregnancy with live birth.<sup>6</sup> Moreover, patients have achieved conception after anastomosis of the vas deferens to a seminiferous tubule<sup>7</sup> or the rete testis.<sup>8</sup> In a similar context, the injection of sperm obtained by testicular biopsy

directly into an oocyte (intracytoplasmic sperm injection [ICSI]) is very successful in achieving fertilization and pregnancy;<sup>9</sup> this observation, however, should be interpreted with caution, because with direct injection into the oocyte, surface protein action at the oocyte membrane is bypassed.

The use of sperm from men with sperm abnormalities should be pursued with some caution. Men with severe oligospermia or azoospermia should receive appropriate genetic counseling and should be offered testing for Y chromosome microdeletions before their sperm are used for ICSI. Sperm obtained from men with Y chromosome microdeletions involving the AZFc region of Yq11 can transmit the deletion to male children, who then will also likely be infertile. In addition, men with certain Y microdeletions, including a portion of AZFc, may have an increased susceptibility for developing testicular germ cell tumors. The outcome in subsequent generations must be assessed and appropriate genetic screening must be developed to avoid the transmission of subtle but important genetic alterations.

Semen forms a gel almost immediately following ejaculation but then is liquefied in 20–30 minutes by enzymes derived from the prostate gland. The alkaline pH of semen provides protection for the sperm from the acid environment of the vagina. This protection is transient, and most sperm left in the vagina are immobilized within 2 hours. The more fortunate sperm, by their own motility, gain entrance into the tongues of cervical mucus that layer over the ectocervix. These are the sperm that enter the uterus; the seminal plasma is left behind in the vagina. This entry is rapid, and sperm have been found in mucus within 90 seconds of ejaculation.<sup>10</sup> The destruction of all sperm in the vagina 5 minutes after ejaculation does not interfere with fertilization in the rabbit, further attesting to the rapidity of transport.<sup>11</sup>

Contractions of the female reproductive tract occur during coitus, and these contractions may be important for entry of sperm into the cervical mucus and further transport.

Presumably successful entry is the result of combined female and male forces (the flagellar activity of the sperm). The success of therapeutic insemination, however, indicates that coitus and female orgasm are not essential for sperm transport.

The sperm swim and migrate through pores in the cervical mucus that are smaller than the sperm head; therefore, the sperm must actively push their way through the mucus.<sup>12</sup> One cause of infertility, presumably, is impaired sperm movement that prevents this transport through the mucus. This movement is probably also influenced by the interaction between the mucus and the surface properties of the sperm head.<sup>13</sup> Abnormal morphology of the sperm head is often associated with impaired flagellar function; however, abnormal head morphology alone can be a cause of poor mucus

penetration.<sup>14,15</sup> A sperm coating protein (beta-defensin 126), acquired in the caudal epididymis, carries a high negative charge and is critical for movement through the cervical mucus.<sup>16</sup> It is generally believed that the cervical mucus has a filtering action; abnormal and less “capable” sperm have difficulty getting through.<sup>17</sup>

Uterine contractions and sperm motility propel the sperm upward, and in the human, sperm can be found in the tube 5 minutes after insemination.<sup>18</sup> Labeled albumin is present in the tubes within 30 seconds after intrauterine instillation.<sup>19</sup> It is possible that the first sperm to enter the tube are at a disadvantage. In the rabbit, these early sperm have only poor motility, and there is frequent disruption of the head membranes.<sup>20</sup> The sperm in this vanguard are unlikely to achieve fertilization. Other sperm that have colonized the cervical mucus and the cervical crypts then make their way more slowly to the ampulla of the tube in order to meet the egg. The number of sperm in the cervical mucus is relatively constant for 24 hours after coitus, and after 48 hours, there are relatively few remaining in the mucus.<sup>21</sup> Although the isthmus region of the fallopian tube functions as a sperm reservoir in many species, this does not appear to be the case in human,<sup>22</sup> where the cervix serves as a reservoir, providing a supply of sperm for up to 72 hours.

Human sperm have been found in the fallopian tube as long as 80 hours after intercourse, and these sperm can still perform fertilization normally with zona-free hamster oocytes.<sup>23</sup> In animals, the fertilizable lifespan is usually one-half the motile lifespan.

The **attrition in sperm** numbers from vagina to tube is substantial.<sup>24</sup> Of an average of 200–300 million sperm deposited in the vagina, at most only a few hundred (rarely reaching 1,000), and often less, achieve proximity to the egg (**Figure 6.3**).<sup>22</sup> Greater numbers are observed in the tubal ampulla at the time of ovulation. The major loss occurs in the vagina, with expulsion of semen from the introitus playing an important role. Other causes for loss are digestion of sperm by vaginal enzymes and phagocytosis of sperm along the reproductive tract. There are also reports of sperm burrowing into or being engulfed by endometrial cells. Many sperm continue past the oocyte to be lost into the peritoneal cavity.

**FIGURE 6.3**

Within the fallopian tube, sperm that are not yet capacitated are bound to the epithelial cells. When these sperm release and undergo capacitation, they display a new pattern of movement that has been called **hyperactivated motility**.<sup>25,26</sup> This motility may be influenced by an interaction with the tubal epithelium that results in greater speed and better direction as well as prevention of attachment and entrapment.

# Structure of the Cervical Mucus

The cervical mucus is a complex structure that is not homogeneous.<sup>27</sup> The mucus is secreted in granular form, and a networked structure of the mucus is formed in the cervical canal. Thus, not all areas of the cervical mucus are equally penetrable by the sperm. It is proposed, based on animal studies, that the outward flow of the cervical mucus establishes a linear alignment of parallel strands that direct the sperm upward. Pressurization of the mucus by contractions of the uterus further aids this alignment and may contribute to the speed of sperm transport. Responding to the midcycle estrogen peak, cervical mucus production, water content, and space between its large glycoproteins reach a maximum in the immediate preovulatory period. The process of capacitation is initiated but not completed during the sperm's passage through the cervix.

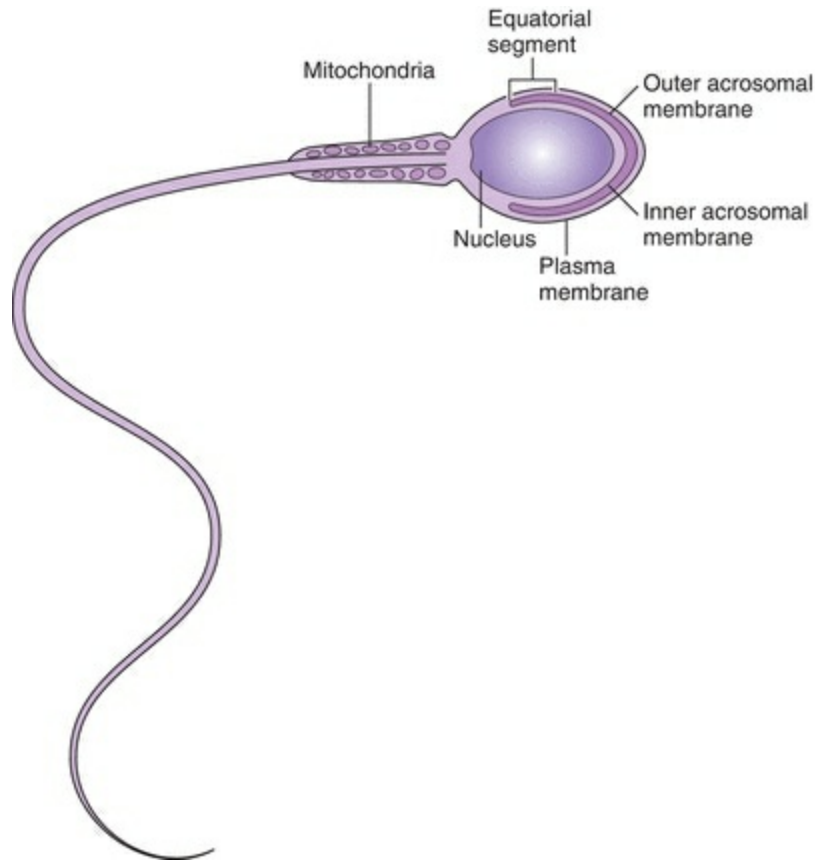

# Capacitation

The discovery, in 1951, that rabbit and rat spermatozoa must spend some hours in the female reproductive tract before acquiring the capacity to penetrate ova stimulated intensive research efforts to delineate the environmental conditions required for this change in the sperm to occur.<sup>28,29</sup> The process by which the sperm were transformed was called **capacitation, the cellular and molecular changes that ejaculated spermatozoa must undergo in order to fertilize.**<sup>30</sup> Attention was focused on the hormonal and time requirements and the potential for in vitro capacitation. Successful experiments to capacitate sperm outside of the female body were subsequently conducted in hamsters<sup>31</sup> and in mice,<sup>32</sup> pioneering the field of in vitro fertilization.

Capacitation occurs while the sperm are in the fallopian tube and is characterized by three accomplishments:

- 1. The ability to bind to the zona pellucida.**
- 2. The ability to undergo the acrosome reaction.**
- 3. The acquisition of hypermotility.**

Capacitation changes the surface characteristics of sperm, as exemplified by removal of seminal plasma factors that coat the surface of the sperm, modification of the surface charge, and restriction of receptor mobility. The protein beta-defensin 126 (DEFB126), derived from the epididymis, is the major coating protein of sperm that facilitates movement through the cervical mucus; its release from the sperm head is essential in order for the sperm to bind to the zona pellucida of the ovum.<sup>16,33</sup> Sperm proteomics have demonstrated a huge collection of receptors coated on the surface of sperm.<sup>34,35</sup> The purpose of the coating proteins may be to produce a reservoir of sperm in the fallopian tubes by promoting the binding of sperm to tubal epithelial cells (**Figure 6.4**).<sup>36</sup>

**FIGURE 6.4**

The surface changes are associated with modifications of sperm cell membrane sterols, lipids, and glycoproteins that cause decreased stability of the plasma membrane and the membrane lying immediately under it, the outer acrosomal membrane. The membranes undergo further, more striking modifications when capacitated sperm reach the vicinity of an oocyte or when they are incubated in follicular fluid. There is a breakdown and merging of the plasma membrane and the outer acrosomal membrane, the **acrosome reaction**.<sup>37</sup> This allows egress of the enzyme contents of the acrosome, the cap-like structure that covers the sperm nucleus. These enzymes, which include hyaluronidase, a neuraminidase-like factor, cumulus-dispersing enzyme, and a protease called acrosin, are all thought to play roles in sperm penetration of the egg investments. The changes in the sperm head membranes also prepare the sperm for fusion with the egg membrane. It is the inner acrosomal membrane that fuses with the oocyte plasma membrane. The acrosome reaction can be induced by zona pellucida proteins of the oocyte and by human follicular fluid in vitro.<sup>38,39</sup> In addition, capacitation endows the sperm with hypermotility, and the increased velocity of the sperm is a very critical factor in achieving zona penetration.<sup>25</sup>

During capacitation, removal of cholesterol from sperm plasma membrane by

albumin occurs first. This increases membrane permeability, which is followed by a critical increase in intracellular calcium concentration due to an influx of extracellular calcium, believed to be induced by progesterone. The events that constitute the process of capacitation are regulated by the redox status of the sperm cell.<sup>40,41</sup> The calcium influx activates secondary messenger systems, activating cAMP and redox reactions. Such activities lead to the phosphorylation of proteins, especially tyrosine residues, an absolute requirement for capacitation.<sup>42</sup> Sperm are stimulated to undergo capacitation when they encounter the alkaline change in pH at the time of ovulation, a response of the fallopian tubes to the midcycle hormonal changes.

Although capacitation classically has been defined as a change sperm undergo in the female reproductive tract, specifically in the fallopian tubes, it is apparent that sperm of some species, including the human, can acquire the ability to fertilize after a short incubation in defined media and without residence in the female reproductive tract. Therefore, success with assisted reproductive technologies is possible. In vitro capacitation requires a culture medium that is a balanced salt solution containing energy substrates such as lactate, pyruvate, and glucose and a protein such as albumin, or a biologic fluid such as serum or follicular fluid. Sperm-washing procedures probably remove factors that coat the surface of the sperm, one of the initial steps in capacitation. The removal of cholesterol from the sperm membrane is believed to prepare the sperm membrane for the acrosome reaction.<sup>43</sup> The loss of cholesterol regulates the expression of sperm cell membrane surface lectins that are involved in sperm surface receptors for the zona pellucida.<sup>44</sup> The time required for in vitro capacitation is approximately 2 hours.<sup>45</sup>

The final dash to the oocyte is aided by the increased motility due to the state of hyperactivity. This change in motility can be measured by an increase in velocity and flagellar beat amplitude. Perhaps the increase in thrust gained by this hyperactivity is necessary for avoiding attachment to tubal epithelium and achieving penetration of the cumulus and zona pellucida.

## Key Points: Steps in Sperm Transport

- Approximately 72 days are required to produce spermatozoa, a time period followed by storage in the epididymis prior to ejaculation.
- Sperm enter the cervical mucus and then the fallopian tubes within minutes, but only a few hundred sperm or less reach the oocyte. The cervix serves as a reservoir of sperm for up to 72 hours.
- Capacitation, a process initiated during the sperm's passage through the cervix and completed in the fallopian tube or during in vitro incubation in an appropriate

medium, is characterized by the acquired ability of sperm to undergo the acrosome reaction, to bind to the zona pellucida, and to acquire hyperactivated motility.

- The acrosome reaction is due to the modification and breakdown, followed by a merger, of the sperm cell membrane and the outer acrosomal membrane, allowing the release of enzymes and changes in the inner acrosomal membrane, necessary for fusion with the oocyte cell membrane.

# EGG TRANSPORT

---

The oocyte, at the time of ovulation, is surrounded by cumulus cells (the **cumulus oophorus**) that attach the oocyte to the granulosa cells that line the wall of the follicle. The **zona pellucida**, a noncellular porous layer of glycoproteins secreted by the oocyte, separates the oocyte from the cumulus cells. The cumulus cells communicate metabolically with the oocyte by means of **gap junctions**. In response to the midcycle surge in luteinizing hormone (LH), maturation of the oocyte proceeds with the resumption of meiosis as the oocyte completes the first meiotic division, enters into the second meiotic division, and arrests in the second metaphase. Just before ovulation, the cumulus cells retract their cellular contacts from the oocyte. The disruption of the gap junctions induces maturation and migration of the cortical granules to the outer cortex of the oocyte.<sup>46</sup> Prior to ovulation, the oocyte and its cumulus mass of cells prepare to leave their long residence in the ovary by becoming detached from the follicular wall.

Egg transport encompasses the period of time from ovulation to the entry of the morula into the uterus. The egg can be fertilized only during the early stages of its sojourn in the fallopian tube. Within 2–3 minutes of ovulation in some animals, the cumulus and oocyte are in the ampulla of the fallopian tube. It takes longer in humans.

In rats and mice, the ovary and distal portion of the tube are covered by a common fluid-filled sac. Ovulated eggs are carried by fluid currents to the fimbriated end of the tube. In contrast, in primates, including humans, the ovulated eggs adhere with their cumulus mass of follicular cells to the surface of the ovary. The fimbriated end of the tube sweeps over the ovary in order to pick up the egg. Entry into the tube is facilitated by muscular movements that bring the fimbriae into contact with the surface of the ovary. Variations in this pattern surely exist, as evidenced by women who achieve pregnancy despite having only one ovary and a single tube located on the contralateral side. Furthermore, eggs deposited in the cul-de-sac by transvaginal injection are picked up by the tubes.<sup>47</sup>

Although there can be a small negative pressure in the tube in association with muscle contractions, oocyte pickup is not dependent on a suction effect secondary to this negative pressure. Ligation of the tube just proximal to the fimbriae does not interfere with pickup.<sup>48</sup>

In order to successfully achieve a pregnancy, not only anatomically patent tubes but also a complex system of tubal transport must be operational to allow a timely favorable interaction between gametes and subsequently provide a supporting conduit for the developing conceptus to reach the uterus. Three different components, (1) ciliary motion, (2) muscular contractility, and (3) tubal fluid, all contribute to varying degrees to effective tubal transport.

The fallopian tube is composed of three layers: an inner mucosal surface, a wall of smooth muscle, and an outer serosal layer. It is lined by a single layer of simple columnar epithelium, composed of nonciliated cells and ciliated cells, that undergoes cyclic changes comparable to the endometrium, in response to the ovarian steroids during the menstrual cycle.<sup>49</sup> These changes can be evident as a higher percentage of ciliated cells in the follicular phase, with gradual transition into a secretory cell–dominant pattern in the luteal phase of the cycle. The nonciliated cells are characterized by major secretory activity during the follicular phase of the cycle, culminating in the release of cytoplasmic components during the passage of the egg, perhaps providing important metabolic factors for transport and implantation. The cilia on the surface of the fimbriae (where they are present in greater concentrations) display adhesive sites, and these seem to have prime responsibility for the initial movement of the egg into the tube. This movement is dependent on the presence of follicular cumulus cells surrounding the egg, because removal of these cells prior to egg pickup prevents effective egg transport.

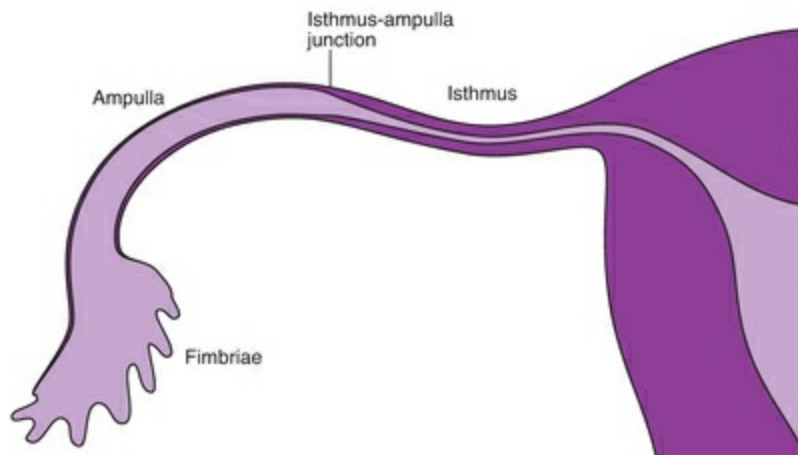

In the ampulla of the tube, the many cilia beat synchronously in the direction of the uterus, and in the fimbria, the ciliary beat is faster in the secretory phase of the menstrual cycle.<sup>50</sup> In women and monkeys, this unidirectional beat is also found in the isthmus of the tube. Various hormonal and neuronal factors have been shown to modulate the ciliary activity as shown by changes in ciliary beat frequency in the fallopian tube. These include adrenergic and cholinergic stimulation, ovarian steroids, prostaglandins, angiotensin II, and adrenomedullin. The specific contribution of the cilia to egg transport in the ampulla and isthmus is an unresolved question. Most investigators have credited muscular contractions of the tubes as the primary force for moving the egg.<sup>51</sup> However, interference with muscle contractility in the rabbit did not block egg transport, implying that the cilia alone are adequate for transporting the ovum.<sup>52</sup> Reversing a segment of the ampulla of the tube so that the cilia in this segment beat toward the ovary interferes with pregnancy in the rabbit without blocking fertilization. The fertilized ova are arrested when they come in contact with the transposed area.<sup>53</sup> This suggests that ciliary beating is crucial for egg transport. Spontaneous pregnancies have been reported in women who suffer from Kartagener syndrome (primary ciliary dyskinesia) in which there is a congenital absence of dynein arms (a protein structure associated with motility) in all bodily cilia, and thus the cilia do not beat.<sup>54</sup> However, motility of cilia in the tube may be disordered and not totally absent. Nevertheless, the pregnancies in women with Kartagener syndrome indicate the importance of uterine and fallopian tube muscular peristalsis.<sup>55</sup> Human fallopian tube muscular contractions are stimulated by prostaglandins  $E_2$  and  $F_{2\alpha}$  and decreased by progestins, human chorionic gonadotropin (hCG), and oxytocin.<sup>56</sup>

Transvaginal endoscopic observation of actual ovum and cumulus oophorus pickup in women revealed that the process is relatively slow (more than 15 minutes), the fimbriae on the ovulating side are distinguished by being erect (probably due to engorged blood vessels and suggesting a local ovarian influence), and the only observable active mechanism involved ciliary movement.<sup>57,58</sup> It is probable, therefore, that in normal circumstances, smooth muscle contractions and the flow of secretory fluid in response to ciliary activity work together to accomplish egg transport.

Secretory epithelium of the tube is actively involved in secretion of a variety of bioactive compounds. Maximal production of tubal fluid is seen in midcycle, and it is believed that its constituents, primarily prostaglandins, play a major role in modulating tubal contractile activity in order to facilitate the ovum pick up and embryo transfer.<sup>59,60</sup> At midcycle, following follicular rupture and ovulation, follicular fluid becomes the major component of the tubal fluid. In addition to the modulatory effects that follicular fluid exerts on ciliary beat frequency and tubal muscular contractility, the simple stream of follicular fluid into the tubal lumen may assist the ovum pick up and transport process.<sup>61</sup>

In most species, transport of the ovum (the fertilized oocyte) through the tube requires approximately 3 days.<sup>62</sup> The time spent within the various parts of the tube varies from one species to another. Transport through the ampulla is rapid in the rabbit, whereas in women, the egg spends about 80 hours in the tube, 90% of which is in the ampulla at the junction of the ampulla with the isthmus. It is in this location that fertilization and dispersion of the cumulus cells are completed.

Attempts to modify tubal function as a method for understanding its physiology have involved three major pharmacologic approaches: **(1)** altering levels of steroid hormones, **(2)** interference with or supplementation of adrenergic stimuli, and **(3)** treatment with prostaglandins. Although there is abundant literature on the effects of estrogen and progesterone on tubal function, it is clouded by the use of different hormones, different doses, and different timing of injections. Because of these variations, it is difficult to obtain a coherent picture and to relate the experimental results to the in vivo situation. In general, pharmacologic doses of estrogen favor retention of eggs in the tube. This “tube-locking” effect of estrogen can be partially reversed by treatment with progesterone (**Figure 6.5**).

**FIGURE 6.5**

The isthmus of the tube has an extensive adrenergic innervation. Surgical denervation of the tube, however, does not disrupt ovum transport. Prostaglandins (PG) of the F series stimulate muscle activity of the tube. Although  $\text{PGF}_{2a}$  stimulates human oviductal motility *in vivo*, it does not cause acceleration of ovum transport.

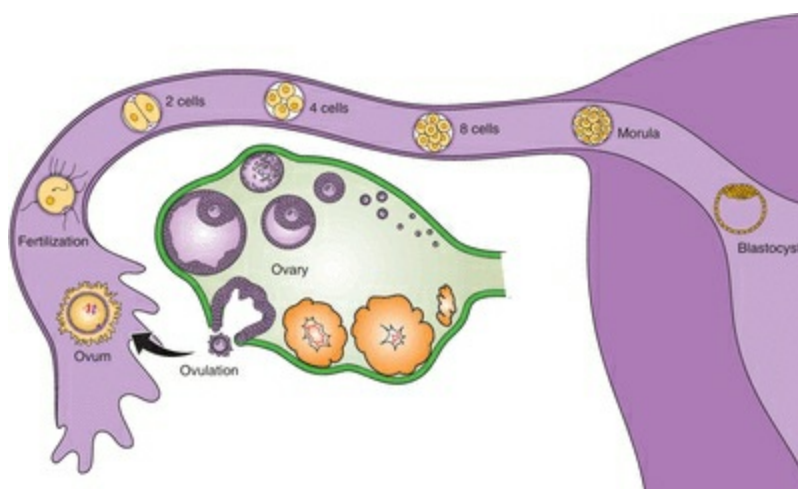

Is there an essential anatomic segment of the tube? Excision of the ampullary-isthmus junction in rabbits does not prevent fertility.<sup>63</sup> This is equally true if small segments of the ampulla are removed, and pregnancy can occur even if the entire isthmus and uterotubal junction are excised. Although the fimbriae are thought to play a crucial role in fertility, spontaneous pregnancies have been reported following sterilization by fimbriectomy or following surgical repair of tubes whose fimbriated ends had been excised.<sup>64,65</sup> The fallopian tube appears to readily adapt to anatomic changes and restrictions.

In most species, a period of residence in the tube appears to be a prerequisite for full development. Rabbit eggs can be fertilized in the uterus, but they do not develop unless transferred to the tubes within 3 hours of fertilization.<sup>66</sup> This implies that there may be a component in uterine fluid during the first 48 hours following ovulation that is toxic to the egg.<sup>66</sup> Indirect evidence of an inhospitable environment is also provided by studies indicating that there must be synchrony between development of the endometrium and the egg for successful pregnancy to occur.<sup>67,68</sup> If the endometrium is in a reduced or advanced stage of development compared with the egg, fertility is compromised. In addition, the blastocyst must undergo cleavage and development in order to gain the capability to implant in the uterus. **Thus, it is conceptually useful to view the fallopian tube not as an active transport mechanism but as a structure that provides an important holding action. This functional behavior is coordinated by the increasing estrogen and progesterone levels after ovulation, although local**

## embryonic signals may also be involved.

Successful pregnancies have occurred in the human following the Estes procedure, in which the ovary is transposed to the uterine cornua.<sup>69</sup> Eggs are ovulated directly into the uterus, completely bypassing the tube. Moreover, when fertilized donor eggs are transferred to women who are receiving hormone supplementation, there are several days during the treatment cycle when the blastocysts will implant. This crucial difference between animal and human physiology is of more than academic importance. There has been speculation about the use of drugs that could accelerate tubal transport as a means of providing contraception by ensuring that the egg would reach the uterus when it was in an unreceptive state. Although this may work in animals, it is of doubtful value in the human because perfect synchrony is not required.

Animal and human reproduction also differ in the occurrence of ectopic pregnancy. Ectopic pregnancies are rare in animals, and in rodents, they are not induced even if the uterotubal junction is occluded immediately following fertilization. The embryos reach the blastocyst stage and then degenerate (**Figure 6.6**).

**FIGURE 6.6**

## Key Points: Egg Transport

- After ovulation, the oocyte and its surrounding cumulus are in the ampulla of the fallopian tube within 15–20 minutes.
- Tubal transport depends on smooth muscle contractions and ciliary-induced flow of secretory fluid.
- The fallopian tube provides an important holding action to allow time for the endometrium to become receptive and the blastocyst to become capable of

implantation, a time period of approximately 80 hours, 90% of which is in the ampulla.

# OOCYTE MATURATION

---

Oocyte maturation, as reviewed in [Chapter 5](#), is regulated by the gonadotropins, the sex hormones, and the complex interaction among an array of growth factors and cytokines in the follicular fluid. In nonmammalian species, a nongenomic action of progesterone causes an increase in intracellular calcium concentrations. In human oocytes, an influx of extracellular calcium occurs in response to estradiol, followed by secondary rises in calcium ions from intracellular stores, characterized by wave-like oscillations.<sup>70</sup> This is a nongenomic response to estradiol at the cell surface, and the transient increases in intracellular calcium improve the quality of the oocyte and contribute to the capability for fertilization.

Calcium oscillations are a property common to mammalian oocytes and are also an early reaction to the fertilizing spermatozoan.<sup>71</sup> Neither the presence of estradiol nor the calcium oscillations are required for oocytes to resume meiosis. However, improved fertilization following estradiol-induced calcium increases indicates an important role for intrafollicular estradiol in overall oocyte maturation.

# FERTILIZATION

---

The fertilizable life of the human oocyte is unknown, but estimates range between 12 and 24 hours. However, immature human eggs recovered for in vitro fertilization can be fertilized even after 36 hours of incubation. Equally uncertain is knowledge of the fertilizable lifespan of human sperm. The most common estimate is 48–72 hours, although motility can be maintained after the sperm have lost the ability to fertilize. The extreme intervals that have achieved pregnancy documented after a single act of coitus are 6 days prior to and 3 days after ovulation.<sup>72</sup> The great majority of pregnancies occur when coitus takes place within the 3-day interval just prior to ovulation.<sup>73</sup>

Contact of sperm with the egg, which occurs in the ampulla of the tube, may not be random; there is some evidence for sperm-egg communication that attracts sperm to the oocyte.<sup>74,75,76</sup> This chemotactic responsiveness of sperm requires the changes that take place in the capacitation process.<sup>77</sup> Thus, this may be a system to select a sperm that is fully capable of fertilization.

The cumulus oophorus undergoes a preovulatory expansion that has at least two important roles. The ampullary space of the human fallopian tube is relatively large (compared with the oocyte), and the expanded cumulus may serve to increase the chances of an encounter with one of the few spermatozoa that have reached the far section of the tube. In addition, this change may facilitate sperm passage through the cumulus. Sperm pass through the cumulus without the release of acrosomal enzymes.<sup>78</sup> It has been suggested, based on in vitro experiments, that the cumulus is essential for full development of the fertilizing ability of sperm; however, removal of the cumulus does not prevent sperm penetration and fertilization.

Despite the evolution from external to internal fertilization over a period of about 100 million years, many of the mechanisms have remained the same.<sup>79,80,81</sup> The acellular zona pellucida that surrounds the egg at ovulation and remains in place until implantation has two major functions in the fertilization process:

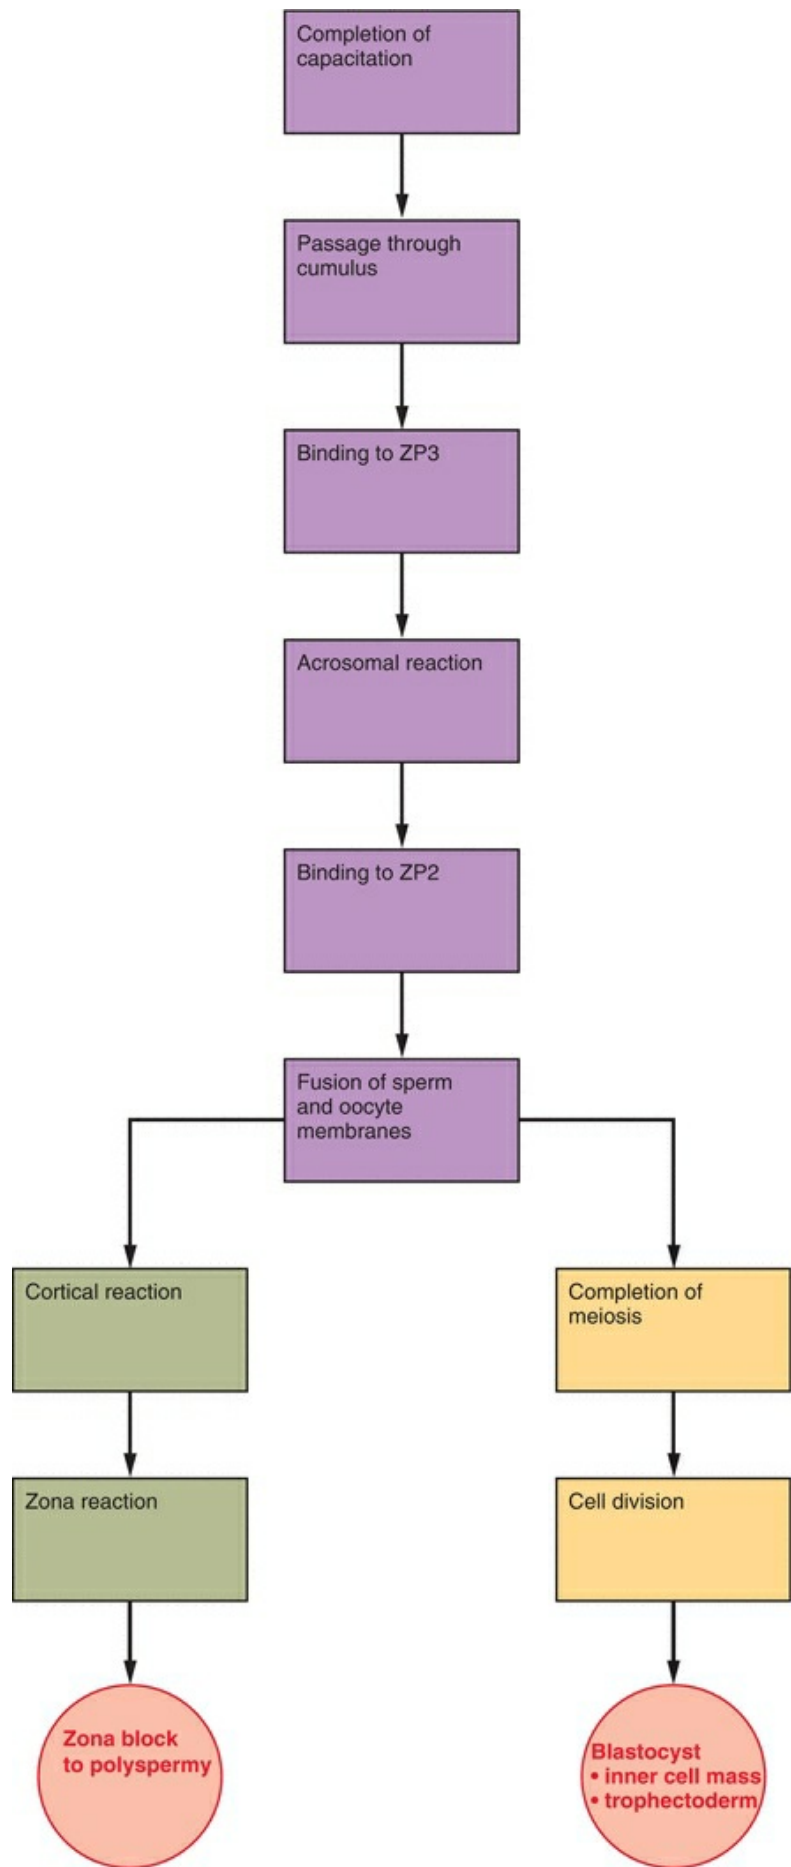

1. The zona pellucida contains ligands for sperm, which are, with some exceptions, relatively species specific.
2. The zona pellucida undergoes the **zona reaction** in which the zona becomes impervious to other sperm once the fertilizing sperm penetrates, and thus, it provides a bar to polyploidy.<sup>82</sup>

Sperm bind to the zona pellucida for about a minute and then penetrate it rapidly, mediated by acrosin, a trypsin-like proteinase that is bound to the inner acrosomal membrane of the sperm.<sup>81,83,84</sup> The pivotal role assigned to acrosin has been disputed.

For example, manipulations that increase the resistance of the zona to acrosin do not interfere with sperm penetration, and thus, sperm motility may be the critical factor. The zona pellucida is a porous structure due to the many glycoproteins assembled into long, interconnecting filaments. Nevertheless, a preponderance of evidence favors tenacious binding of capacitated spermatozoa to the zona pellucida as a requirement for penetration, although it is clear that penetration requires physical thrust with active motility not only of the tail but of the head as well. Indeed, sperm undergo rapid lateral oscillations of the head about a fulcrum at the head-tail junction, suggesting a scythe-like action on the zona.<sup>2,81</sup>

The acrosome is a lysosome-like organelle in the anterior region of the sperm head, lying just beneath the plasma membrane like a cap over the nucleus. The lower part of the two arms is called the equatorial segment. The acrosome contains many enzymes that are exposed by the **acrosome reaction, immediately before fertilization. This reaction is one of exocytosis, the fusion of an intracellular storage vesicle with the inner surface of the cell membrane, followed by release of the vesicle contents.** The acrosome reaction requires an influx of calcium ions, the efflux of hydrogen ions, an increase in pH, and fusion of the plasma membrane with the outer acrosomal membrane, leading to the exposure and escape of the enzymes contained on the inner acrosomal membrane. Binding to the zona pellucida is required to permit a component of the zona to induce the acrosomal reaction. This component is believed to be a glycoprotein sperm receptor, which thus serves dual functions: binding of sperm and induction of the acrosomal reaction.

The initial contact between the sperm and the oocyte is a receptor-mediated process. The zona pellucida is composed of glycoproteins secreted by the oocyte, known as ZP1, ZP2, ZP3, and ZP4, with ZP3 being the most abundant.<sup>85,86,87,88</sup> In humans, ZP3 and ZP4 are the primary ligands for sperm and ZP2 binding occurs after the acrosome reaction, participating in the zona reaction to prevent polyspermy.<sup>89</sup> Structural alteration of these glycoproteins leads to a loss of activity; inactivation of these ligands after fertilization is probably accomplished by one or more cortical granule enzymes. The ZP gene is expressed only in growing oocytes. DNA sequence similarities of the ZP3 gene in various mammals indicate that this gene has been evolutionarily conserved and that the sperm-ligand interaction is a common mechanism among mammals (**Figures 6.7 and 6.8**).<sup>90</sup> Mice with a disrupted ZP3 gene produce oocytes lacking a zona pellucida and are unable to become pregnant.<sup>91,92</sup> A vaccine against zona pellucida glycoproteins from pigs is used to control reproduction in a variety of female animals, including female elephants and deer.<sup>93</sup> Human use of such a vaccine has been hampered by the difficulty in preparing pure glycoproteins, but this is now possible using recombinant techniques.<sup>94</sup>

**FIGURE 6.7**

**FIGURE 6.8**

The initial binding of the sperm to the zona requires recognition on the part of the sperm of the carbohydrate component of the species-specific glycoprotein ligand molecule.<sup>88,95</sup> Once binding is accomplished, the acrosome reaction is triggered by the peptide chain component of the receptor glycoprotein. At least one receptor on the sperm head is a tyrosine kinase that is activated by binding to the ZP3 glycoprotein and is an initiator of the acrosome reaction.<sup>96,97</sup> This interaction is analogous to the general principle of behavior for hormone-receptor binding and activity. In the case of sperm and oocyte, recognition of the oocyte zona ligand involves an enzyme on the surface of the sperm that becomes exposed during capacitation. Formation of the ZP3-enzyme complex, therefore, not only produces binding but also induces the acrosome reaction. The G-protein signaling system is present on sperm heads, and activation at this point in time by progesterone, in an extragenomic mechanism, opens calcium channels to increase intracellular levels of calcium ions, a requirement for the acrosome reaction.<sup>98,99,100</sup> Thus, the initial sperm-zona interaction depends on binding of acrosome-intact spermatozoa, followed by a process mediated by the enzymes released by the zona-induced acrosome reaction. Protein kinase C activation is an important step in the acrosomal reaction, leading to phosphorylation of sperm proteins involved in the

process.<sup>101,102</sup>

Glycodelin is a glycoprotein with many isoforms found in endometrium, the fallopian tubes, follicular fluid, and in seminal fluid. The various forms of glycodelin modulate sperm function and fertilization by maintaining sperm in the uncapacitated state and inhibiting binding of sperm to the zona pellucida by competing for zona receptors. A specific receptor for glycodelin is present on sperm, and thus, it makes sense that down-regulation of glycodelin expression would be associated with the hormonal changes at ovulation coinciding with the opening of the fertilization window.<sup>103</sup>

Spermatozoa enter the perivitelline space at an angle. The oocyte is a spherical cell covered with microvilli. The sperm head is like a flat dish, and the thickness of the head is a little less than the distance between the oocyte microvilli.<sup>104</sup> The region of the equatorial segment of the sperm head, the distal portion of the acrosome, makes initial contact with the vitelline membrane (the egg plasma membrane or oolemma). At first, the egg membrane engulfs the sperm head, and, subsequently, there is fusion of egg and sperm membranes. Bedford has opined that the tangential trajectory of this process allows closure with expansion of the blastocyst, preventing the persistence of a hole that would allow herniation or interfere with the normal hatching that occurs later within the uterus.<sup>105</sup>

Sperm-egg fusion is mediated by specific proteins. Two membrane proteins from the sperm head have been sequenced; one (PH-20, also called SPAM1) is involved in binding to the zona pellucida, and the other (PH-30, also called fertilin) is involved in fusion with the oocyte.<sup>106,107</sup> PH-20, with hyaluronidase activity, is also active in dispelling the cumulus.<sup>108</sup> The cell membrane of the unfertilized oocyte contains integrin adhesion/fusion molecules that recognize peptides such as fibronectin, laminin, and collagen.<sup>109</sup> Fibronectin appears on the spermatozoa, but it is disputed whether it appears with caudal maturation or after capacitation. Vitronectin is a sperm protein that is activated after capacitation and the acrosome reaction and may be the key peptide interacting with oocyte cell membrane integrins.<sup>110</sup> These steps in the fusion process will occur only with sperm that have undergone the acrosome reaction. Multiple sperm-associated surface proteins are involved in binding to the oocyte membrane, but no single peptide has been identified as absolutely essential for fertilization, implying redundancy.<sup>111,112</sup>

Fusion of the sperm and oocyte membrane to form a zygote is followed by the cortical reaction and metabolic activation of the oocyte. An increase in intracellular-free calcium in a periodic, oscillatory pattern always precedes the cortical reaction and oocyte activation at fertilization, and this is believed to be the mechanism by which the

spermatozoon triggers these developmental events.<sup>71,113,114</sup> It is believed that calcium signaling in fertilization is initiated by the introduction of a sperm factor into the egg, a phospholipase protein that activates inositol 1,4,5-trisphosphate leading to calcium release.<sup>114</sup> An analysis of failed fertilizations in one couple after ICSIs indicated a high prevalence of failed oocyte activation; repeated ICSI after initiating oocyte activation with a calcium ionophore resulted in a successful pregnancy.<sup>115</sup>

The initiation of the block to penetration of the zona by other sperm is mediated by the **cortical reaction**, another example of exocytosis with the release of materials from the **cortical granules**, lysosome-like organelles that are found just below the egg surface.<sup>116</sup> As with other lysosome-like organelles, these materials include various hydrolytic enzymes. Changes brought about by these enzymes lead to the **zona reaction, the hardening of the extracellular layer by cross-linking of structural proteins, and inactivation of ligands for sperm receptors.**<sup>117</sup> Thus, the zona block to polyspermy is accomplished. The initial change in this zona block is a rapid depolarization of the oocyte membrane associated with a release of calcium ions from calmodulin.<sup>118,119</sup> The increase in intracellular calcium acts as a signal or trigger to activate protein synthesis in the oocyte. The depolarization of the membrane initiates only a transient block to sperm entry. The permanent block is a consequence of the cortical reaction and the release of enzymes, also apparently triggered by the increase in calcium.

Approximately 3 hours after fertilization, meiosis is completed.<sup>120</sup> The second polar body is released, leaving the egg with a haploid complement of chromosomes. The addition of chromosomes from the sperm restores the diploid number to the now fertilized egg. The chromatin material of the sperm head decondenses, and the male pronucleus is formed. The male and the female pronuclei migrate toward each other, and as they move into close proximity, the limiting membranes break down, and a spindle is formed on which the chromosomes become arranged. Thus, the stage is set for the first cell division.

Embryonic genome activity in the human begins early; DNA synthesis activity can be detected 9–10 hours after insemination.<sup>121</sup> Human gene expression (transcription) begins between the 4- and 8-cell stages of preimplantation cleavage, 2–3 days after fertilization.<sup>122</sup> Earlier embryonic signals may be derived from a store of maternal messenger RNAs, termed the “maternal legacy.”<sup>123,124</sup> In addition, proteomics have identified RNAs and transcription factors within sperm that suggest a mechanism for a paternal contribution to the early development of the embryo.<sup>35,125</sup>

Clinicians are interested not only in how normal fertilization takes place but also in the occurrence of abnormal events that can interfere with pregnancy. It is worthwhile, therefore, to consider the failures that occur in association with in vivo fertilization.

Studies in the nonhuman primate have involved monkeys and baboons. A surgical method was used to flush the uterus of regularly cycling rhesus monkeys, and 9 preimplantation embryos and 2 unfertilized eggs were recovered from 22 flushes. Two of the nine embryos were morphologically abnormal and probably would not have implanted.<sup>126</sup> Hendrickx and Kraemer used a similar technique in the baboon and recovered 23 embryos, of which 10 were morphologically abnormal.<sup>127</sup> This suggests that, in nonhuman primates, some ovulated eggs are not fertilized and that many early embryos are abnormal and, in all likelihood, will be aborted. Similar findings have been reported in the human in the classic study of Hertig et al.<sup>128</sup> They examined 34 early embryos recovered by flushing, and examination of reproductive organs removed at surgery. Ten of these embryos were morphologically abnormal, including 4 of the 8 preimplantation embryos. Because the 4 preimplantation losses would not have been recognized clinically, there would have been 6 losses recorded in the remaining 30 pregnancies.

In each ovulatory cycle, only 20–30% of normally fertile couples can achieve a pregnancy.<sup>129</sup> By using sensitive pregnancy tests, it has been suggested that 20% of pregnancies are lost after implantation and before the pregnancy is clinically perceived.<sup>130,131</sup> In the postimplantation period, if only clinically diagnosed pregnancies are considered, the generally accepted figure for spontaneous miscarriage in the first trimester in young women is 15%. Approximately 50–60% of these abortuses have chromosome abnormalities.<sup>132</sup> This suggests that a minimum of 7.5% of all human conceptions are chromosomally abnormal. The fact that only 1 in 200 newborns has a chromosome abnormality attests to the powerful selection mechanisms operating in early human gestation.

## Key Points: Fertilization

- Sperm penetration of the zona pellucida depends on a combination of sperm motility, an acrosomal proteinase, and binding of sperm head receptors to zona ligands.
- Binding of sperm head receptors and zona ligands produces an enzyme complex that induces the acrosome reaction, releasing enzymes essential for the fusion of the sperm and oocyte membranes.
- Fusion of the sperm and oocyte membranes triggers the cortical reaction, the release of substances from the cortical granules, organelles just below the egg cell membrane.
- The cortical reaction leads to the enzyme-induced zona reaction, the hardening of the zona, and the inactivation of ligands for sperm receptors, producing an

obstacle to polyspermy.

- Cell division begins promptly after fertilization; human embryonic gene expression begins between the 4- and 8-cell stages.

# IMPLANTATION AND PLACENTATION

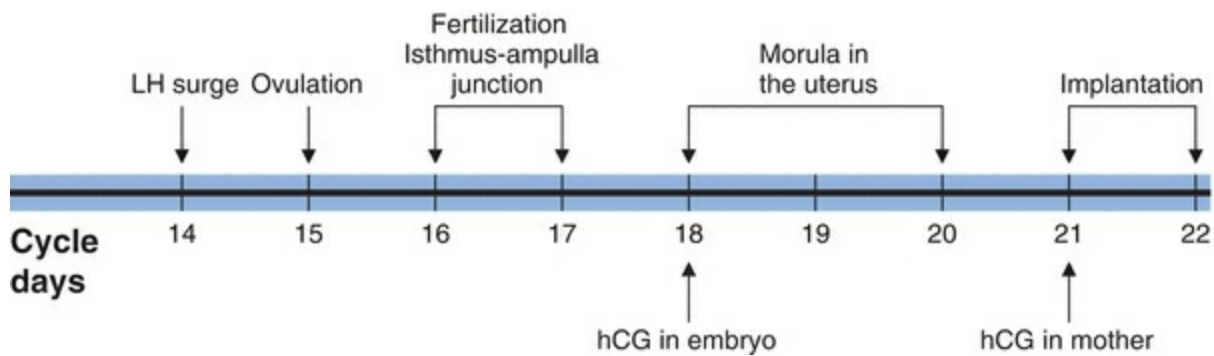

---

A normal pregnancy is, of course, impossible without successful implantation and placentation. Because there are differences among the various species, we will focus on the physical and biochemical events that are relevant in human reproduction.<sup>133,134</sup> Shortly after the 8-cell morula enters the uterine cavity about 4 days after the gonadotropin surge and 3 days after ovulation, a blastocyst (a preimplantation embryo of varying cell number, from 32 to 256) is formed. Implantation (the embedding of the blastocyst in the endometrial stroma) begins with the loss of the zona pellucida (hatching) about 1–3 days after the morula enters the uterine cavity.

# Preparation for Implantation

The change from proliferative to secretory endometrium, described in detail in [Chapter 3](#), is an essential part of achieving the receptive conditions required for implantation. The primary endocrine requirement is the presence of progesterone; in the monkey, implantation and pregnancy can be achieved in the absence of luteal phase estrogen.<sup>135</sup> **This crucial histologic change is termed decidualization, the process of endometrial fibroblasts transforming into specialized secretory decidual cells, and is caused by many underlying biochemical and molecular events orchestrated by progesterone.** In most species, the implanting embryo triggers the decidualization process. In human beings, however, decidualization is under maternal control and initiated during the mid-secretory phase of each cycle in response to elevated progesterone and rising cellular cAMP levels. The human endometrium is 10–14 mm thick at the time of implantation in the midluteal phase. By this time, secretory activity has reached a peak, and the endometrial cells are rich in glycogen and lipids. Decidualization is indispensable for pregnancy as it confers immune tolerance to the developing fetal semi-allograft, regulates trophoblast invasion, and both nourishes and protects the peri-implantation conceptus against a variety of physiologic stressors associated with pregnancy.<sup>136</sup> Indeed, nourishment of the human fetus is dependent on contributions from the endometrial glands until the end of the first trimester of pregnancy, when a high level of maternal blood flow is reached within the placenta.<sup>137</sup>

Understanding the dynamic endocrine behavior of the endometrium ([Chapter 3](#)) increases the appreciation for its active participation in the implantation process. The window of endometrial receptivity is restricted to days 16–22 of a 28-day normal cycle (5–10 days after the LH surge) and days 16–19 of cycles stimulated by exogenous gonadotropins.<sup>68,138,139,140</sup> The harmonious synchronization of a large cast of biochemical and molecular players is a complex achievement required for normal implantation. It is not surprising that gene expression studies have begun to identify the presence of dysregulated endometrial genes in women with repeated implantation failures.<sup>141</sup> The maximal chance of a normal implantation is only about 40% per cycle under optimal conditions<sup>142</sup> ([Figure 6.9](#)).

**FIGURE 6.9**

Endometrial receptivity is heralded by the progesterone-induced formation of **pinopodes (also called uterodomes)**, surface epithelial cells that lose their microvilli and develop smooth protrusions, appearing and regressing during the window of receptivity.<sup>143</sup> The pinopodes may serve to absorb fluid from the uterine cavity forcing the blastocyst to be in contact with the endometrial epithelium. Blastocysts adhere at sites with pinopodes where the cell surface loses its nonadhesive character.<sup>144</sup> The most critical feature of the pinopode is the removal of adhesion-inhibiting mucin during the window of implantation.<sup>145</sup> Pinopodes appear around day 21 and are present only for a few days during implantation, following the peak in progesterone levels and marked by a decrease in progesterone receptor B in the endometrium.<sup>146</sup> However, this limited appearance of pinopodes is controversial as others have described their appearance throughout the luteal phase and into pregnancy.<sup>147</sup>

While it has been known for long time that progesterone exerts a profound influence on uterine function during early gestation and is crucial for implantation, our understanding of the underlying molecular mechanisms mediated by progesterone action have grown substantially over the past decade by detailed molecular studies in genetically engineered mouse models. These studies have revealed that several progesterone-regulated pathways involved in endometrial function during implantation are conserved in mice and humans. Several progesterone receptor-regulated genes such as *Ihh*, *Bmp2*, *Wnt4*, *Hoxa10*, and *Hand2* are essential for implantation and decidualization.<sup>148,149</sup>

Even before the blastocyst adheres to the surface epithelium, but after hatching from the zona pellucida, a dialogue between the mother and the early embryo has begun. Early pregnancy factor (EPF) can be detected in the maternal circulation within 1–2 days after fertilization.<sup>150</sup> Prior to implantation, EPF is apparently produced by the ovary in response to a signal from the embryo. After implantation, EPF is no longer secreted by the ovary but is derived from the embryo. EPF has immunosuppressive

properties and is associated with cell proliferation and growth. Indeed, there is reason to believe that endometrial receptivity for implantation requires appropriate signals from the embryo. One such signal is hCG.

Blastocysts grown in culture produce and secrete hCG, beginning days 7–8 after fertilization.<sup>151</sup> Messenger RNA for hCG can be found in 6- to 8-cell human embryos.<sup>152</sup> Because the 8- to 16-cell stage is achieved about 3 days after fertilization, it is believed that the human embryo begins to produce hCG before implantation when it can be detected in the mother (about 6–7 days after ovulation). The embryo is capable, therefore, of preimplantation signaling, and higher levels of estradiol and progesterone can be measured in the maternal circulation even before maternal hCG is detectable, presumably because of stimulation of the corpus luteum by hCG delivered directly from the uterine cavity to the ovary.<sup>153</sup> Function of the corpus luteum is crucial during the first 7–9 weeks of pregnancy, and luteectomy early in pregnancy can precipitate abortion.<sup>154</sup> Similarly, early pregnancy loss in primates can be induced by injections of anti-hCG serum.<sup>155</sup> Another substance secreted very early by the preimplantation embryo is platelet-activating factor, perhaps part of the immunosuppressive activity required to induce maternal tolerance of the embryo. In the rabbit, platelet-activating factor also induces the production of EPF.<sup>156</sup> Indeed, many growth factors are produced by the early embryo.<sup>157</sup>

In rodents and rabbits, implantation can be interrupted by injection of prostaglandin inhibitors.<sup>158,159</sup> Indomethacin prevents the increase in endometrial vascular permeability normally seen just prior to implantation. Additional evidence for a role by prostaglandins in the earliest stages of implantation is the finding of increased concentrations of prostaglandins at implantation sites, similar to any inflammatory response.<sup>160</sup> The blastocysts of mice, rabbits, sheep, and cows produce prostaglandins, and prostaglandin E<sub>2</sub> release from human blastocysts and embryos has been demonstrated.<sup>161</sup>

The secretory endometrial epithelial cells are also a source of prostaglandin E<sub>2</sub> (but not prostaglandin F<sub>2α</sub>), and its synthesis may be stimulated by the tissue response that accompanies implantation. However, decidual synthesis of prostaglandins is significantly reduced compared with proliferative and secretory endometrium, apparently a direct effect of progesterone activity and perhaps a requirement in order to maintain the pregnancy.<sup>160</sup> Nevertheless, prostaglandin E<sub>2</sub> synthesis is increased at the implantation site, perhaps in response to blastocyst factors, for example, platelet-activating factor, and correlates with an increase in vascular permeability.<sup>160,162</sup> It is now well accepted that decidua-derived prostaglandin E<sub>2</sub> is one of the major regulators

of trophoblastic invasion, activating other signaling proteins.<sup>163</sup>

As discussed in [Chapter 3](#), the many cytokines, peptides, and lipids secreted by the endometrium are interrelated through the stimulating and inhibiting actions of estrogen and progesterone, as well as the autocrine/paracrine activities of these substances on each other. The response to implantation certainly involves the many members of the growth factor and cytokine families.

Angiogenesis, the growth of blood vessels from preexisting vessels, is a key feature of the endometrial cycle and implantation. This process is regulated indirectly by the sex steroids and directly by growth factors, especially members of the fibroblast growth factor family, the angiopoietins, and the vascular endothelial cell growth factor (VEGF) family. There are at least five VEGF isoforms and four receptors. Two angiopoietins, Ang-1 and Ang-2, share a common tyrosine kinase receptor, Tie2. VEGF-A seems critical for vascular growth and is up-regulated in the presence of reduced oxygen. The angiopoietins also promote the growth of blood vessels and act synergistically with VEGF. Controlled growth as well as appropriate regression reflect the balance between an ever-increasing number of stimulatory and inhibitory factors discovered by scientists in this field ([Table 6.1](#)).<sup>164,165</sup>

## **TABLE 6.1 Growth Factors**

<b>Lipids</b>	<b>Cytokines</b>	<b>Growth Factors</b>
Prostaglandins	Interleukin-1 $\alpha$	Epidermal growth factor family
Thromboxanes	Interleukin-1 $\beta$	EGF
	Interleukin-6	Heparin-binding EGF
	Interleukin-11	TGF- $\alpha$
	Colony-stimulating factor-1	Insulin-like growth factor family
	Tumor necrosis factor- $\alpha$	IGF-I
	Leukemia-inhibiting factor	IGF-II
	Interferon- $\gamma$	IGFBPs 1–6
		Platelet-derived growth factor
		Transforming growth factor- $\beta$
		Fibroblast growth factors
		Vascular endothelial growth factors
		Angiopoietins

# Implantation

**Implantation is defined as the process by which an embryo attaches to the uterine wall and penetrates first the epithelium and then the circulatory system of the mother to form the placenta.** The embryo completely invades the endometrium only in great apes and humans. Implantation is a process that is limited in both time and space, beginning 2–3 days after the fertilized egg enters the uterus usually on day 18 or 19 of the cycle (3 or 4 days after ovulation).<sup>140</sup> Thus, implantation occurs 5–7 days after fertilization. A careful study of women attempting to conceive documented that the first hormonal evidence of implantation (the appearance of hCG) occurred on 8, 9, or 10 days after ovulation; the earliest was 6 days and the latest 12 days.<sup>166</sup> The risk of spontaneous early miscarriage markedly increases with late implantations (later than 9 days after ovulation). Implantation consists of three stages: apposition, adhesion, and invasion (also called migration to denote its benign nature).

## Apposition and Adhesion

The human blastocyst remains in the uterine secretions for approximately 1–3 days and then hatches from its zona pellucida in preparation for attachment. The implantation site in the human uterus is usually in the upper, posterior wall in the midsagittal plane. Implantation is marked initially by apposition of the blastocyst to the uterine epithelium, usually about 2–4 days after the morula enters the uterine cavity. A prerequisite for this contact is a loss of the zona pellucida, which, *in vitro*, can be ruptured by contractions and expansions of the blastocyst. *In vivo*, this activity is less critical, because the zona can be lysed by components of the uterine fluid. Nevertheless, blastocyst movement and escape from the zona pellucida appear to involve cytoplasmic projections (this leads to penetrations of the zona by the trophoctoderm prior to zona hatching).<sup>167</sup> By this time, the blastocyst has differentiated into an inner cell mass (embryo) and trophoctoderm (placenta), both essential for implantation.

The endometrium produces at least three cytokines involved in implantation.<sup>168</sup> These are colony-stimulating factor-1 (CSF-1), leukemia-inhibitory factor (LIF), and interleukin-1 (IL-1). CSF-1 expression and receptors for CSF-1 are found in both the human endometrium (peaking in decidua) and the preimplantation embryo. Mice with an inactivating mutation in the CSF-1 gene are infertile because of low rates of implantation and fetal viability.<sup>169</sup> LIF displays the same pattern of expression as CSF-1, and mice with an LIF gene mutation have a failure of blastocyst implantation.<sup>170,171</sup> Blocking the interleukin-1 receptor in mice also prevents implantation.<sup>168</sup> Interleukin-1 stimulates hCG release from human trophoblast cells, and the endometrium increases VEGF expression and regulates the tissue inhibitors of metalloproteinases (TIMPs);

GnRH is produced in the human blastocyst and stimulates endometrial expression of interleukin-1.<sup>172</sup> Perhaps the first maternal change in the implantation process, increased permeability of the capillaries near the adherent blastocyst, is due to a blastocyst-directed change in heparin-binding epidermal growth factor (HB-EGF) expression in the surface epithelium.<sup>173</sup> In addition, the blastocyst contains receptors for epidermal growth factor that respond to HB-EGF and promote growth and zona hatching.

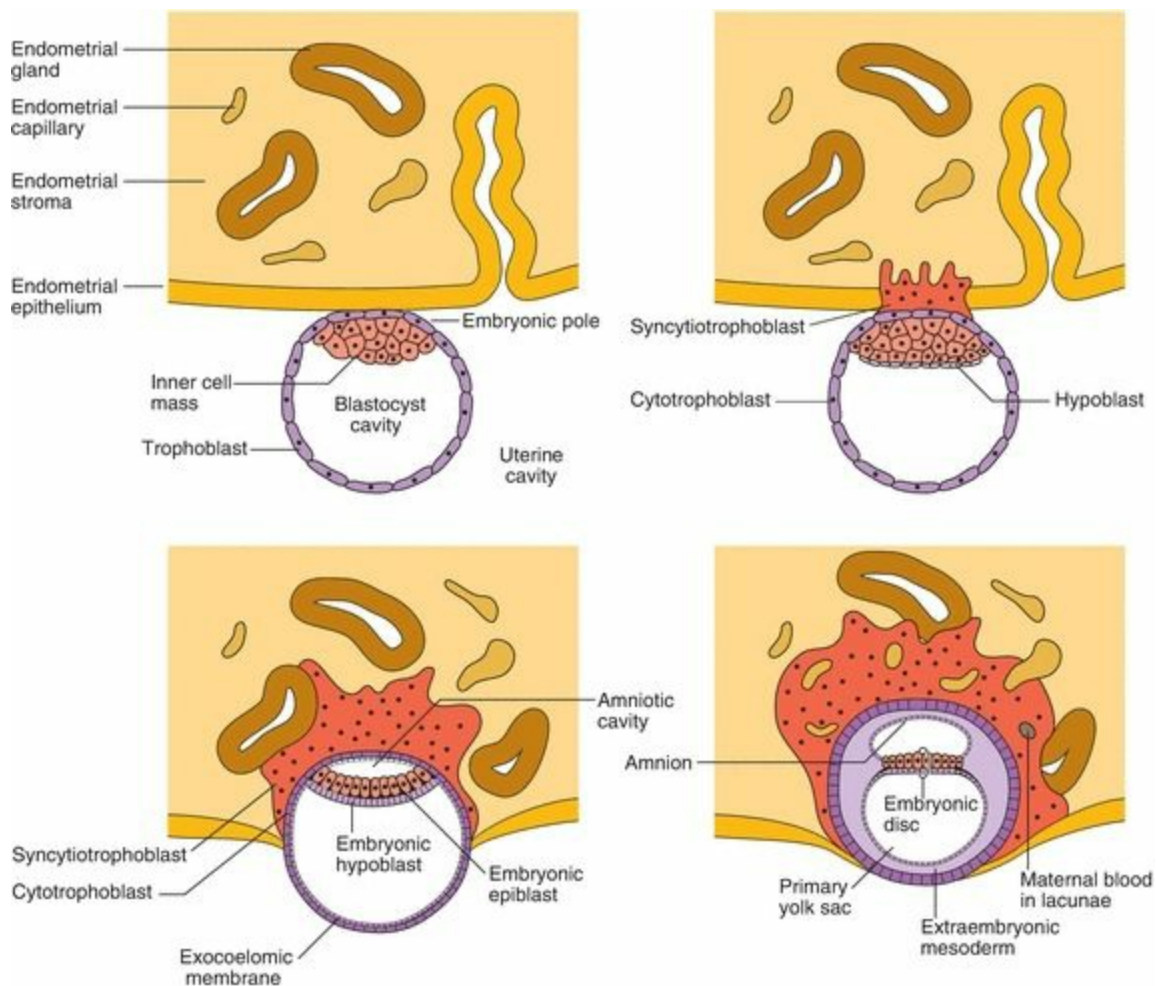

The adhesion process further involves a collection of adhesion molecules, including integrins, selectins, and trophinin.<sup>174</sup> The decidualized endometrium and the early embryo express extracellular matrix components, especially laminin and fibronectin, which mediate cell adhesion by binding to the adhesion molecules.<sup>175</sup> Cells are fixed and supported by the extracellular matrix components such as laminin and fibronectin through attachments to these components via cell surface receptors, especially the integrins. An increase in specific isoforms of laminin in decidua at the time of implantation suggests an important interaction with the invading trophoblast.<sup>176</sup> Thus, implantation starts with adhesion due to binding with endometrial proteins, followed by invasion (migration) of the trophoblast by proteinase degradation of the extracellular matrix.

Integrins are members of a family of transmembrane cell surface receptors for collagen, fibronectin, and laminin. Integrins are utilized in cell-cell and cell-matrix interactions, contributing to cell migration, cell differentiation, and tissue structure. A cyclic change in integrin expression in the endometrial epithelial cells indicates peak expression at the time of implantation.<sup>177</sup> It has been suggested that a lack of integrin expression during the implantation window can be a cause of infertility.<sup>178</sup> The blastocyst also expresses integrins in a time sequence and at a site (outgrowing trophoblast cells) that are appropriate for key activity during implantation.<sup>179</sup> The integrins are a diverse collection of receptors, reflecting various combinations of the  $\alpha$  and  $\beta$  subunits in the structure of the receptor, as well as variations in the cytoplasmic domain in the subunits. Stimulation and inhibition of cellular proliferation in the endometrium and decidua are influenced by specific expression of the appropriate subunits.<sup>180</sup> Mechanisms that control variation in the structure through splicing would account for the expression of an integrin variant appropriate for proliferation early in the endometrial cycle and prevention of proliferation in the decidua, and perhaps prevention of trophoblastic invasion.

Ephrins are peptides that bind to tyrosine kinase cell membrane receptors. Ephrin expression can be detected in both endometrial epithelial cells and in blastocysts.<sup>181</sup> This is another system for the cell-to-cell communication involved in trophoblastic migration.

The process of tissue disruption is accompanied by an increase in lymphocytes, another source for cytokines and growth factors in addition to trophoblast and endometrial cells. The distinction between cytokines and growth factors is not always clear, but T lymphocytes and macrophages are significant secretors of cytokines.

**In general, cytokines, growth factors, and their receptors have been identified in virtually all tissues associated with implantation. The cataloging is lengthy and often confusing.<sup>168,182</sup> It is helpful to simply view these various substances as the biochemical tools by which the physical process of trophoblast adhesion and invasion is accomplished (Figure 6.10).**

**FIGURE 6.10**

Even if the hormonal milieu and protein composition of the uterine fluid are hospitable, implantation may not occur if the embryo is not at the proper stage of development. It has been inferred from this information that there must be developmental maturation of the surface of the embryo before it is capable of attachment and implantation.

Reports of changes in the surface charge of preimplantation embryos differ in their findings, and it is unlikely that changes in surface charge are solely responsible for adherence of the blastocyst to the surface of epithelial cells. Binding of the lectin concanavalin A to the blastocyst changes during the preimplantation period, an indication that the surface glycoproteins of the blastocyst are in transition.<sup>183</sup> It is reasonable to assume that these changes in configuration on the surface occur in order to enhance the ability of the early embryo to adhere to the maternal surface.

As the blastocyst comes into close contact with the endometrium, the microvilli on the surface flatten and interdigitate with those on the luminal surface of the epithelial cells. A stage is reached where the cell membranes are in very close contact and junctional complexes are formed. The early embryo can no longer be dislodged from the surface of the epithelial cells by flushing the uterus with physiologic solutions.

Intense research efforts are undergoing to define the transcriptional profile of the endometrium throughout the menstrual cycle and window of implantation.<sup>184,185</sup> Eventually, the characterization of an endometrium that is normally receptive to implantation will allow medical interventions. It is not far-fetched to consider therapeutic manipulations that will either improve implantation rates or provide contraception.

## **Invasion and Placentation**

In the 2nd week after ovulation, the placenta is formed.<sup>175</sup> By this time, the trophoblasts at the implantation site have formed masses of cytotrophoblasts and syncytiotrophoblasts, and invasion of maternal blood vessels has begun. The walls of the spiral arteries are destroyed, as sinusoidal sacs are formed lined with endovascular trophoblast. The fundamental change is a replacement of maternal vascular cells with cytotrophoblast cells. The purpose of placental invasion is to remodel the uterine vasculature, establishing a structure that will allow and maintain a high blood flow interchange between mother and fetus, replacing small, high-resistance vessels with large, low-resistance vessels. **The invading placental cells are special trophoblast cells, known as the extravillous trophoblast, that arise by proliferation and differentiation of cytotrophoblast stem cells within the chorionic villi.**

Three types of interactions between the implanting trophoblast and the uterine epithelium have been described.<sup>186</sup> First, trophoblast cells intrude between uterine epithelial cells on their path to the basement membrane. In the second type of interaction, the epithelial cells lift off the basement membrane, an action that allows the trophoblast to insinuate itself underneath the epithelium. Last, fusion of the trophoblast with individual uterine epithelial cells has been identified by electron microscopy in the

rabbit.<sup>187</sup> This latter method of gaining entry into the epithelial layer raises interesting questions about the immunologic consequences of mixing embryonic and maternal cytoplasm.

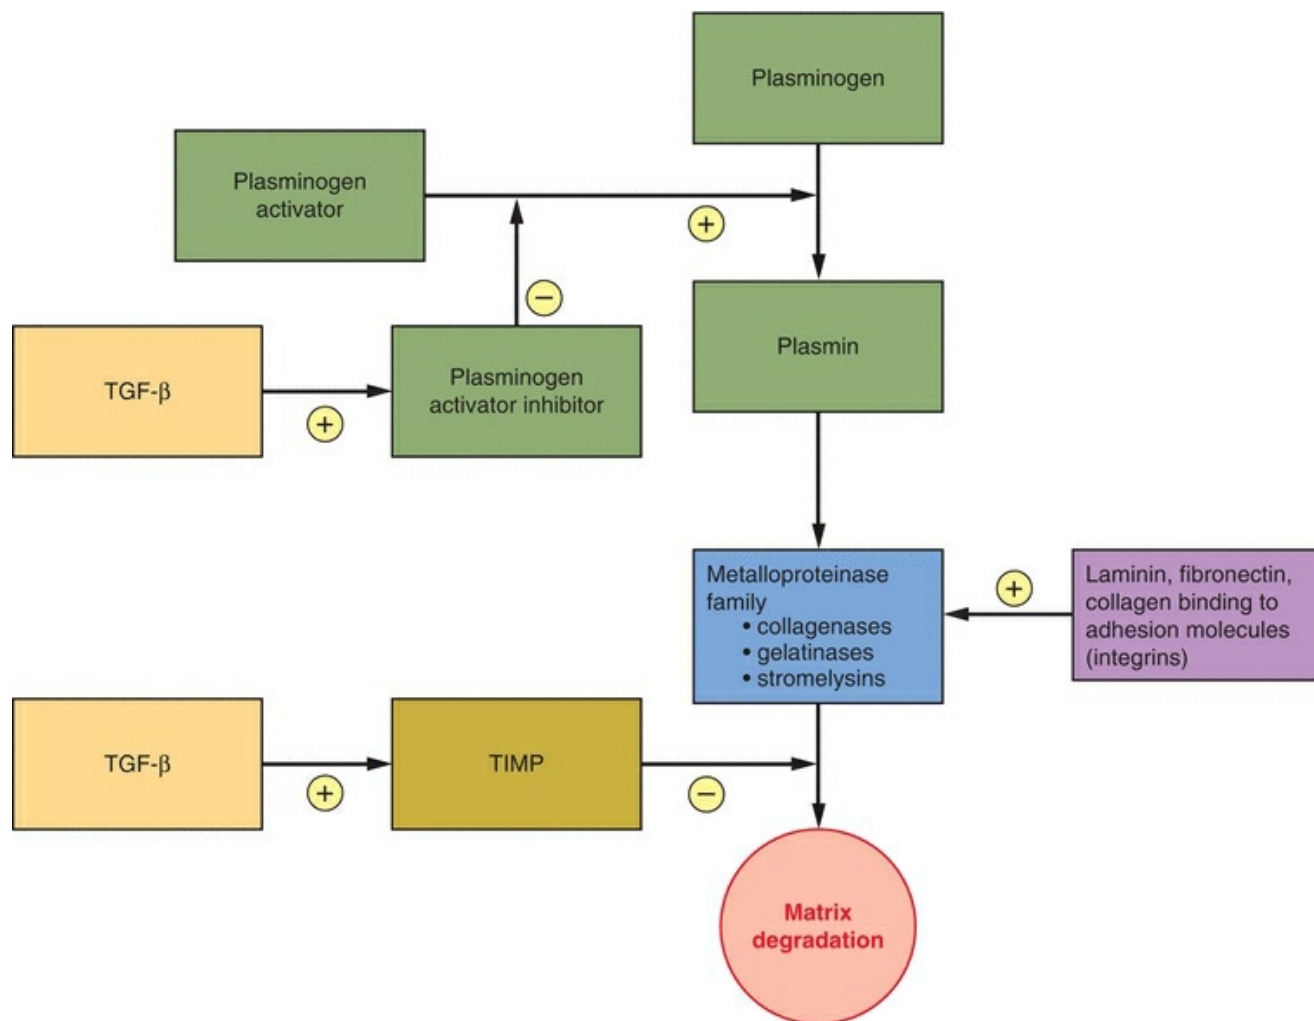

Trophoblast has the ability to phagocytose a variety of cells, but, in vivo, this activity seems largely confined to removal of dead endometrial cells, or cells that have been sloughed from the uterine wall. Similarly, despite the invasive nature of the trophoblast, destruction of maternal cells by enzymes secreted by the embryo does not play a major role in implantation; there is virtually no necrosis. The early embryo does secrete a variety of enzymes (e.g., collagenase and plasminogen activators), and these are important for digesting the intercellular matrix that holds the epithelial cells together. Studies in vitro have demonstrated the presence of plasminogen activator in mouse embryos and in human trophoblast, and its activity is important in the attachment and early outgrowth stages of implantation.<sup>188,189</sup> Urokinase and proteases, trophoblastic enzymes that convert plasminogen to plasmin, are inhibited by hCG, indicating regulation of this process by the embryo.<sup>190</sup>

The trophoblast at a somewhat later stage of implantation can digest, in vitro, a complex matrix composed of glycoproteins, elastin, and collagen, all of which are components of the normal intercellular matrix.<sup>191,192</sup> Studies in vitro indicate that cells move away from trophoblast in a process called “contact inhibition.”<sup>193</sup> Trophoblast then spreads to fill the spaces vacated by the cocultured cells. Once the extracellular matrix has been lysed, this movement of epithelial cells away from trophoblast would allow space for the implanting embryo to move through the epithelial layer. Trophoblast movement is aided by the fact that only parts of its surface are adhesive, and the major portion of the surface is nonadhesive to other cells.

The highly proliferative phase and migration of trophoblastic tissue during early embryogenesis are regulated by the many growth factors and cytokines produced in both fetal and maternal tissues.<sup>194</sup> VEGF is important for the growth of new blood vessels, and the angiopoietins recruit perivascular cells to provide vascular stability. The interaction of VEGF and angiopoietins is important in the remodeling of maternal vessels necessary to develop the uteroplacental circulation. Another signal from the fetus to induce maternal blood vessels to grow is hCG, which of course is available even before implantation to bind to its receptor in the endometrium and stimulate vessels directly as well as the expression of angiogenic factors, such as VEGF.<sup>195,196</sup> Preeclampsia is characterized by insufficient spiral artery remodeling, and it has been suggested that alterations in circulating angiogenic factors play a pathogenic role in preeclampsia. Women with preeclampsia have been shown to have increased levels of the antiangiogenic factors, soluble fms-like tyrosine kinase 1 (sFlt-1), and soluble endoglin (sEng), which are thought to trap circulating VEGF, placental growth factor

(PGF), and transforming growth factor  $\beta$  (TGF $\beta$ ), respectively, decreasing their free levels, leading to endothelial dysfunction and the clinical manifestations of the disease.<sup>197,198</sup>

Invasion of the early trophoblast requires the expression of integrins, stimulated by trophoblast-derived insulin-like growth factor-II and decidua-derived IGF-binding protein-1, and inhibited by decidua-derived TGF $\beta$  (**Figure 6.11**).<sup>199,200</sup> Actively migrating trophoblast cells have a different integrin profile than nonmigrating cells, specifically cell surface receptors that preferentially bind laminin.<sup>175,201</sup> The controlling mechanism (not yet known) for this change in integrin expression must be a key regulator of trophoblast invasion. The specific nature of integrin expression can determine binding to matrix components, a requirement for migration.

**FIGURE 6.11**

Integrin cell surface binding for the matrix components can be also regulated by

activating and inactivating the integrins. This would allow trophoblast cells to alternate between adhesive and nonadhesive states, thus achieving directional cell migration.<sup>202</sup> The role of integrin cell surface receptors is not simply to bind to a structural component in extracellular matrix but also to activate intracellular signaling pathways (similar to the classic endocrine tropic hormone-cell membrane receptor pathway) that result in activation of enzymes that ultimately promote adhesion and to regulate cellular gene transcription.<sup>175</sup> IGF-binding protein-1 can stimulate trophoblastic cell migration independently of the IGF system by binding to an integrin receptor and activating kinase pathways.<sup>203</sup>

The uterine spiral arterioles are invaded by cytotrophoblasts, and the maternal endothelium is replaced by cytotrophoblast tissue as far as the first third of the myometrium. The maternal vascular invasion by trophoblast cells and replacement of vascular endothelium with endovascular trophoblast may utilize a different class of surface molecules, the selectin family.<sup>175</sup> The selectins have been demonstrated to be present in decidual vascular endothelial cells, but only at the site of implantation. The selectins are responsive to inflammatory mediators, including cytokines. As the trophoblast cells replace maternal endothelium, the receptor profile for adhesion peptides of the trophoblast changes to resemble endothelial cells.<sup>204</sup> **It has been long recognized that this invasion process is limited in pregnancies with preeclampsia, and this is the fundamental cause of the poor placental perfusion associated with preeclampsia and intrauterine growth retardation.** The relative failure in this process in preeclampsia is characterized by insufficient conversion to endothelial adhesion receptors as well as low levels of IGF-binding protein-1 and matrix metalloproteinases.<sup>205,206,207</sup>

The matrix metalloproteinases, significantly involved in the process of menstruation (Chapter 3), are also key players in matrix degradation during trophoblast invasion. The metalloproteinases include collagenases, gelatinases, and the stromelysins. Integrin-mediated adhesion can activate this family of proteolytic enzymes, which then accomplish the degradation of matrix proteins that is necessary in order for trophoblast migration to take place. Production of the metalloproteinases is regulated by the combined actions of plasminogen activators, cytokines, and tissue inhibitors (TIMPs). Early trophoblastic invasion is enhanced by trophoblast-derived GnRH that suppresses the expression of TIMPs, the inhibitors of matrix metalloproteinases.<sup>208</sup>

Further penetration and survival depend on factors that are capable of suppressing the maternal immune response to fetal antigens. The endometrial tissue makes a significant contribution to growth factor activity and immune suppression by synthesizing proteins in response to the blastocyst even before implantation.<sup>209,210</sup> One of the great mysteries associated with implantation is the mechanism by which the

mother rejects a genetically abnormal embryo or fetus. Evidence from several mammalian species indicates that the endometrium is capable of “sensing” the quality of the attaching embryo, mounting a decidualization response that is tailored to individual embryos. Microarray analysis of bovine endometrium has revealed differential gene expression depending on the origin (somatic cell nuclear transfer, IVF, or artificial insemination) and developmental potential of the implanting embryo.<sup>211</sup> In humans, endometrial stromal cells have been shown in vitro in a coculture model to respond selectively to low-quality embryos by inhibiting the secretion of key implantation factors, including IL1-beta, HB-EGF, and LIF.<sup>212</sup> In addition, low-quality embryos elicit an endoplasmic stress response in human endometrial stromal cells in vitro, as well as in mouse uterus in vivo.<sup>213</sup>

The embryonic signals will be effective only in a proper hormone milieu. Much of the knowledge concerning the hormone requirements for implantation in animals has been gained from studies of animals with delayed implantation. In a number of species, preimplantation embryos normally lie dormant in the uterus for periods of time, which may extend for as long as 15 months before implantation is initiated. In other species, delayed implantation can be imposed by postpartum suckling or by performing ovariectomy on day 3 of pregnancy. This produces a marked decrease in synthesis of DNA and protein by the blastocyst. The embryo can be maintained at the blastocyst stage by injecting the mother with progesterone. Using this model, hormonal requirements for implantation have been determined. In mice, there is a requirement for estrogen and progesterone. In other species, including the primate, the nidatory stimulus of estrogen is not required, and progesterone alone is sufficient.<sup>135</sup> However, genomic profiling indicates that the presence of some estrogen facilitates the progesterone-induced gene expression associated with implantation.<sup>214</sup>

Although it is known that the hormone milieu of delayed implantation renders the embryo quiescent, it is not known whether this represents a direct effect on the embryo or whether there is a metabolic inhibitor present in uterine secretions that acts on the embryo. Removal of the embryo from the uterus to culture dishes allows rapid resumption of normal metabolism, suggesting that in fact, there has been a release from the inhibitory effects of a uterine product.

## **Limitation of Invasion**

Unlike the tissue invasion associated with cancer, trophoblast invasion must be limited, confining the placenta to its intrauterine location and within the time constraint of a pregnancy.

Invasion of the endometrial stromal compartment, breaching of the basement membrane, and penetration of maternal blood vessels are mediated by serine proteases

and metalloproteinases. The serine proteases are plasminogen activators that provide plasmin for proteolytic degradation of the extracellular matrix and activation of the metalloproteinase family. Trophoblast cells contain plasminogen activator receptors. Binding of plasminogen activator to this receptor is believed to be a method by which plasmin proteolysis is exerted in a controlled and limited site.<sup>215</sup>

Many components of the inflammatory response play roles in the process of implantation. Cytokine secretion from the lymphocyte infiltrate in the endometrium activates cellular lysis of trophoblast, perhaps an important process in limiting invasion.<sup>216</sup> The decidua at the time of implantation contains a large number of natural killer cells (large granular lymphocytes). It has been proposed that an interaction between these cells and a human leukocyte antigen uniquely present in invading trophoblast limits invasion by producing appropriate cytokines.<sup>217</sup>

Invasion by the trophoblast is limited by the formation of the decidual cell layer in the uterus. Fibroblast-like cells in the stroma are transformed into glycogen and lipid-rich cells. In the human, decidual cells surround blood vessels late in the nonpregnant cycle, but extensive decidualization does not occur until pregnancy is established. Ovarian steroids govern decidualization, and in the human, a combination of estrogen and progesterone is critical. Tissue factor (TF), expressed in decidualized endometrium, is a receptor for factor VII and its active form, VIIa. Concentrated in perivascular sites, TF forms what Lockwood calls a “hemostatic envelope” to promote hemostasis by providing fibrin.<sup>218,219</sup> TF is appropriately positioned to counteract the threat of hemorrhage associated with trophoblastic invasion.

Limitation of trophoblastic invasion is attributed to the balance of promoting and restraining growth factors, cytokines, and enzymes. Plasminogen activator inhibitor-1 (PAI-1) is a major product of decidual cells, inhibiting excessive bleeding during menses and restraining trophoblast invasion in early pregnancy.<sup>218,220</sup> PAI-1 binds plasminogen activator with a high affinity and is regulated by cytokines and growth factors. The metalloproteinases that degrade the extracellular matrix components, such as collagens, gelatins, fibronectin, and laminin, are restrained by TIMPs. In addition, metalloproteinase degradation can be suppressed by inhibiting trophoblast production of these enzymes and by preventing conversion from an inactive to an active form.<sup>221</sup> Decidual TGF- $\beta$  is a key growth factor involved in limitation of trophoblast invasion by inducing the expression of both TIMP and PAI-1. In addition, TGF- $\beta$  can inhibit integrin expression and influence cytotrophoblasts to differentiate into noninvasive syncytiotrophoblasts.<sup>199,222</sup> Decorin is a decidua-derived binding proteoglycan that can bind TGF- $\beta$ , storing it for when it is needed to limit invasion when it is freed and activated by plasmin. In addition, decorin exerts antiproliferative, antimigratory, and anti-invasive effects on trophoblast independently of TGF- $\beta$ .<sup>223</sup> Even hCG may exert a

governing force by inhibiting protease activity.<sup>190,224</sup>

In the baboon, the lower estrogen levels in early pregnancy permit trophoblast invasion, but the increasing estrogen levels later in pregnancy suppress maternal spiral artery invasion, an effect mediated by estrogen-induced decreases in cytotrophoblast VEGF expression.<sup>225,226</sup>

## Key Points: Implantation

- The early embryo enters the uterine cavity as an 8-cell morula and becomes a 32 to 256-cell blastocyst before implantation.
- Implantation begins with hatching from the zona pellucida about 1–3 days after the morula enters the uterine cavity.
- The endometrium is prepared for implantation by the complex activity of cytokines, growth factors, and lipids modulated by the sex hormones, especially progesterone. The endometrium is receptive for implantation for only a few days.
- The process of implantation begins with apposition and adhesion of the blastocyst to the uterine epithelium, about 2–4 days after the morula enters the uterine cavity. This process is mediated by cytokines and involves adhesion molecules (integrins) that interact with extracellular components, especially laminin and fibronectin.
- Trophoblastic invasion rapidly follows adhesion of the blastocyst, mediated by proteinase degradation of the extracellular matrix. The placenta is formed in the 2nd week after ovulation. Limitation of trophoblastic invasion is due to a restraint imposed by proteinase inhibitors, especially plasminogen activator inhibitor and tissue inhibitors of metalloproteinases.

# The Endocrinology of Pregnancy

Who is in charge of pregnancy, the mother or her fetus? From the vantage point of an outsider looking in, it seems as if the mother is in charge. But from the fetal point of view, it is overwhelmingly logical that the maternal adaptations of pregnancy are controlled by the fetus. For the fetus, one of the crucial aspects of intrauterine life is its dependency on the effective exchange of nutritive and metabolic products with the mother. It is logical that mechanisms exist by which a growing fetus can influence or control the exchange process and, hence, its environment. The methods by which a fetus can influence its own growth and development involve a variety of messages transmitted, in many cases, by hormones. Hormonal messengers from the conceptus can affect metabolic processes, uteroplacental blood flow, and cellular differentiation. Furthermore, a fetus may signal its desire and readiness to leave the uterus by hormonal initiation of parturition. On the other hand, from a teleologic standpoint, since pregnancy is such a great biologic investment, it would be logical for the mother to allocate its precious resources focusing on supporting competent embryos. Indeed, it appears that the endometrium acts as a biosensor responding favorably to competent embryos but less favorably to poorly viable embryos, which are destined to fail. This chapter reviews the mechanisms of maternal-conceptus crosstalk and by which the fetus establishes influence over important events during pregnancy. The important process of lactation is discussed in [Chapter 16](#).

# STEROID HORMONES IN PREGNANCY

---

Steroidogenesis in the fetoplacental unit does not follow the conventional mechanisms of hormone production within a single organ. Instead, the final products result from critical interactions and interdependence of separate organ systems that individually do not possess the necessary enzymatic capabilities. It is helpful to view the process as consisting of a fetal compartment, a placental compartment (specifically the syncytiotrophoblast), and a maternal compartment (**Figure 7.1**). Separately, the fetal and placental compartments lack certain steroidogenic activities. Together, however, they are complementary and form a complete unit that utilizes the maternal compartment as a source of basic building materials and as a resource for clearance of steroids.

**FIGURE 7.1**

# Progesterone

In its key location as a way station between mother and fetus, the placenta can use precursors from either mother or fetus to circumvent its own deficiencies in enzyme activity. The placenta converts little, if any, acetate to cholesterol or its precursors. Cholesterol and pregnenolone are obtained from the maternal bloodstream for progesterone synthesis. The fetal contribution is negligible because progesterone levels remain high after fetal demise. Thus, the massive amount of progesterone produced in pregnancy depends on placental-maternal cooperation, although some have argued that the fetal liver is an important source of cholesterol (discussed later).

Progesterone is largely produced by the corpus luteum until about 10 weeks of gestation. Pulsatile pituitary luteinizing hormone (LH) and eventually human chorionic gonadotropin (hCG) from the implanting pregnancy stimulate progesterone production by the corpus luteum, which is essential for pregnancy maintenance until approximately the seventh week,<sup>1</sup> when placental progesterone production is sufficient. In the setting of assisted reproductive technologies (ART), luteal phase dysfunction is a common side effect. The exact cause of this is still unclear, but possible explanations include hypothalamic suppression of gonadotropin-releasing hormone (GnRH), pituitary down-regulation or blockade of GnRH receptors, and disruption of granulosa cell mass during oocyte retrieval. Exogenous progesterone administration has been used successfully in IVF to overcome this deficiency, and failure to use progesterone for luteal phase support results in low pregnancy rates between 0% and 18%.<sup>2</sup> While it is clear that progesterone support is needed in patients undergoing ART, there is significant debate regarding the optimal dose, timing, and route of administration.<sup>3</sup> Exogenous support for an early pregnancy (until 10 weeks) requires 100 mg of progesterone daily, associated with a maternal circulating level of approximately 10 ng/mL.<sup>4</sup> Despite this requirement, patients pregnant after ovarian stimulation with one of the techniques of assisted reproductive technology have concluded a successful pregnancy after experiencing extremely low progesterone levels.<sup>5,6</sup> Thus, individual variation is great, and very low circulating levels of progesterone can be encountered occasionally in women who experience normal pregnancies. The predictive value, therefore, of progesterone measurements is limited.

In the luteal phase of conception cycles, progesterone concentrations increase from about 1–2 ng/mL on the day of the LH surge to a plateau of approximately 10–35 ng/mL over the subsequent 7 days. The concentrations remain within this luteal phase range until the placenta takes over. After a transition period of shared function between the 7th week and 10th week called the luteal-placental shift, the placenta emerges as the major source of progesterone synthesis, and maternal circulating levels progressively increase

(Figure 7.2).<sup>4,7,8</sup> At term, progesterone levels range from 100 to 200 ng/mL, and the placenta produces about 250 mg/day. Most of the progesterone produced in the placenta enters the maternal circulation.

**FIGURE 7.2**

In contrast to estrogen, progesterone production by the placenta is largely independent of the quantity of precursor available, the uteroplacental perfusion, fetal well-being, or even the presence of a live fetus. This is because the fetus contributes essentially no precursor. The majority of placental progesterone is derived from maternal cholesterol that is readily available. This is evident as progesterone levels remain high even after fetal demise. At term, a small portion (3%) is derived from maternal pregnenolone.

The cholesterol utilized for progesterone synthesis enters the trophoblast from the maternal bloodstream as low-density lipoprotein (LDL) cholesterol, by means of the process of endocytosis (internalization, as described in Chapter 1) involving the LDL cell membrane receptors, a process enhanced in pregnancy by estrogen (Figure 7.1).<sup>9,10</sup> Hydrolysis of the protein component of LDL may yield amino acids for the fetus, and essential fatty acids may be derived from hydrolysis of the cholesteryl esters. Unlike

steroidogenesis elsewhere, it is not clear whether placental progesterone production requires the control of tropic hormones. Although some evidence suggests that tropic hormone support is not necessary, other evidence indicate that a small amount of hCG must be present.<sup>11,12</sup>

There is evidence in the baboon that estrogen (estradiol) regulates progesterone production in the placenta.<sup>13</sup> The fetoplacental units in human and baboon pregnancies are virtually identical. Estradiol increases LDL cholesterol uptake in baboon trophoblastic tissue by increasing LDL receptor gene transcription, and in human syncytiotrophoblast, estradiol increases progesterone production by means of an increase in LDL uptake.<sup>13,14</sup> Estrogen also stimulates cholesterol production in the human fetal liver to provide circulating LDL cholesterol substrate for steroidogenesis.<sup>15</sup> In addition, estrogen increases placental P450<sub>scc</sub> enzyme activity that converts cholesterol to pregnenolone, the immediate precursor for progesterone. Because estrogen production ultimately depends on the fetal adrenal gland for precursors, the influence of estrogen on progesterone production would be another example of fetal direction and control in the endocrinology of pregnancy. The proponents of this interaction and dependence of progesterone production on fetal precursors argue that the lack of impact by conditions of estrogen deficiency (e.g., anencephaly, fetal demise) on progesterone production is due to the fact that active, unbound estrogen remains within a critical, effective range, and what is lost reflects the degree of excess production in pregnancy.<sup>13</sup>

The human decidua and fetal membranes also synthesize and metabolize progesterone.<sup>16</sup> In this case, neither cholesterol nor LDL cholesterol are significant substrates; pregnenolone sulfate may be the most important precursor. This local steroidogenesis may play a role in regulating parturition.

Amniotic fluid progesterone concentration is maximal between 10 and 20 weeks and then decreases gradually. Myometrial levels are about 3 times higher than maternal plasma levels in early pregnancy, remain high, and are about equal to the maternal plasma concentration at term.

In early pregnancy, the maternal levels of 17 $\alpha$ -hydroxyprogesterone rise, marking the activity of the corpus luteum. By the 10th week of gestation, this compound has returned to baseline levels, indicating that the placenta has little 17 $\alpha$ -hydroxylase activity. However, beginning about the 32nd week, there is a second, more gradual rise in 17 $\alpha$ -hydroxyprogesterone, due to placental utilization of fetal D5-sulfoconjugated precursors, to approximately 7 ng/mL, a level that persists until term.<sup>17</sup>

There are two active metabolites of progesterone that increase significantly during pregnancy. There is about a 10-fold increase of the 5 $\alpha$ -reduced metabolite, 5 $\alpha$ -

pregnane-3-20-dione.<sup>18</sup> This compound contributes to the resistance in pregnancy against the vasopressor action of angiotensin II. The circulating level, however, is the same in normal and hypertensive pregnancies. The maternal blood concentration of deoxycorticosterone (DOC) at term is 1,200 times the nonpregnant levels. Some of this is due to the 3- to 4-fold increase in cortisol-binding globulin during pregnancy, but a significant amount is due to 21-hydroxylation of circulating progesterone in the kidney.<sup>19</sup> This activity is significant during pregnancy because the rate is proportional to the circulating concentration of progesterone. The fetal kidney is also active in 21-hydroxylation of the progesterone secreted by the placenta into the fetal circulation. Currently, there is no known physiologic role for DOC during pregnancy.

Progesterone has a role in parturition as discussed later in this chapter. It has been suggested that progesterone is also important in suppressing the maternal immunologic response to fetal antigens, thereby preventing maternal rejection of the trophoblast. And, of course, progesterone prepares and maintains the endometrium to allow implantation. The human corpus luteum makes significant amounts of estradiol, but it is progesterone and not estrogen that is required for successful implantation.<sup>20</sup> Because implantation normally occurs about 5–6 days after ovulation, and hCG must appear by the 10th day after ovulation to rescue the corpus luteum, the blastocyst must successfully implant and secrete hCG within a narrow window of time. In the first 5–6 weeks of pregnancy, hCG stimulation of the corpus luteum results in the daily secretion of about 25 mg of progesterone and 0.5 mg of estradiol. Although estrogen levels begin to increase at 4–5 weeks due to placental secretion, progesterone production by the placenta does not significantly increase until about 10–11 weeks after ovulation.

Progesterone serves as the substrate for fetal adrenal gland production of glucocorticoids and mineralocorticoids; however, cortisol synthesis is also derived from LDL cholesterol synthesized in the fetal liver and obtained from the fetal circulation.<sup>15,21</sup> The fetal zone in the adrenal gland is extremely active but produces steroids with a  $3\beta$ -hydroxy- $\Delta^5$  configuration like pregnenolone and dehydroepiandrosterone (DHEA), rather than 3-keto- $\Delta^4$  products such as progesterone. The fetus, therefore, lacks significant activity of the  $3\beta$ -C,  $\Delta^{4,5}$  isomerase system. Thus, the fetus must borrow progesterone from the placenta to circumvent this lack in order to synthesize the biologically important corticosteroids. In return, the fetus supplies what the placenta lacks: 19-carbon compounds to serve as precursors for estrogens.

Steroid levels have been compared in maternal blood, fetal blood, and amniotic fluid obtained at fetoscopy in women undergoing termination of pregnancy at 16–20 weeks of gestation.<sup>22</sup> Cortisol, corticosterone, and aldosterone are definitely secreted by the fetal adrenal gland independently of the mother. The fetal arteriovenous differences confirm that placental progesterone is a source for fetal adrenal cortisol and

aldosterone.

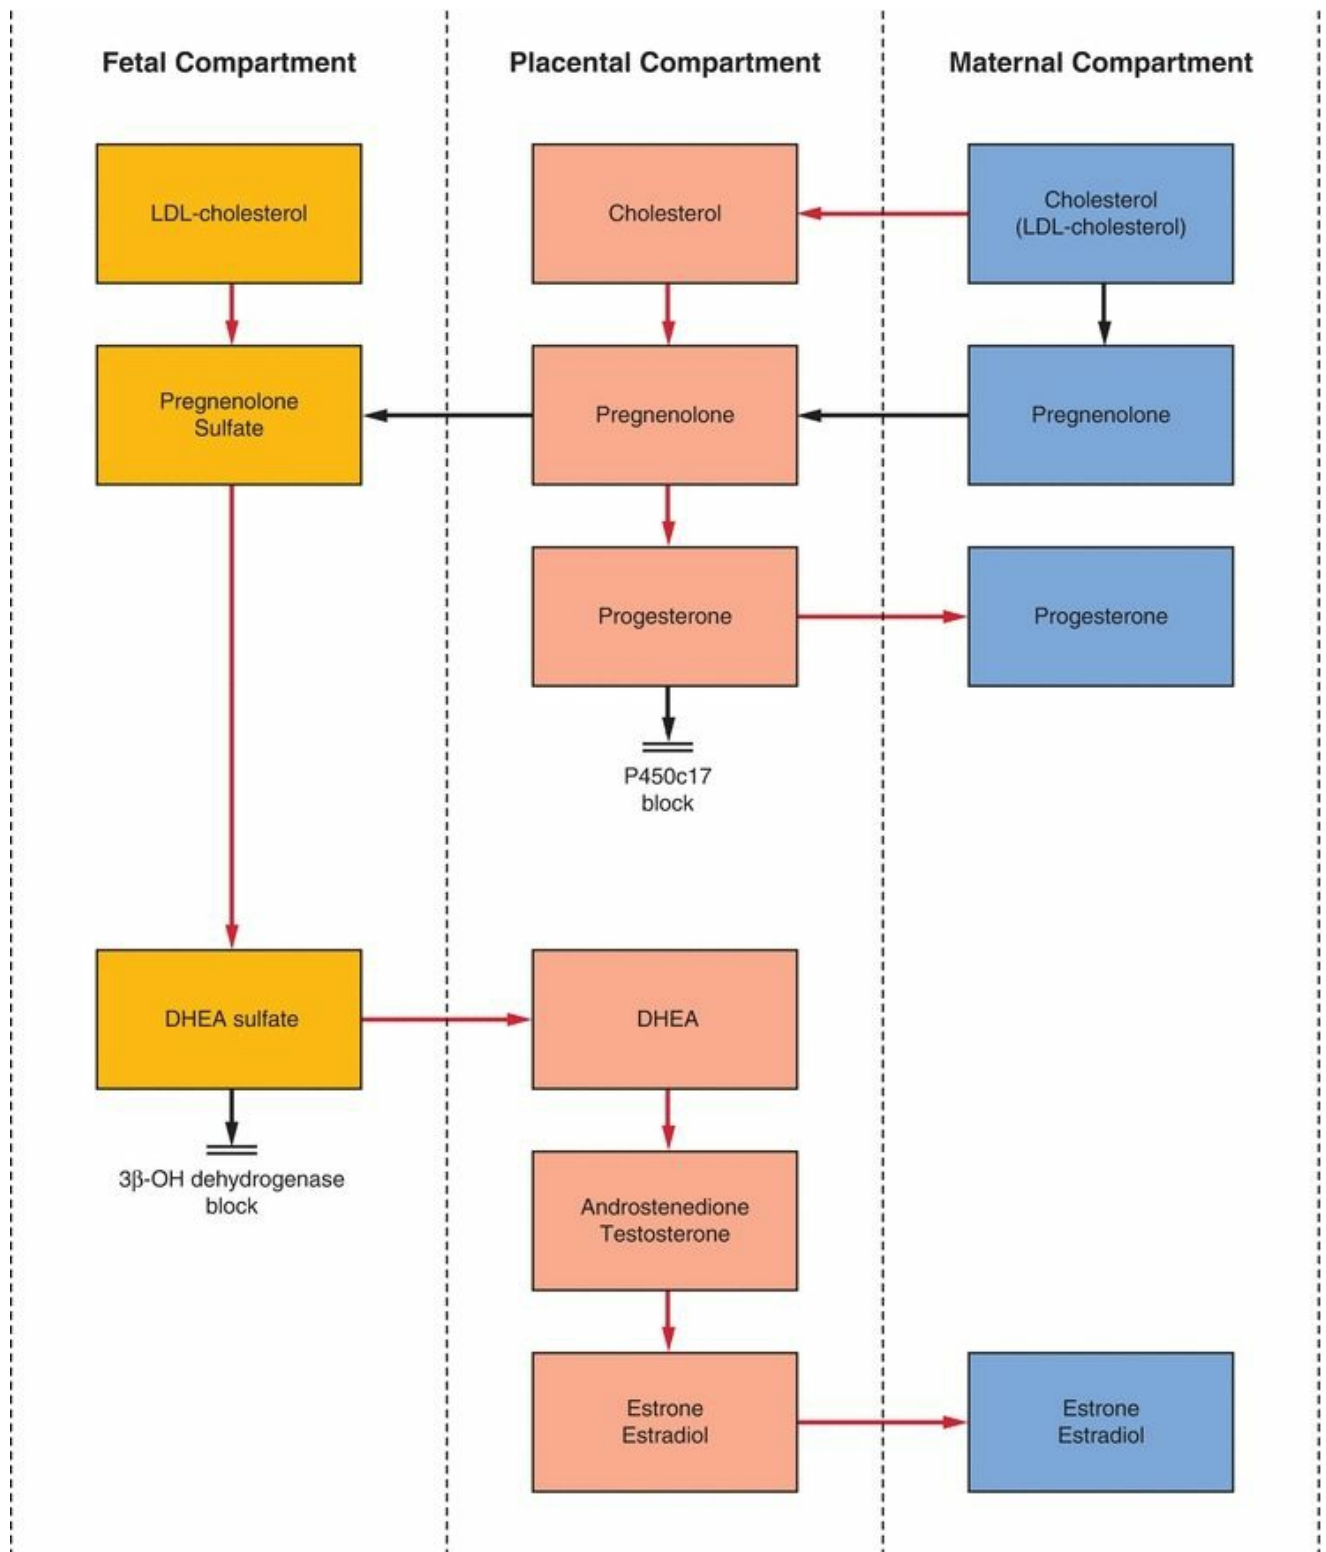

# Estrogens

The corpus luteum is the exclusive source of  $17\beta$ -estradiol during the first 5–6 weeks of gestation. After the first trimester, the placenta becomes the major source of circulating  $17\beta$ -estradiol.<sup>8</sup> Estrogen production in pregnancy is under the control of the fetus and is a fundamental signaling method by which the fetus directs important physiologic processes that affect fetal well-being. Estrogen influences progesterone production, uteroplacental blood flow, mammary gland development, and fetal adrenal gland function.<sup>13</sup>

The basic precursors of estrogens are 19-carbon androgens. However, there is a virtual absence of  $17\alpha$ -hydroxylation and 17,20 desmolase (lyase) activity (P450c17) in the human placenta. As a result, 21-carbon products (progesterone and pregnenolone) cannot be converted to 19-carbon steroids (androstenedione and DHEA). Like progesterone, estrogen produced by the placental aromatase (P450arom) enzyme system must derive precursors from outside the placenta.<sup>23</sup>

The androgen compounds utilized for estrogen synthesis in human pregnancy are, in the early months of gestation, derived from the maternal bloodstream. By the 20th week of pregnancy, the vast majority of estrogen excreted in the maternal urine is derived from fetal androgens. In particular, approximately 90% of estriol excretion can be accounted for by dehydroepiandrosterone sulfate (DHEAS) production by the fetal adrenal gland.<sup>23,24</sup> The high output of DHEAS by the fetal zone is due to low  $3\beta$ -hydroxysteroid dehydrogenase gene expression.<sup>25</sup> Removed from these conditions, this gene becomes active in response to adrenocorticotrophic hormone (ACTH).

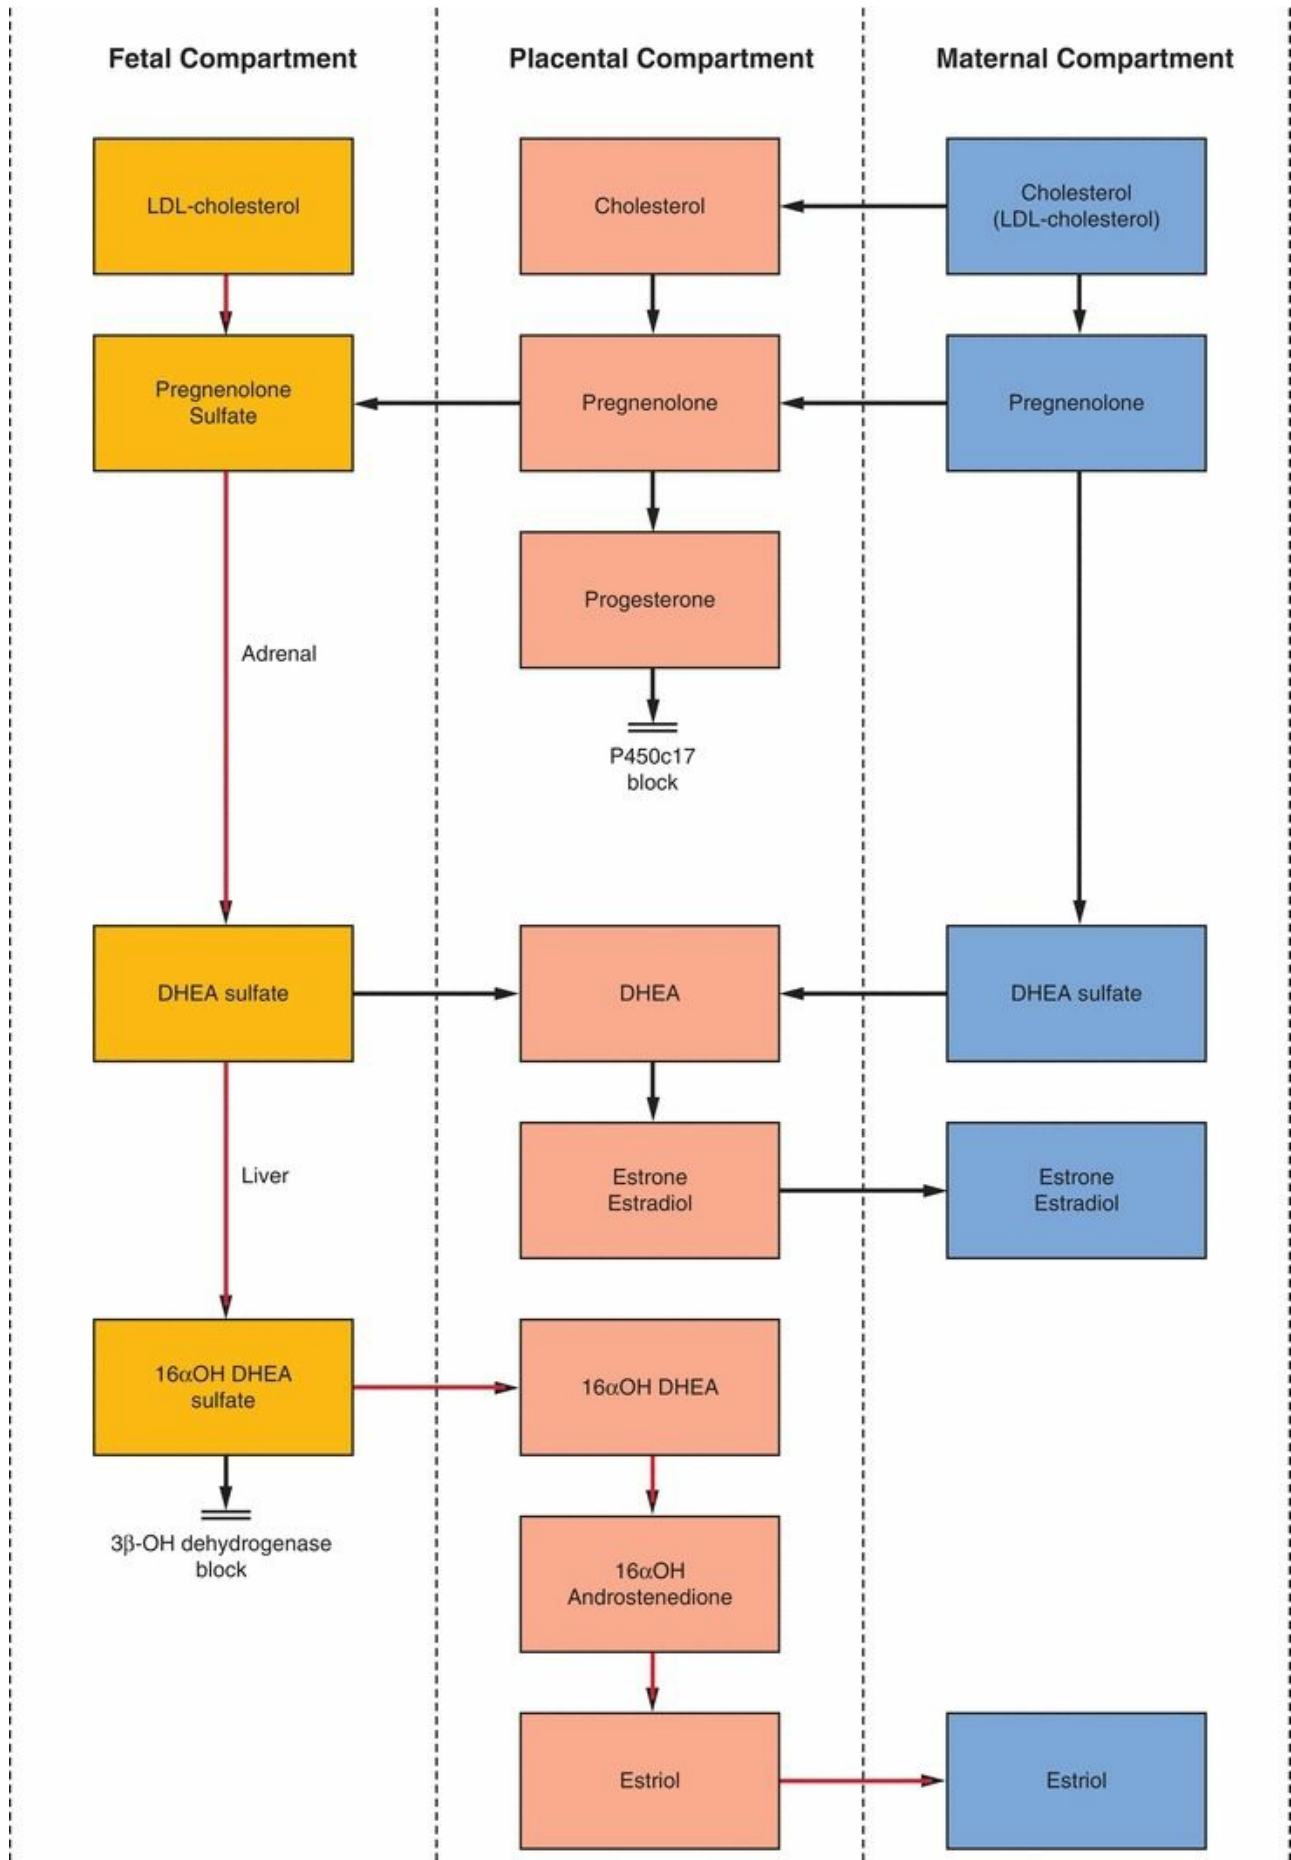

The major source of fetal adrenal DHEAS is LDL cholesterol circulating in the fetal blood. A minor source of fetal adrenal DHEAS is derived from pregnenolone secreted by the placenta. The fetal endocrine compartment is characterized by rapid and extensive conjugation of steroids with sulfate. This is a protective mechanism, blocking the biologic effects of potent steroids present in such great quantities. In order to utilize fetal precursors, the placenta must be extremely efficient in cleaving the sulfate conjugates brought to it via the fetal bloodstream (**Figure 7.3**). Indeed, the sulfatase activity in the placenta is rapid and quantitatively very significant. It is recognized that a deficiency in placental sulfatase is associated with low estrogen excretion, giving clinical importance to this metabolic step. This syndrome is discussed in greater detail later in this chapter.

**FIGURE 7.3**

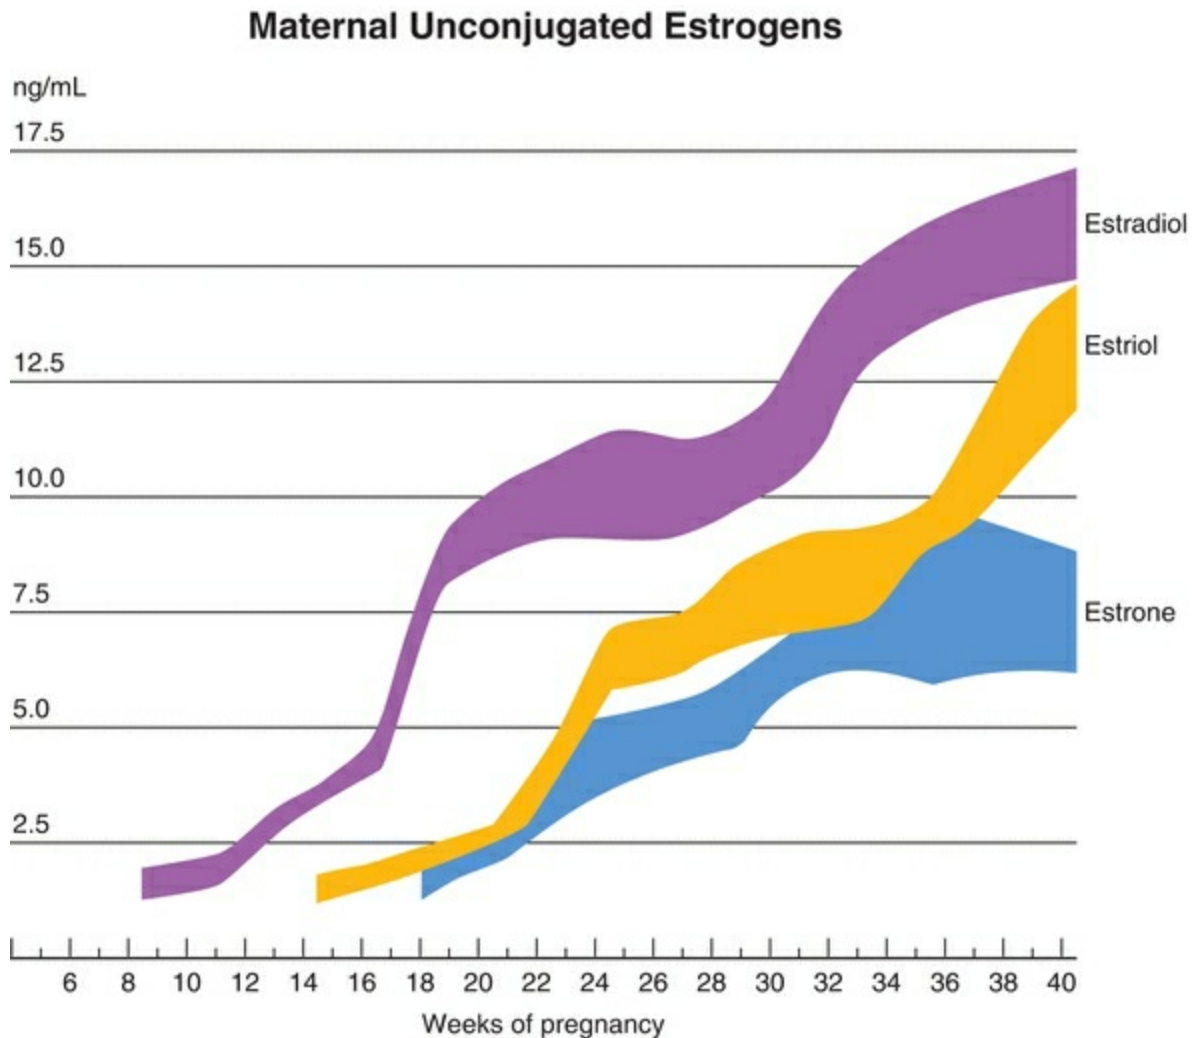

The fetal adrenal provides DHEAS as a precursor for placental production of estrone and estradiol. However, the placenta lacks 16 $\alpha$ -hydroxylation ability, and estriol with its 16 $\alpha$ -hydroxyl group must be derived from an immediate fetal precursor. The fetal

adrenal, with the aid of  $16\alpha$ -hydroxylation in the fetal liver, provides the  $16\alpha$ -hydroxydehydroepiandrosterone sulfate for placental estriol formation (**Figure 7.4**). After birth, neonatal hepatic  $16\alpha$ -hydroxylation activity rapidly disappears. The maternal contribution of DHEAS to total estrogen synthesis must be negligible because, in the absence of normal fetal adrenal glands (as in an anencephalic infant), maternal estrogen levels and excretion are extremely low. The fetal adrenals secrete more than 200 mg of DHEAS daily, about 10 times more than the mother.<sup>26</sup> Estriol is the estrogen produced in greatest quantity during pregnancy; estrone and estradiol are derived equally from fetal and maternal precursors.<sup>24</sup>

## FIGURE 7.4

The profiles of the unconjugated compounds in the maternal compartment for the three major estrogens in pregnancy are as follows (Figure 7.5):

## FIGURE 7.5

1. A rise in estrone begins at 6–10 weeks, and individual values range from 2 to 30 ng/mL at term.<sup>27</sup> This wide range in normal values precludes the use of estrone measurements in clinical applications.
2. A rise in estradiol begins in weeks 6–8 when placental function becomes apparent.<sup>4</sup> Individual estradiol values vary between 6 and 40 ng/mL at 36 weeks of gestation and then undergo an accelerated rate of increase.<sup>27</sup> At

**term, an equal amount of estradiol arises from maternal DHEAS and fetal DHEAS, and its importance in fetal monitoring is negligible.**

- 3. Estriol is first detectable at 9 weeks when the fetal adrenal gland secretion of precursor begins. This temporal relationship closely corresponds to the early stages of steroidogenic maturation in the fetal adrenal cortex, and the continued production of estriol is dependent upon the presence of a living fetus. Estriol is first detectable at approximately 0.05 ng/mL by 9 weeks and steadily increases to a range of approximately 10–30 ng/mL at term. Estriol concentrations plateau at 31–35 weeks and then increase again at 35–36 weeks.**<sup>28</sup>

During pregnancy, estrone and estradiol production is increased about 100 times over nonpregnant levels. However, the increase in maternal estriol excretion is about a 1,000-fold. The traditional view that estriol in pregnancy is a weak estrogen metabolite is not accurate. A weak estrogen provided in high concentrations can produce a biologic response equivalent to that of estradiol.<sup>29</sup> Because of its high production rate and concentration, estriol is an important hormone in pregnancy. The maternal level of estradiol is higher than in the fetus; in contrast, the estriol level in the fetus is greater than in the mother.

The maternal cardiovascular adaptations to pregnancy that are so necessary to serve the fetus are appropriately under the influence of the fetus and significantly regulated by estrogen.<sup>30</sup> Blood volume is increased by estrogen stimulation of the maternal and trophoblastic renin-angiotensin systems, and uteroplacental blood flow, which is so critical for the fetus, is influenced by the vasodilatory effects of estrogen.

The enzyme responsible for estrogen synthesis is the cytochrome P-450 aromatase enzyme (P450arom or aromatase), the product of the CYP19 gene.<sup>31</sup> The CYP19 gene is regulated in various tissues by tissue-specific promoters. The placenta, with its huge capacity for estrogen synthesis, triggers aromatase transcription from a powerful unique promoter that allows specific regulation. An autosomal recessive disorder due to mutations in the P450arom gene is associated with a failure to convert androgen precursors to estrogen by placental aromatase.<sup>32</sup> Consequently, a female fetus and the mother can undergo virilization. Nevertheless, growth and development of the fetus are not impaired, and this disorder raises the question: How much, if any, estrogen is essential in human pregnancy? Is this another example of backup mechanisms operating to achieve the goal?

Normally, placental aromatization is so efficient that little androgen presented to the placenta escapes.<sup>33</sup> For this reason, fetuses are well protected against masculinization, and even in the presence of an androgen-secreting tumor, extremely large amounts of

aromatizable androgens or the secretion of nonaromatizable androgens is required to produce unwanted virilization.

The estrogens presented to the maternal bloodstream are rapidly metabolized by the maternal liver prior to excretion into the maternal urine as a variety of more than 20 products. The bulk of these maternal urinary estrogens is composed of glucosiduronates conjugated at the 16 position. Significant amounts of the 3-glucosiduronate and the 3-sulfate-16-glucosiduronate are also excreted. Only approximately 8–10% of the maternal blood estriol is unconjugated.

# The Fetal Adrenal Cortex

The fetal adrenal cortex is unique, differentiating by 8–9 weeks of gestational age into a thick inner fetal zone and a thin outer definitive zone, which is the source of cortisol and the forerunner of the adult cortex.<sup>34</sup> Early in pregnancy, adrenal growth and development are remarkable, and the gland achieves a size equal to or larger than that of the kidney by the end of the first trimester. After 20–24 weeks, the adrenal glands slowly decrease in size until a second spurt in growth begins at about 34–35 weeks. The gland remains proportionately larger than the adult adrenal glands. After delivery, the fetal zone (about 85% of the bulk of the gland) rapidly involutes to be replaced by simultaneous expansion of the outer definitive zone to form the zona glomerulosa and the transitional zone to form the zona fasciculata and the zona reticularis (which expands again during adrenarche at puberty). By age 1, the fetal zone is gone, replaced by the adult adrenal cortex. Thus, the specific steroidogenic characteristics of the fetus are associated with a specific adrenal morphology that is dependent on specific factors present during intrauterine life.

Fetal DHEA and DHEAS production rises steadily concomitant with the increase in the size of the fetal zone and adrenal weight.<sup>35</sup> DHEA and DHEAS are the major secretory products of the fetal zone because  $3\beta$ -hydroxysteroid dehydrogenase-isomerase activity and the expression of this enzyme's gene are suppressed.<sup>25,36</sup> The well-known increase in maternal estrogen levels is significantly influenced by the increased availability of fetal DHEAS as a precursor. Indeed, the accelerated rise in maternal estrogen levels near term can be explained, in part, by an increase in fetal DHEAS. The stimulus for the substantial adrenal growth and steroid production has been a puzzle.

Early in pregnancy, the adrenal gland can grow and function without ACTH, perhaps in response to hCG.<sup>34</sup> After 15–20 weeks, fetal ACTH is required. However, during the last 12–14 weeks of pregnancy when fetal ACTH levels are declining, the adrenal quadruples in size.<sup>37</sup> Because pituitary prolactin is the only fetal pituitary hormone to increase throughout pregnancy, paralleling fetal adrenal gland size changes, it was proposed that fetal prolactin is the critical tropic substance. In experimental preparations, however, only ACTH exerts a steroidogenic effect. There is no fetal adrenal response to prolactin, hCG, growth hormone, melanocyte-stimulating hormone (MSH), or thyrotropin-releasing hormone (TRH).<sup>38,39</sup> Furthermore, in patients treated with bromocriptine, fetal blood prolactin levels are suppressed, but DHEAS levels are unchanged.<sup>40</sup> Nevertheless, interest in prolactin persists because both ACTH and prolactin can stimulate steroidogenesis *in vivo* in the fetal baboon.<sup>41</sup>

There is no question that, in the second half of pregnancy, ACTH is essential for the

morphologic development and the steroidogenic mechanism of the fetal adrenal gland.<sup>42,43</sup> ACTH activates adenylate cyclase, leading to steroidogenesis. Soon, the supply of cholesterol becomes rate limiting. Further ACTH action results in an increase in LDL receptors, leading to an increased uptake of circulating LDL cholesterol, largely derived from the fetal liver.<sup>21</sup> With internalization of LDL cholesterol, hydrolysis by lysosomal enzymes of the cholesteryl ester makes cholesterol available for steroidogenesis. For this reason, fetal plasma levels of LDL are low, and after birth, newborn levels of LDL rise as the fetal adrenal involutes. In the presence of low levels of LDL cholesterol, the fetal adrenal is capable of synthesizing cholesterol de novo.<sup>44</sup> Thus, near term, both de novo synthesis and utilization of circulating LDL cholesterol are necessary to sustain the high rates of DHEAS and estrogen formation. In addition, ACTH increases adrenal response by increasing the expression of its own receptor.<sup>45</sup>

The tropic support of the fetal adrenal gland by ACTH from the fetal pituitary is protected by placental estrogen. The placenta prevents cortisol that is present in higher levels in the mother from reaching the fetus by converting cortisol to cortisone. The converting enzyme, 11 $\beta$ -hydroxysteroid dehydrogenase, is abundantly expressed in syncytiotrophoblast at the interface between fetal tissue and maternal blood and is stimulated by placental estrogen.<sup>46,47</sup> Regulation of this enzyme by estrogen thus influences fetal ACTH secretion. With increasing estrogen levels in late gestation, even greater 11 $\beta$ -hydroxysteroid dehydrogenase activity would result in even less maternal cortisol reaching the fetal circulation. Thus, it is proposed that near labor, fetal ACTH secretion increases, the fetal adrenal gland undergoes greater maturation, and fetal cortisol synthesis from endogenous cholesterol increases.<sup>48</sup> A relative deficiency in 11 $\beta$ -hydroxysteroid dehydrogenase type 2 (the high-affinity isoform) would expose the fetus to excessively high cortisol levels and is correlated with low birth weight, which in turn is correlated with insulin resistance, abnormal lipids, and hypertension in adult life.<sup>49,50,51</sup> A reduction of type 2 11 $\beta$ -hydroxysteroid dehydrogenase activity has been reported in pregnancies complicated by smoking and pre-eclampsia, conditions known to be associated with intrauterine growth retardation.<sup>52,53</sup> A similar reduction in activity has been documented with idiopathic intrauterine growth retardation, accompanied by a decreased ratio of cortisone to cortisol in umbilical artery blood.<sup>51</sup>

An interaction has been demonstrated in vitro between progesterone and the lipoxygenase pathways that lead to the products of arachidonic acid other than prostaglandins in regard to the regulation of 11 $\beta$ -hydroxysteroid dehydrogenase activity.<sup>54</sup> Progesterone down-regulates 11 $\beta$ -hydroxysteroid dehydrogenase expression, as do the products of lipoxygenase activity. Because the lipoxygenase products increase progesterone output by trophoblast cells, an increase in lipoxygenase activity because of infection could increase progesterone levels, which in turn would decrease 11 $\beta$ -

hydroxysteroid dehydrogenase activity, resulting in higher cortisol levels in the fetus with the consequences of stress and growth retardation.

It has been suggested that the increase in fetal cortisol secretion during normal pregnancy competes with progesterone for the glucocorticoid receptor in the placenta, thus blocking the inhibitory action of progesterone on corticotropin-releasing hormone (CRH) synthesis, leading to an increase in CRH.<sup>55</sup> Placental production of CRH and the size of the fetal adrenal gland are closely correlated in several primates, both reaching a peak in humans at the time of parturition. The increase in CRH would augment fetal ACTH secretion, producing adrenal growth and even more fetal cortisol in a positive feedback relationship, as well as more DHEAS to serve as precursor for the increase in estrogen that occurs prior to parturition. However, fetal ACTH levels in the last half of pregnancy are not increasing but slightly decreasing. It is significant that CRH, as demonstrated in vitro, also directly stimulates DHEAS synthesis by the fetal adrenal gland.<sup>56,57</sup>

This is an important fetoplacental-adrenal cycle. Cortisol from the adrenal gland increases placental CRH production; CRH induces ACTH receptor expression in the definitive zone of the fetal adrenal gland, leading to even greater adrenal cortisol secretion, and that in turn increases placental CRH biosynthesis as gestation advances.<sup>58</sup> Direct stimulation of the fetal zone by CRH, supported by the presence of ACTH, augments the increasing production of DHEA and DHEAS required for estrogen synthesis in late gestation.<sup>57</sup>

Adrenal gland steroidogenesis involves autocrine and paracrine regulation by various growth factors.<sup>34</sup> Fetal adrenal cells produce inhibin, and the  $\alpha$  subunit (present only in inhibin) is preferentially increased by ACTH.<sup>59,60</sup> In the fetal adrenal, the  $\beta$  subunit is not expressed; thus, inhibin-A and activin-A are the principal forms.

Activin enhances ACTH-stimulated steroidogenesis while inhibiting mitogenesis in human fetal zone adrenal cells.<sup>60</sup> This effect on steroidogenic activity is not present in adult adrenal cells. In vitro, activin enhances a shift in fetal adrenal cells from ACTH stimulation of DHEAS production to cortisol production. This shift is analogous to the shift that occurs after birth. Perhaps, activin plays this role in the remodeling of the fetal zone in the newborn. A specific action for inhibin in fetal adrenal cells has not been described.

We should not expect the fetal adrenal gland to be an exception to the ubiquitous presence and actions of all growth factors.<sup>34</sup> Basic fibroblast growth factor has potent mitogenic activity mediating the growth response of the fetal adrenal cortex to ACTH. Evidence indicates that the epidermal growth factor (EGF) receptor is activated in the fetal adrenal, but the ligand using this receptor is probably transforming growth factor-

$\alpha$ . Like activin, transforming growth factor- $\beta$  inhibits fetal zone cellular proliferation and, in addition, suppresses steroidogenesis.

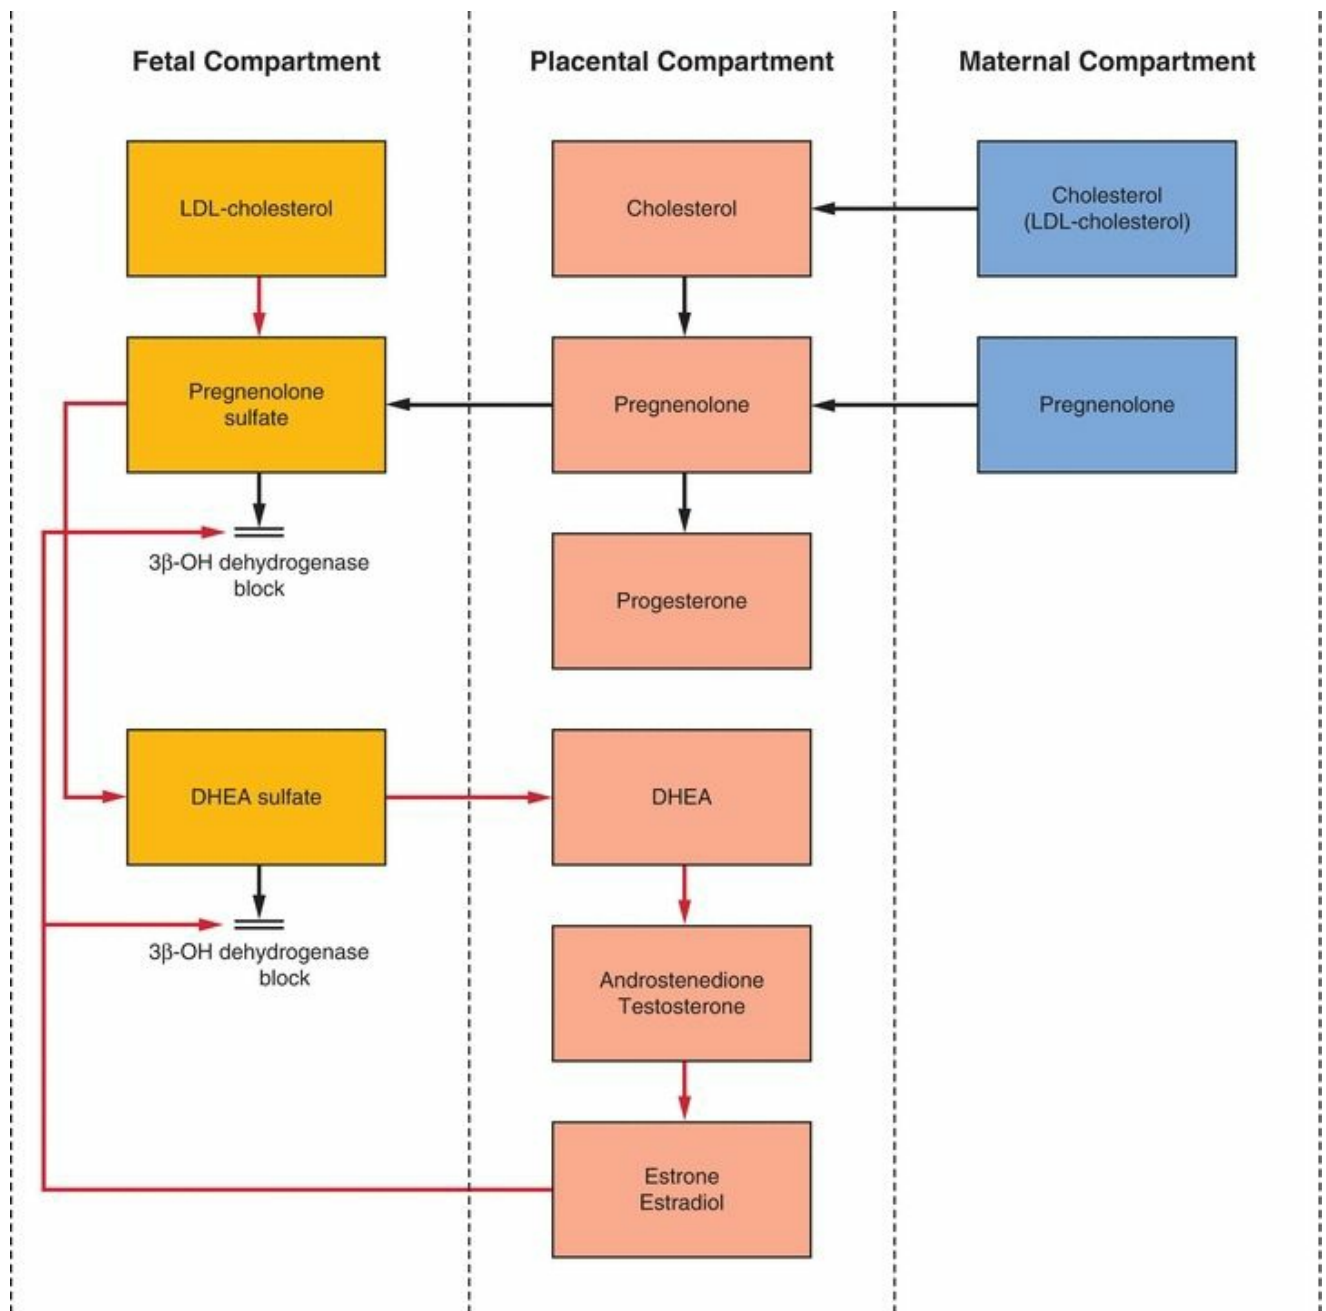

The insulin-like growth factors (IGF-I and IGF-II) are important in mediating the tropic effects of ACTH, particularly increasing adrenal responsiveness to ACTH in the second half of pregnancy.<sup>61</sup> IGF-II production in the fetal adrenal is very significant and is stimulated by ACTH. IGF-II is believed to be important in prenatal growth.<sup>62</sup> The abundance of IGF-II in the fetal adrenal gland implicates this growth factor as a mediator of ACTH-induced growth.<sup>63</sup> Both IGF-I and IGF-II are equally mitogenic in a cell culture system of fetal adrenal cells and enhance the proliferation stimulated by basic fibroblast growth factor and EGF.<sup>63</sup> However, only transcription of IGF-II is stimulated by ACTH. IGF-II augments ACTH-stimulated steroidogenesis in the fetal adrenal, specifically by increasing the expression of P450c17.<sup>61</sup> Thus, the growth-promoting and steroidogenic effects of ACTH are mediated by various growth factors, with a principal role played by IGF-II. In this regard, the fetal adrenal differs from the adult adrenal where IGF-I is predominant; however, IGF-II is able to modulate responsiveness to ACTH in the fetal adrenal by activating the IGF-I receptor.

Steroidogenic factor-1 (SF-1) and DAX-1 (named for the location of its gene on the X chromosome) are nuclear receptors for which specific ligands have not been identified (“orphan receptors”). SF-1 influences the expression of genes that encode steroidogenic enzymes, and when genetic expression of SF-1 is disrupted in mice, gonads and adrenal glands fail to develop.<sup>64,65</sup> Mutations in the DAX-1 gene result in adrenal hypoplasia, and DAX-1 is believed to work with SF-1 in regulating development and function of steroid-producing tissues.<sup>66</sup>

The production of DHEA is dependent on the CYP17 gene that is responsible for both 17 $\alpha$ -hydroxylase and 17,20-lyase enzyme activity. Differential regulation of these two activities with an increase in 17,20-lyase could account for the increase in DHEA in the fetal zone of the adrenal gland. The SULT2A1 gene is responsible for the sulfation and production of DHEAS. Modulation of this gene would also contribute to the steroidogenic activity of the fetal zone.

The unique features of the fetal adrenal gland can be ascribed to its high-estrogen environment. Tissue culture studies have demonstrated that hormonal peptides of pituitary or placental origin are not the factors that are responsible for the behavior of the fetal adrenal gland.<sup>67,68,69</sup> Estrogens at high concentration inhibit 3 $\beta$ -hydroxysteroid dehydrogenase-isomerase activity in the fetal adrenal gland and, in the presence of ACTH in conjunction with IGF-II, enhance the secretion of DHEA.<sup>70</sup> Estradiol concentrations of 10–100 ng/mL are required to inhibit cortisol secretion.<sup>71</sup> The total estrogen concentrations in the fetus are easily in this range (**Figure 7.5**). A study of the

kinetics of  $3\beta$ -hydroxysteroid dehydrogenase activity in human adrenal microsomes reveals that all steroids are inhibitory and, most notably, estrone and estradiol at levels found in fetal life cause almost total inhibition.<sup>72</sup> In a study utilizing a human adrenocortical cell line, estradiol in high concentrations inhibited  $3\beta$ -hydroxysteroid dehydrogenase, and the mechanism appeared to be independent of the estrogen receptor.<sup>73</sup> The increase in DHEAS secretion by the fetal zone is a consequence of suppression of the gene (HSD3B2) that controls  $3\beta$ -hydroxysteroid dehydrogenase expression; transcriptional factors necessary for the activity of this gene are absent in the fetal zone (Figure 7.6).<sup>74</sup>

## FIGURE 7.6

The development of the adrenal gland during human fetal life and during the neonatal period is paralleled in the baboon.<sup>75</sup> The adrenal cortex of the fetal baboon is characterized by the same deficiency in  $3\beta$ -hydroxysteroid dehydrogenase as that seen in the human, with the same diversion of steroidogenesis into production of DHEA and DHEAS. Experimental studies in the baboon suggest that placental estrogen maintains the production of DHEA and DHEAS by the fetal adrenal cortex, but excessive adrenal growth and steroidogenesis are at the same time suppressed by the increasing estrogen levels in late pregnancy.<sup>76,77</sup>

Tissue growth in mammals is a consequence of cellular proliferation promoted by the cell regulators, cyclin D1 and cyclin E, which dimerize with kinases to form enzymes that carry out key phosphorylations during cell cycles. These key regulators are expressed in increasingly high concentrations in the baboon fetal adrenal cortex, beginning in early gestation to midgestation, especially in the outer definitive zone (destined to be the adult adrenal cortex and the source of cortisol).<sup>78</sup> This early increase in the definitive zone is followed by a progressive decrease in these factors required for cellular proliferation in the definitive zone in late gestation. The cells in the fetal zone are derived from the definitive zone, and these changes indicate that the continued growth of the fetal adrenal cortex during gestation predominantly reflects cellular hypertrophy. Furthermore, because there is a progressive increase in the expression of  $3\beta$ -hydroxysteroid dehydrogenase within the fetal definitive zone, the decline in proliferation is associated with functional differentiation as the definitive zone acquires the ability to produce mineralocorticoids and glucocorticoids.<sup>78</sup> Here again, the key modulator of this change may be estrogen, specifically an estrogen-induced decrease in cyclin expression with advancing gestation.

The explanation that estrogen regulates  $3\beta$ -hydroxysteroid dehydrogenase is challenged by in vitro studies of human fetal zone cells indicating that estradiol and IGF-II combine to direct steroidogenesis to DHEAS in a mechanism not due to inhibition of  $3\beta$ -hydroxysteroid dehydrogenase.<sup>70</sup> **Nevertheless, it is an attractive and useful hypothesis to view the principal mission of the fetal adrenal as providing DHEAS as the basic precursor for placental estrogen production. Estrogen, in turn, feeds back to the adrenal to direct steroidogenesis along the  $\Delta^5$  pathway to provide even more of its precursor, DHEAS. Thus far, this is the only known function of DHEAS. With birth and loss of exposure to estrogen, the fetal adrenal gland quickly changes to the adult type of gland. It seems reasonable to conclude that this complex change in the fetal adrenal cortex is orchestrated by the interplay**

**among fetal pituitary ACTH, placental estrogen, and placental growth factors (PLGFs).**

# Measurement of Estrogen in Pregnancy

Because pregnancy is characterized by a great increase in maternal estrogen levels and estrogen production is dependent on fetal and placental steroidogenic cooperation, the amount of estrogen present in the maternal blood or urine reflects both fetal and placental enzymatic capability and, hence, well-being. Attention focused on estriol because 90% of maternal estriol is derived from fetal precursors. The end product to be assayed in the maternal blood or urine is influenced by a multitude of factors. Availability of precursor from the fetal adrenal gland is a prime requisite, as well as the ability of the placenta to perform its conversion steps. Maternal metabolism of the product and the efficiency of maternal renal excretion of the product can modify the daily amount of estrogen in the urine. Blood flow to any of the key organs in the fetus, placenta, and mother becomes important.<sup>79,80</sup> Fetal hypoxemia due to acute reductions in uteroplacental blood flow is associated with a marked increase in adrenal androgen production in response to an increase in fetal ACTH and, in response to the availability of androgen precursors, an increase in maternal estrogen levels.<sup>81</sup> The response to acute stress is in contrast to the effect of chronic uteroplacental insufficiency, which is associated with a reduction in fetal androgens and maternal estrogens. In addition, drugs or diseases can affect any level in the cascade of events leading up to the assay of estrogen.

For years, measurement of estrogen in a 24-hour urine collection was the standard hormonal method of assessing fetal well-being. This was replaced by immunoassay of unconjugated estriol in the plasma.<sup>82</sup> Because of its short half-life (5–10 minutes) in the maternal circulation, unconjugated estriol has less variation than urinary or total blood estriol. However, assessment of maternal estriol levels has been superseded by various biophysical fetal monitoring techniques such as nonstress testing, stress testing, and measurement of fetal breathing and activity. In recent times, screening for fetal aneuploidy (discussed later in the chapter) utilized three markers in the maternal circulation:  $\alpha$ -fetoprotein, hCG, and unconjugated estriol. Hormonal testing for aneuploidy screening has been largely replaced by cell-free DNA (cfDNA) testing.

## Amniotic Fluid Estrogen Measurements

Amniotic fluid estriol is correlated with the fetal estrogen pattern rather than the maternal. Most of the estriol in the amniotic fluid is present as 16-glucosiduronate or as 3-sulfate-16-glucosiduronate. A small amount exists as 3-sulfate. Very little unconjugated estriol is present in the amniotic fluid because free estriol is rapidly transferred across the placenta and membranes. Estriol sulfate is low in concentration because the placenta and fetal membranes hydrolyze the sulfated conjugates, and the free estriol is then passed out of the fluid. Because the membranes and the placenta have no

glucuronidase activity, the glucosiduronate conjugates are removed slowly from the fetus. The glucosiduronates, therefore, predominate in the fetal urine and the amniotic fluid. Because of the slow changes in glucosiduronates, measurements of amniotic fluid estriol have wide variations in both normal and abnormal pregnancies. An important clinical use for amniotic fluid estrogen measurements has not emerged.

## **Estetrol**

Estetrol (15 $\alpha$ -hydroxyestriol) is formed from a fetal precursor and is very dependent on 15 $\alpha$ -hydroxylation activity in the fetal liver. The capacity for 15 $\alpha$ -hydroxylation of estrogens increases during fetal life, reaching a maximum at term. This activity then declines during infancy and is low, absent, or undetectable in adults. Estetrol may contribute to the estrogen effects taking place during pregnancy as maternal estetrol levels steadily increase with advancing gestation and fetal levels are higher than maternal levels.<sup>83</sup> Because of wide variations within and between individuals, there is no clinical use for maternal blood or urine estetrol measurements during pregnancy. However, estetrol, given in sufficient doses, is a potent, orally active estrogen that has potential for pharmacologic therapy.<sup>84</sup>

# Placental Sulfatase Deficiency

Steroid sulfatase (STS) is a key enzyme in the biosynthesis of estriol in the human placenta. There is an X-linked metabolic disease characterized by a **placental sulfatase deficiency** in the syncytiotrophoblast and postnatal ichthyosis (also known as X-linked ichthyosis or XLI), occurring in about 1 in 2,000–3,000 newborn males.<sup>85</sup> Patients with the placental sulfatase disorder are unable to hydrolyze DHEAS or 16 $\alpha$ -hydroxy-DHEAS; therefore, the placenta cannot form normal amounts of estrogen. A deficiency in placental sulfatase is usually discovered when patients go beyond term and are found to have extremely low estriol levels and no evidence of fetal distress. The patients usually fail to go into labor and require delivery by cesarean section. Most striking is the failure of cervical softening and dilation; thus, cervical dystocia occurs that is resistant to oxytocin stimulation. There are many case reports of this deficiency, almost all detected by finding low estriol levels. It was suggested that mothers who are carriers of this disorder are at increased risk for intrauterine growth retardation and perinatal complications even if the fetus is not affected.<sup>86</sup> However, a careful analysis of unexplained low estriol levels concluded that this is a rare occurrence (about 3 per 10,000 pregnancies) and that perinatal complications in pregnancies at risk for placental sulfatase deficiency are not increased (other than a higher cesarean section rate).<sup>87</sup> XLI is inherited in X-linked recessive manner, therefore affecting almost exclusively males. However, rare cases of XLI were described in females homozygous for STS gene mutation.<sup>88,89</sup> The STS X-linked recessive ichthyosis locus (the STS gene) has been mapped to the distal short arm portion of the X chromosome, Xp22.32. Ninety percent of the cases of ichthyosis have a complete deletion of this gene plus flanking genes, and approximately 10% of patients have a point mutation or partial deletion of the STS gene. There are no known geographic or racial factors that affect the gene frequency. The characteristic steroid findings are as follows: extremely low estriol and estetrol levels in the mother with extremely high amniotic fluid DHEAS and normal amniotic fluid DHEA and androstenedione. The normal DHEA and androstenedione with a high DHEAS rule out congenital adrenal hyperplasia. The small amount of estriol that is present in these patients probably arises from 16 $\alpha$ -hydroxylation of DHEAS in the maternal liver, thus providing 16 $\alpha$ -hydroxylated DHEA to the placenta for aromatization to estriol. Maternal estrone and estradiol are also low but not as markedly reduced because of their utilization of maternal precursors. Measurement in maternal urine of steroids derived from fetal sulfated compounds is a simple and reliable means of prenatal diagnosis. Demonstration of a high level of DHEAS in the amniotic fluid is confirmatory. The diagnosis was established by demonstrating a decrease in sulfatase activity in an in vitro incubation of placental tissue. The clinician should keep in mind that fresh tissue is needed for this procedure because freezing lowers enzyme activity.

STS activity can be assayed in leukocytes and modern diagnosis is done by genetic testing of the STS gene.

It is now recognized that STS deficiency is present in other tissues and can persist after birth. These children develop ichthyosis beginning between birth and 6 months of age, characterized by hyperkeratosis (producing scales on the neck, trunk, and palms) and associated with mild corneal opacities, pyloric stenosis, and cryptorchidism. The skin fibroblasts have a low activity of STS, and scale formation that occurs early in the first year of life is thought to be due to an alteration in the cholesterol:cholesteryl ester ratio (due to the accumulation of cholesterol sulfate). This inherited disorder, thus, represents a single entity: placental sulfatase deficiency and X-linked ichthyosis, both reflecting a deficiency of microsomal sulfatase. More extensive deletions include contiguous genes and result in attention deficit hyperactivity disorder, autism, and mental retardation.<sup>90</sup>

A family history of scaling in males (as well as repeated postdate pregnancies and cesarean sections) should prompt a consideration for prenatal diagnosis. Because the clinical use of estriol measurements has declined, there is no effective method to identify the presence of this problem in women with normal obstetrical histories. However, a low maternal level of unconjugated estriol can be encountered with multiple marker screening (discussed later in this chapter). Furthermore, consideration should be given to antenatal screening by estriol measurement in pregnancies in which a male fetus is present and there is a previous history of a growth-retarded or stillborn male. However, perinatal outcome is good even when placental sulfatase deficiency is not known to be present and only a very small number of affected boys have serious manifestations of the disorder; therefore, it is difficult to justify the need for antenatal diagnosis.<sup>87</sup>

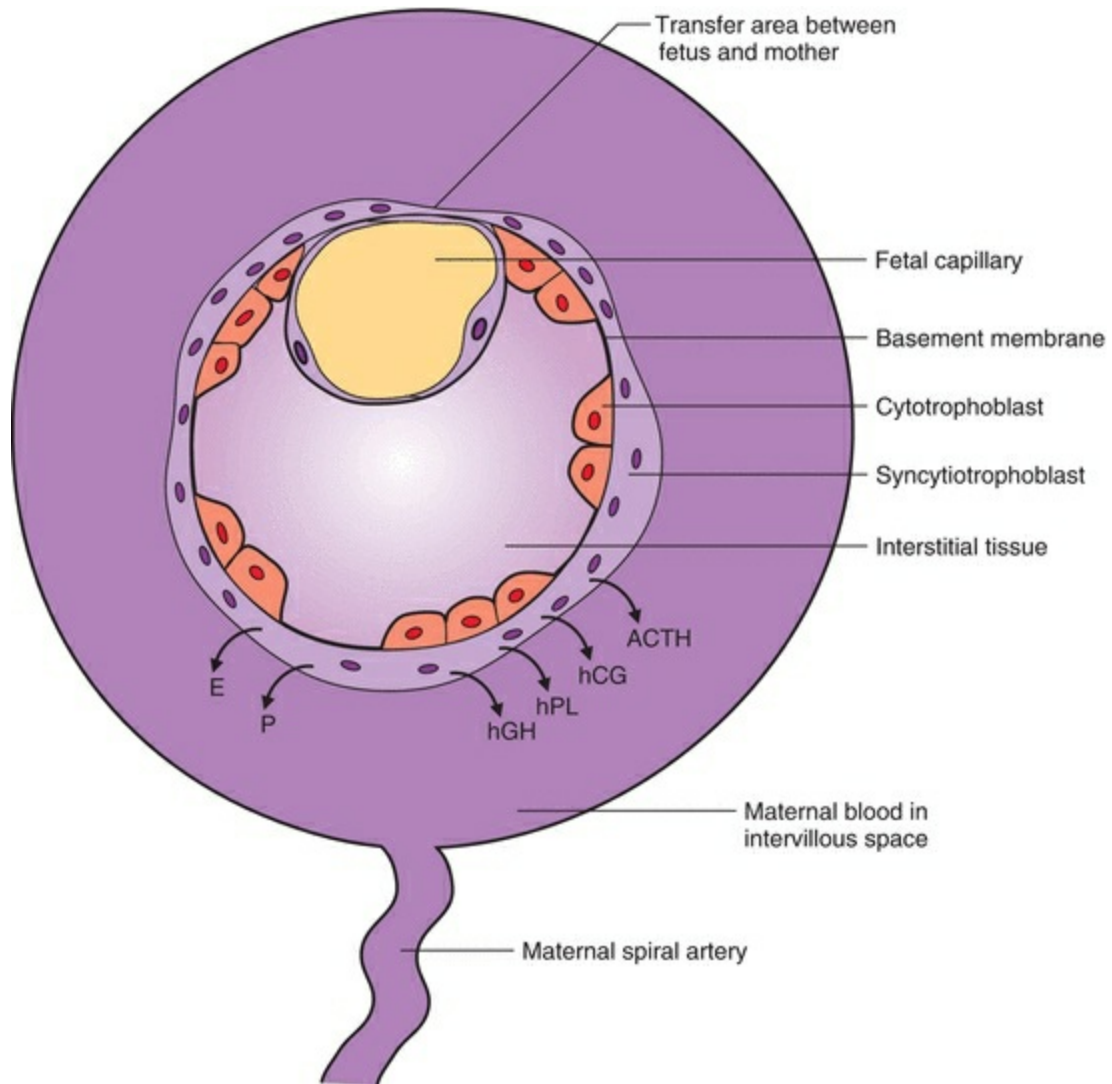

## Key Points: The Differential Diagnosis of an Extremely Low Estriol

- **Impending or present fetal demise**
- **Adrenal hypofunction**
- **Placental sulfatase deficiency**
- **Placental aromatase deficiency**
- **Drug-related effects**

# PROTEIN HORMONES OF PREGNANCY

---

The placental villus is composed of trophoblast, mesenchymal cells, and fetal blood vessels. The two main trophoblastic layers consist of the cytotrophoblast, separate mononuclear cells prominent early in pregnancy and sparse late in pregnancy, and the syncytiotrophoblast, a continuous multinuclear layer on the surface of the villi. The cytotrophoblast is the basic placental stem cell from which the syncytiotrophoblasts arise by differentiation. The syncytiotrophoblast is, therefore, the functional cell of the placenta, the major site of hormone and protein production. Control of this important cellular differentiation is still not understood; however, the process is influenced by hCG and, undoubtedly, a variety of growth factors.<sup>91</sup> The protein hormone system is complicated because individual peptides can have multiple functions (**Figure 7.7**).<sup>92</sup> The surface of the syncytiotrophoblast is in direct contact with the maternal blood in the intervillous space. This may be a reason why placental proteins are secreted preferentially into the mother (**Table 7.1**).

**FIGURE 7.7**

**TABLE 7.1 Proteins Associated with Pregnancy**

<b>Fetal Compartment</b>	<b>Placental Compartment</b>	<b>Maternal Compartment</b>
$\alpha$ -fetoprotein	Hypothalamic-like hormones	Decidual proteins
	GnRH	Prolactin
	CRH	Relaxin
	TRH	Progesterone-associated endometrial protein
	Somatostatin	IGFBP-1
	GHRH	Interleukin-1
	Neuropeptide Y	Colony-stimulating factor-1
	Pituitary-like hormones	Corpus luteum proteins

# Hypothalamic-Like Releasing Hormones

The human placenta contains many releasing and inhibiting hormones, including GnRH, CRH, TRH, and somatostatin.<sup>93</sup> Because of the presence of hypothalamic-like releasing hormones in an organ that produces tropic hormones, we are motivated to construct a system of regulation analogous to the hypothalamic-pituitary axis. However, as we shall see, this proves to be very difficult.

## Placental Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone produced by the placenta is biologically and immunologically similar to the hypothalamic GnRH decapeptide. Immunoreactive GnRH can be localized in the cytotrophoblast and syncytiotrophoblast. Evidence indicates that placental GnRH regulates placental steroidogenesis and release of prostaglandins, as well as hCG.<sup>93,94,95,96,97</sup> In some studies, the highest amount of GnRH was present early in pregnancy when the number of cytotrophoblasts is greatest and hCG secretion reaches its peak; however, others report relatively constant levels throughout pregnancy.<sup>98,99</sup> In fact, GnRH provides little augmentation of hCG secretion in first-trimester placental culture, likely because hCG production is already close to maximum. At the second trimester, however, GnRH augments hCG release in a dose-dependent fashion, with this effect diminishing in the term placenta.<sup>100,101</sup> All isoforms of GnRH are expressed in the human placenta, but GnRH-I is the predominant form.<sup>102,103</sup>

The placental receptors for GnRH have a lower affinity than that of GnRH receptors in the pituitary, ovary, and testis.<sup>104,105</sup> This reflects the situation in which the binding site is in close proximity to the site of secretion for the regulatory hormone. A higher affinity is not necessary because of the large amount of GnRH available in the placenta, and the low-affinity receptors avoid response to the low levels of circulating GnRH. GnRH receptors, present in both cytotrophoblasts and syncytiotrophoblasts, are produced in a pattern that parallels the curve of hCG secretion, a further evidence that placental GnRH and its receptor regulate hCG secretion.<sup>106</sup> GnRH release is increased by estrogen, activin-A, insulin, and prostaglandins and inhibited by progesterone, endogenous opiates, inhibin, and follistatin.<sup>92</sup> The GnRH receptor is highly expressed in the fetal zone of the adrenal gland, raising the possibility of another pathway by which the placenta can influence fetal adrenal function.<sup>103</sup>

## Placental Corticotrophin-Releasing Hormone

CRH, identical in structure to hypothalamic CRH, is produced in the trophoblast, the

fetal membranes, and the decidua.<sup>92</sup> Its production is regulated by steroids, decreased by progesterone, and, in contrast to the usual negative feedback action in the hypothalamus, increased by glucocorticoids.<sup>107</sup> These interactions are consistent with the increase in fetal cortisol associated with the last weeks of pregnancy and the increase in ACTH with labor. Placental CRH is further regulated (as in the hypothalamus) by an array of substances such as vasopressin, norepinephrine, angiotensin II, prostaglandins, neuropeptide Y, and oxytocin. CRH release is stimulated by activin and interleukin and inhibited by inhibin and nitric oxide. The progressive increase in maternal CRH levels during pregnancy is due to the secretion of intrauterine CRH into the maternal circulation. The highest levels are found at labor and delivery. A binding protein for CRH exists in the human circulation, and it is produced in placenta, membranes, and decidua.<sup>108</sup> Maternal levels of this binding protein are not different in pregnancy until a slight increase at 35 weeks, followed by a major decrease until term, increasing the bioavailability of CRH in late gestation. Maternal CRH levels are elevated in women with pregnancies under stress, for example, with pre-eclampsia and preterm labor.<sup>92</sup> An increase in placental CRH may be a response to the activation of fetal pituitary ACTH and adrenal cortisol secretion in the presence of hypoxemia. Placental CRH has multiple roles, including stimulation of the fetal adrenal plus parturition and regulation of blood flow. It is not certain to what extent CRH contributes to the increase in maternal adrenal secretion during pregnancy.

Trophoblast, amnion, chorion, and decidua also produce a peptide similar to CRH, named urocortin, that binds to CRH receptors and CRH-binding protein.<sup>109</sup> Urocortin displays activities similar to CRH, such as inducing the secretion of prostaglandins and matrix metalloproteinases in placental cells and fetal membrane cells and directly stimulating steroidogenesis in cells derived from the fetal zone of the adrenal gland.<sup>57,110,111</sup>

## **Placental Thyrotropin-Releasing Hormone**

Thyrotropin-releasing hormone is different from the tripeptide produced by the hypothalamus. It is produced by the placenta from early pregnancy until term. It is localized mainly in the syncytiotrophoblast but also in the fetal and maternal blood vessels as well as in the extravillous trophoblast. Placental TRH is secreted into both the maternal and fetal sides, but the concentration is higher in the fetal circulation, likely due to rapid degradation by proteases on the maternal side.<sup>112</sup> Since placental TRH is predominantly released into the fetal circulation, this placental neuropeptide may be involved in the regulation of thyroid function during fetal life. However, there is no conclusive evidence for this, and the possible paracrine effects of placental TRH remain unclear.<sup>113</sup>

## **Placental Growth Hormone–Releasing Hormone**

The structure of placental growth hormone–releasing hormone (GHRH) is identical to the hypothalamic peptide. It is secreted by the placenta but does not contribute to maternal circulating levels. The presence of GHRH receptor in the placenta suggests a possible paracrine action, but GHRH does not regulate placental GH production.<sup>114</sup> Thus, its function remains unknown.

# Human Chorionic Gonadotropin

Human chorionic gonadotropin is a glycoprotein, a peptide framework to which carbohydrate side chains are attached.<sup>115</sup> Alterations in the carbohydrate component (about one-third of the molecular weight) change the biologic properties. For example, the long half-life of hCG is approximately 24 hours as compared with 2 hours for LH, a 12-fold difference, which is due mainly to the greater sialic acid content of hCG. As with the other glycoproteins, follicle-stimulating hormone (FSH), LH, and thyroid-stimulating hormone (TSH), hCG consists of two subunits, noncovalently linked by disulfide bonds, called alpha ( $\alpha$ ) and beta ( $\beta$ ).<sup>116</sup> The  $\alpha$  subunit in these glycoprotein hormones is identical, consisting of 92 amino acids. Unique biologic activity as well as specificity in immunoassays is attributed to the molecular and carbohydrate differences in the  $\beta$  subunits (see “Heterogeneity” in [Chapter 1](#)).

$\beta$ -hCG is the largest  $\beta$  subunit, containing 145 amino acid residues, including a unique carboxyl terminal tailpiece of 24 amino acid groups. It is this unique part of the hCG structure that allows the production of highly specific antibodies and the utilization of highly specific immunologic assays. The extended sequence in the carboxyl-terminal region of  $\beta$ -hCG contains four sites for glycosylation, the reason why hCG is glycosylated to a greater extent than LH, a difference that is responsible for the longer circulating half-life of hCG. The long half-life in the presence of pregnancy assures the stability of the corpus luteum, while the short half-life of LH allows for the loss of progesterone production in the absence of pregnancy and resumption of menstrual cyclicity. This extended biologic availability of hCG is commonly utilized in ART in lieu of LH for triggering final oocyte maturation.

All human tissues appear to make hCG, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving it biologic activity through a long half-life. The carbohydrate components of the glycoproteins are composed of fructose, galactose, mannose, galactosamine, glucosamine, and sialic acid. Although the other sugars are necessary for hormonal function, sialic acid is the critical determinant of biologic half-life. Removal of sialic acid residues in hCG, FSH, and LH leads to very rapid elimination from the circulation.

Genes for tropic hormones contain promoter and enhancer or inhibitor regions located in the 5' flanking regions upstream from the transcription site. These sites respond to second messengers (cyclic AMP) as well as steroids and other yet unknown regulators. Differences in hCG structure are associated with a different promoter and transcriptional site that is located upstream in the hCG  $\beta$  subunit gene compared with the transcriptional site in the LH  $\beta$  subunit gene. The hCG  $\beta$  subunit promoter does not contain steroid hormone response elements, allowing hCG secretion to escape feedback regulation by the sex steroids, in contrast to FSH and LH.

The protein cores of the two glycoprotein subunits are the products of distinct genes.<sup>117</sup> There is a single human gene for the expression of the  $\alpha$  subunit. The gene for the  $\alpha$  subunit shared by FSH, LH, hCG, and TSH is located on chromosome 6p21.1–23. A single promoter site subject to multiple signals and hormones regulates transcription of the  $\alpha$  gene in both placenta and pituitary. The  $\alpha$  subunit gene is expressed in several different cell types, but the  $\beta$  subunit genes are restricted in cell type. The TSH  $\beta$  gene is expressed only in thyrotrophs regulated by the thyroid hormone; the FSH  $\beta$  gene is expressed in gonadotrophs regulated by GnRH, activin, inhibin, and gonadal steroids; the LH  $\beta$  gene, also expressed in gonadotrophs, is regulated by GnRH and is unaffected by activin and inhibin.<sup>118</sup>

The  $\alpha$  subunit gene requires the activation of distinct regulatory elements in thyrotroph and gonadotroph cells, as well as in the placenta. It is the activation of these cell-specific elements that produces tissue specificity for  $\alpha$ -gene expression. In gonadotrophs, the GnRH-signaling pathway for  $\alpha$ -gene transcription utilizes phosphorylase stimulation of diacylglycerol (DAG) and inositol triphosphate (IP<sub>3</sub>) that lead to a release of intracellular calcium stores. GnRH also stimulates the influx of calcium at the cell membrane. DAG, IP<sub>3</sub>, and calcium work together to stimulate protein kinase C activity. Protein kinase regulation of the  $\alpha$  promoter is a principal part of the overall mechanism. This pituitary process is influenced by multiple factors including growth factors and gonadal steroids. In the placenta, the mechanism also utilizes specific regulatory elements, but the primary signal is mediated by the cyclic AMP-protein kinase A pathway.

The genes that encode for the  $\beta$  subunits of LH, hCG, and TSH are located in a cluster on chromosome 19q13.3. There are six genes for the  $\beta$  subunit of hCG and only one for  $\beta$ -LH.<sup>119</sup> Transcription for the six hCG genes, each with different promoter activity, varies, and it is not certain why hCG requires multigenic expression (perhaps this is necessary to reach the extremely high level of production in early pregnancy). It is thought that  $\beta$ -hCG evolved relatively recently from  $\beta$ -LH, and the unique amino acid terminal extension of  $\beta$ -hCG arose by a read-through mutation of the translation stop codon in the  $\beta$ -LH gene; the DNA sequences of the  $\beta$ -hCG genes and the  $\beta$ -LH gene are 96% identical.<sup>119</sup> Gene studies have indicated that the  $\beta$ -hCG gene originated in the common ancestor of monkeys, apes, and humans after the anthropoids diverged from tarsiers, about 35–55 million years ago.<sup>120,121</sup>

Only primates and equine species have been demonstrated to have genes for the  $\beta$  subunit of chorionic gonadotropin. In contrast to hCG, equine chorionic gonadotropin exerts both LH and FSH activities in many mammalian species because it contains peptide sequences in its  $\beta$  subunit that are homologous to those in the pituitary gonadotropins of other species. The equine  $\beta$ -chorionic gonadotropin gene is identical

to the equine  $\beta$ -LH gene, and although the primate  $\beta$ -hCG gene evolved from the same ancestral  $\beta$ -LH gene, the equine chorionic gonadotropin gene evolved in a different way. The  $\beta$ -LH gene is not expressed in the placenta.

The genetic complexity for the transcription of  $\beta$ -hCG raises the possibility for mutations of these genes as causes of reproductive problems. A search for  $\beta$ -hCG gene deletions in women with recurrent miscarriage or unexplained infertility and for duplications in women with gestational trophoblastic neoplasia found only normal gene structures.<sup>122</sup>

hCG production and secretion are the result of complex interactions among the sex steroids, cytokines, GnRH, and growth factors. GnRH is synthesized by placental cells; GnRH receptors are present on placental cells; and GnRH stimulates the secretion of hCG and the steroid hormones in in vitro studies of placental cells.<sup>123,124,125</sup> Similar responses can be demonstrated with other peptides, such as interleukin- $1\beta$ .<sup>126</sup> Similar to opiate action in the hypothalamus, the endorphins are a major inhibiting influence on hCG secretion.<sup>127</sup> Also similar to the pituitary secretion of gonadotropins, inhibin restrains and activin enhances the GnRH-hCG system, with a positive influence of estrogen and a negative impact by progesterone.<sup>128,129</sup> Follistatin, by binding activin, prevents the stimulatory activity of activin. Other growth factors, specifically IGF-I, IGF-II, TGF- $\alpha$ , and EGF, also influence hCG secretion.

Although a relatively clear story can be constructed into a working concept regarding the autocrine/paracrine interactions in the regulation of the menstrual cycle (Chapter 6), placental function is more complex, and a simple presentation of the many interactions cannot be produced. For example, EGF stimulates hCG secretion but also stimulates inhibin secretion in placental cells, and inhibin suppresses GnRH stimulation of hCG.<sup>130</sup> Inhibin secretion in the placenta is further stimulated by prostaglandins.<sup>131</sup>

Can the cytotrophoblast-syncytiotrophoblast relationship be compared with the hypothalamic-pituitary axis? It does appear that hypothalamic-like peptides (CRH, GnRH) originate in the cytotrophoblast and influence the syncytiotrophoblast to secrete pituitary-like hormones (hCG, hPL, ACTH). Unraveling the interaction is made more difficult by the incredible complexity of the syncytiotrophoblast, a tissue that produces and responds to steroid and peptide hormones, growth factors, and neuropeptides. The best we can say is that locally produced hormones, growth factors, and peptides work together to regulate placental function.

To this day, the only definitely known function for hCG is support of the corpus luteum, taking over for LH on about the eighth day after ovulation, 1 day after implantation, when  $\beta$ -hCG first can be detected in maternal blood. hCG has been detected at the 8-cell stage in the embryo using molecular biology techniques.<sup>132</sup>

Continued survival of the corpus luteum is totally dependent on hCG, and, in turn, survival of the pregnancy is dependent on steroids from the corpus luteum until the seventh week of pregnancy.<sup>1</sup> From the seventh week to the tenth week, the corpus luteum is gradually replaced by the placenta, and by the tenth week, removal of the corpus luteum will not be followed by steroid withdrawal abortion.

It is very probable, but not conclusively proven, that hCG stimulates steroidogenesis in the early fetal testes, so that androgen production will ensue and masculine differentiation can be accomplished.<sup>133</sup> However, normal masculine differentiation occurs in mouse models lacking LH receptors, and molecular evidence indicates that fetal Leydig cells (but not adult cells) respond to ACTH as well as hCG.<sup>134</sup> It is also possible that the function of the inner fetal zone of the adrenal cortex depends on hCG for steroidogenesis early in pregnancy. The  $\beta$ -hCG gene is expressed in fetal kidney and fetal adrenal, suggesting that hCG may affect the development and function of these organs.<sup>135</sup> In addition, hCG may regulate placental development by influencing the differentiation of cytotrophoblasts.<sup>136</sup>

hCG gene expression is present in both cytotrophoblast and syncytiotrophoblast, but it is synthesized mainly in the syncytiotrophoblast.<sup>137</sup> The maternal circulating hCG concentration is approximately 100 IU/L at the time of the expected but missed menses. A maximal level of about 100,000 IU/L in the maternal circulation is reached at 8–10 weeks of gestation. Why does the corpus luteum involute at the time that hCG is reaching its highest levels? One possibility is that a specific inhibitory agent becomes active at this time and another is down-regulation of receptors by the high levels of hCG. In early pregnancy, down-regulation may be avoided because hCG is secreted in an episodic fashion.<sup>138</sup> For unknown reasons, the fetal testes escape desensitization; no receptor down-regulation takes place.<sup>133</sup>

hCG levels decrease to about 10,000–20,000 IU/L by 18–20 weeks and remain at that level to term. It is not certain why hCG levels are decreased in the second half of pregnancy. Advancing gestation is associated with increasing amounts of “nicked” hCG molecules in the maternal circulation.<sup>139</sup> These molecules are missing a peptide linkage on the  $\beta$  subunit, and, therefore, they dissociate into free  $\alpha$  and  $\beta$  subunits. At any one point in time, the maternal circulation contains hCG, nicked hCG, free subunits, and fragments of hCG. In addition, the carbohydrate content of hCG varies throughout pregnancy, with more glycosylation present in early pregnancy (hyperglycosylated hCG). Overall, there are about 20–30 isoforms in the maternal blood, and the production of normal molecules is maximal in early gestation when the biologic actions of hCG are so important.<sup>140</sup> A major route of clearance for hCG is renal metabolism in which a final reduced fragment of the  $\beta$  subunit is produced, known as the  $\beta$ -core fragment.

In the complex process of hCG regulation, several inhibiting factors have been identified, including inhibin and progesterone. The decline in hCG occurs at the time of increasing placental progesterone production, and a direct inhibition by this steroid could explain the lower levels of hCG after the tenth week of gestation.<sup>141</sup>

hCG levels close to term are higher in women bearing female fetuses. This is true of serum levels, placental content, urinary levels, and amniotic fluid concentrations. The mechanism and purpose of this difference are not known. Women who have markedly elevated levels of hCG in the second trimester, with no apparent explanation, have increased risks of spontaneous miscarriage, small-for-gestational-age infants, pre-eclampsia, and preterm delivery.<sup>142</sup>

There are two clinical conditions in which blood hCG titers are especially helpful: trophoblastic disease and ectopic pregnancies. Early pregnancy is characterized by the sequential appearance of hCG, followed by  $\beta$ -hCG and then  $\alpha$ -hCG. The ratio of  $\beta$ -hCG to whole hCG remains constant after early pregnancy. Trophoblastic disease is distinguished by very high  $\beta$ -hCG levels (3–100 times higher than normal pregnancy). Ectopic production of  $\alpha$ - and  $\beta$ -hCG by nontrophoblastic tumors is rare but does occur.

In the United States, hydatidiform moles occur in approximately 1 in 600 induced abortions and 1 in 1,000–2,000 pregnancies. About 20% of patients with hydatidiform moles will develop malignant complications. Following molar pregnancies, the hCG titer should fall to a nondetectable level by 16 weeks in patients without persistent disease. Patients with trophoblastic disease show an abnormal curve (a titer  $>500$  IU/L) frequently by 3 weeks and usually by 6 weeks.<sup>143,144</sup> A diagnosis of gestational trophoblastic disease is made when the  $\beta$ -hCG plateaus or rises over a 2-week period or a continued elevation is present 16 weeks after evacuation. In the United States, the rare occurrence of this disease mandates consultation with a certified subspecialist in gynecologic oncology. Following treatment, hCG should be measured monthly for at least a year, then twice yearly for 5 years. To avoid missing the diagnosis of nonmolar trophoblastic disease, abnormal bleeding after any pregnancy should be evaluated with an hCG measurement, and all patients with elevated hCG levels and early pregnancy losses should be followed with serial hCG testing.

Choriocarcinoma is associated with the increased secretion of  $\beta$ -hCG that is glycosylated to a greater degree, so-called hyperglycosylated hCG, sometimes called invasive trophoblast antigen.<sup>145,146</sup> Hyperglycosylated hCG detected in mothers in the first weeks of normal pregnancies is the major circulating form of hCG, but the levels decrease rapidly to be replaced by the usual hCG isoform by the second trimester.<sup>147</sup> These findings suggest that hyperglycosylated hCG plays a role in regulating trophoblastic invasion; it is suggested that hyperglycosylated hCG is mainly autocrine in its activity, whereas regular hCG functions as a classic hormone in maintaining the

corpus luteum. Measurement of hyperglycosylated hCG in the first weeks of pregnancy may have a role in screening for Down syndrome, but clinical uses for assays that are specific for the many isoforms of hCG have yet to emerge.<sup>148,149</sup> Some of the inaccuracy associated with routine pregnancy testing, especially home pregnancy tests, can be attributed to the variability in detecting hyperglycosylated hCG.

We are just beginning to appreciate the complex heterogeneity of hCG, expressed by the many isoforms that are present in biologic fluids.<sup>149</sup> It is likely that a specific form of hCG can eventually be linked to a specific condition, offering the possibility of clinical application. For example, an assay specific for hyperglycosylated hCG may be of clinical value in assessing implantation and the early weeks of pregnancy; a low level predicts a failing pregnancy.<sup>150</sup> General clinical use awaits improvements in available assays, requiring the development of pure standards and specific antibodies. Meanwhile, clinicians should keep in mind that current assays measure a pool of hCG and its various molecules.

Virtually all ectopic pregnancies are associated with detectable hCG. The hCG level increases at different rates in normal and ectopic pregnancies, and the quantitative measurement of hCG combined with pelvic ultrasonography has had an enormous impact on the diagnosis and management of ectopic pregnancy. This important clinical problem is discussed fully in [Chapter 33](#).

## Key Points: Summary of Contributions of hCG Measurement

- The quantitative measurement of hCG can assess pregnancy viability. A normal rate of rise (at least a 50% increase every 2 days) usually indicates a normal pregnancy.
- When the hCG titer exceeds 1,500–3,000 IU/L, vaginal ultrasonography should identify the presence of an intrauterine gestation.
- Declining hCG levels are consistent with effective treatment, and persistent or rising levels indicate the presence of viable trophoblastic tissue.

With the use of modern sensitive assays, it is now appreciated that virtually all normal human tissues produce the intact hCG molecule. hCG can be detected in the blood of normal men and women, where it is secreted in a pulsatile fashion in parallel with LH; the source of this circulating hCG is the pituitary gland, perhaps a consequence of evolution when hCG was derived from LH.<sup>151,152,153,154</sup> The concentration of this

pituitary hCG normally approximates the sensitivity of the usual modern assay, and for this reason, many laboratories will not report the presence of hCG unless the level is 5–10 IU/L or higher. hCG produced in sites other than the placenta has little or no carbohydrate; therefore, it has a very short half-life and is rapidly cleared from the circulation. Significant levels of free  $\alpha$  subunit are also present in the circulation of healthy individuals; however, the levels of the  $\beta$  subunit are extremely low.

# False-Positive Tests or “Phantom” hCG

False-positive results with the hCG assay occasionally occur and have been long-recognized, resulting in inappropriate surgical or medical treatment. The level is relatively low, usually less than 150 IU/L. There are many causes, including the hCG secreted by the pituitary, but this clinical problem is usually due to interference in the assay by other substances, especially antibodies to LH or antianimal immunoglobulins.<sup>155</sup> The capture or tracer antibodies used in the hCG assays may be from various animals, and some humans have antibodies that can cross-react with these animal antigens in a nonspecific fashion. These are referred to as heterophilic antibodies. Humans with recent exposure to mononucleosis and those with IgA deficiency syndrome are prone to develop heterophile antibodies leading to false-positive results.<sup>156</sup> In addition, nontrophoblastic tumors can secrete detectable hCG.

A false-positive result usually remains at the same level over time, neither increasing nor decreasing. When the clinical presentation is uncertain or not consistent with laboratory results (especially an absence of trophoblastic tissue), a positive hCG can be confirmed by several procedures.

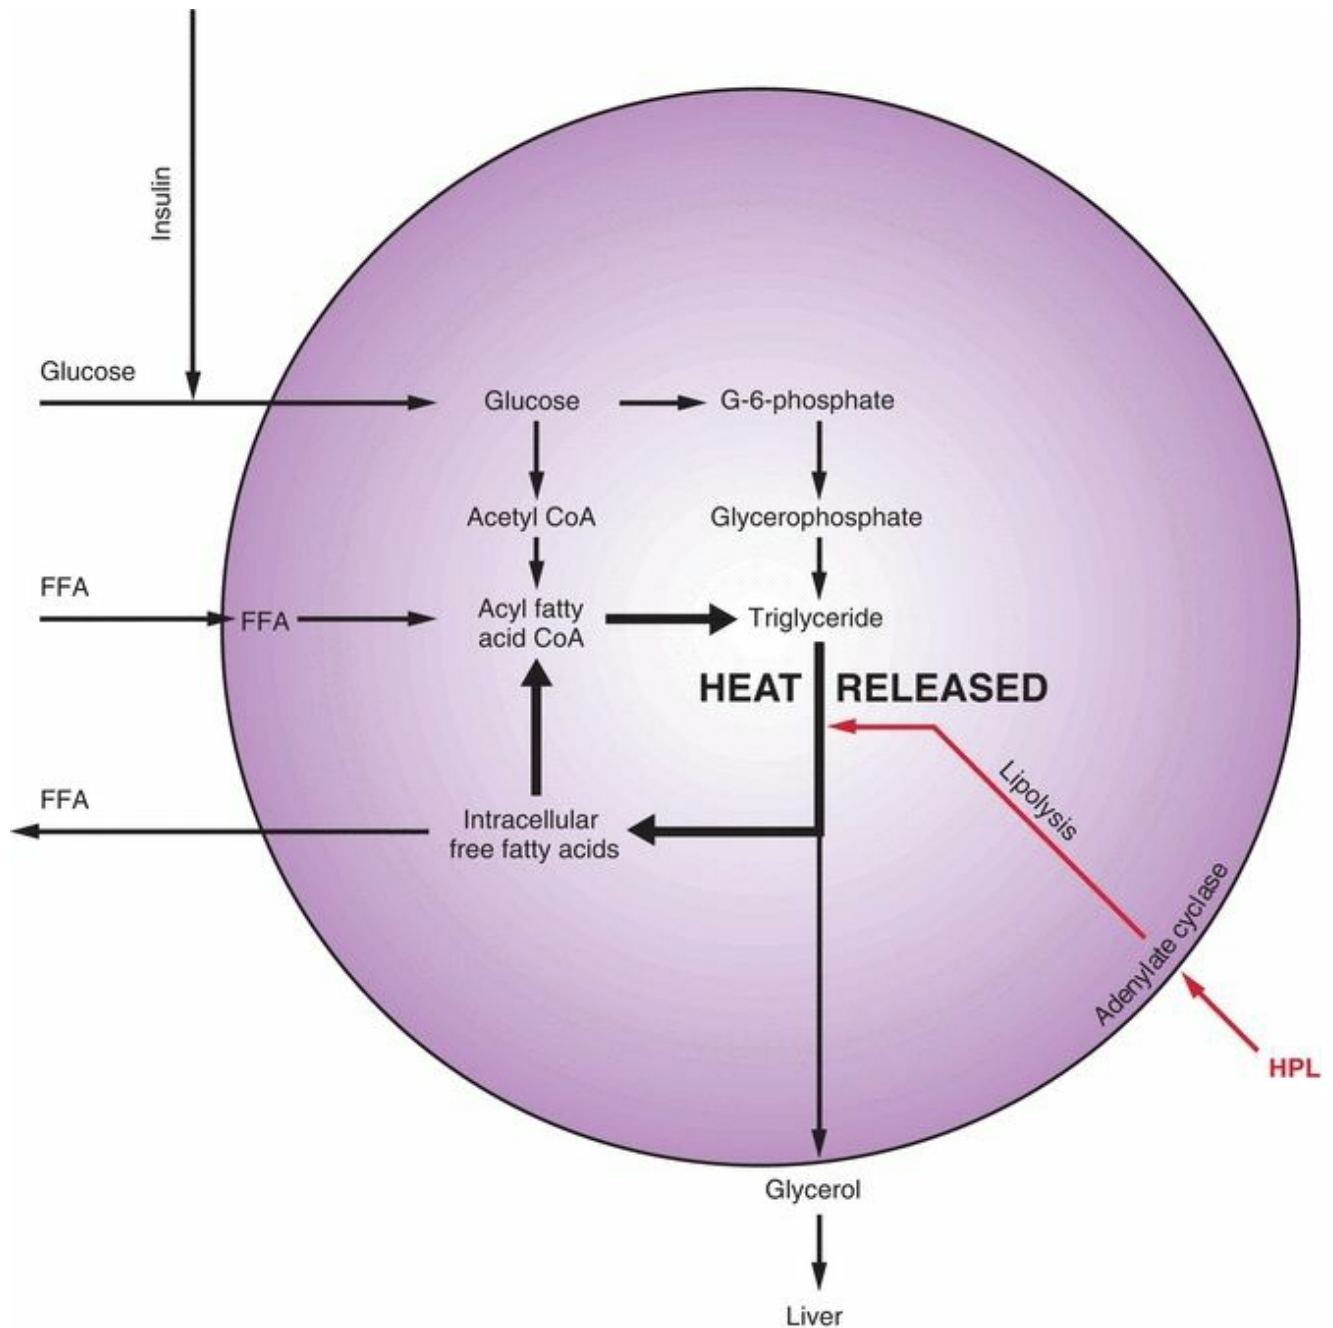

## Key Points: Positive hCG Confirmation

- Obtaining a similar result with a different assay method. If the results from a lab using an alternative commercial assay are negative or vary greatly, then a false-positive hCG can be assumed.
- Demonstrating the presence of hCG in the urine. Since large molecules like heterophilic antibodies do not cross the glomerular basement membrane, there will be no detectable hCG in the urine in the case of a false-positive hCG.
- Demonstrating parallel results with serial dilutions of the hCG standard and the patient’s serum sample. In the presence of heterophilic antibodies, the results will not decrease as expected by performing a serial dilution.

# Human Placental Lactogen

Human placental lactogen (hPL) (sometimes called human chorionic somatomammotropin), also secreted by the syncytiotrophoblast, is a single-chain polypeptide of 191 amino acids held together by 2 disulfide bonds. It is very similar in structure to human growth hormone (hGH) but has only 3% of hGH somatotropin activity. The growth hormone-hPL gene family consists of 5 genes on chromosome 17q22–q24. Two genes encode for hGH, one in the pituitary and one in the placenta, and three for hPL; however, only two of the hPL genes are abundantly active in the placenta, each producing the same hPL hormone.<sup>157</sup> The third hPL gene does generate a protein in the placenta, but its activity is limited.<sup>158</sup>

The half-life of hPL is short, about 15 minutes, hence its appeal as an index of placental problems. The level of hPL in the maternal circulation is correlated with fetal and placental weight, steadily increasing until plateauing in the last 4 weeks of pregnancy (5–10 mg/mL). There is no circadian variation, and only minute amounts of hPL enter the fetal circulation. Very high maternal levels are found in association with multiple gestations; levels up to 40 mg/mL have been found with quadruplets and quintuplets. An abnormally low level is anything less than 4 mg/mL in the last trimester (**Figure 7.8**).

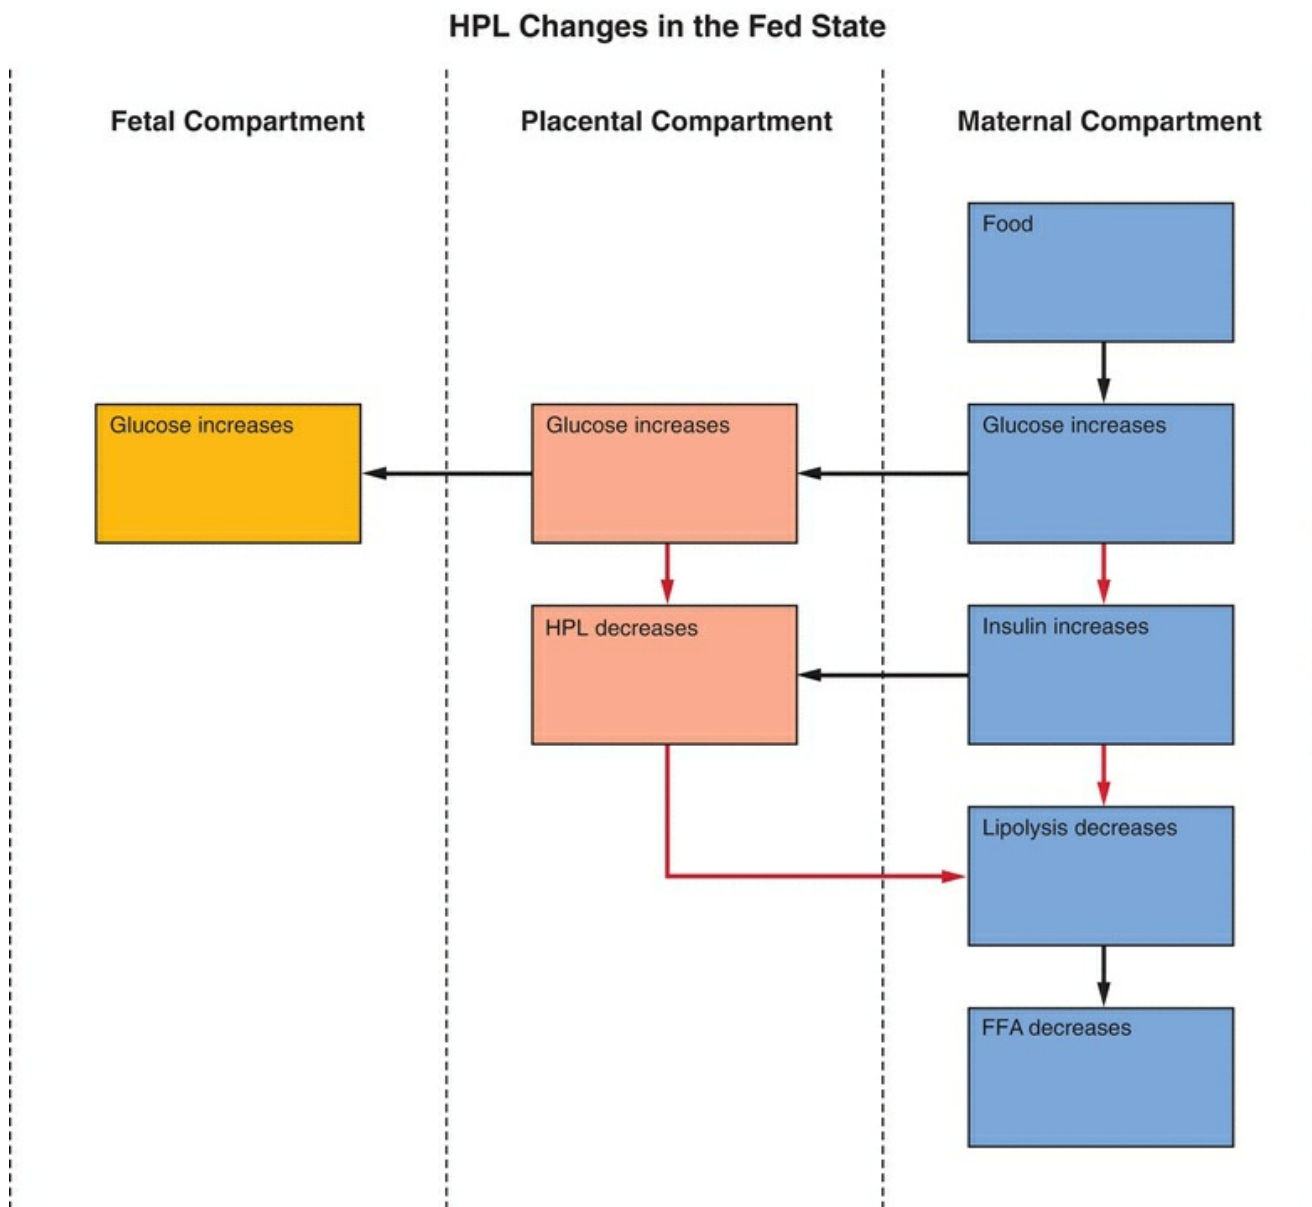

**FIGURE 7.8**

## Physiologic Function

Although hPL is similar in structure to growth hormone, neither growth hormone-releasing hormone nor somatostatin influence placental hPL secretion. One would expect the regulatory mechanism to involve PLGFs and cytokines, as is the case with other placental steroids and peptides. Although hPL has about 50% of the lactogenic activity of sheep prolactin in certain bioassays, its lactogenic contribution in human pregnancy is uncertain.

In the mother, hPL stimulates insulin secretion and IGF-I production and induces insulin resistance and carbohydrate intolerance. However, the well-recognized insulin resistance in pregnancy is not solely an effect of hPL; for example, placental cytokines (especially TNF- $\alpha$ ) influence this metabolic state.<sup>159</sup> Experimentally, the maternal level of hPL can be altered by changing the circulating level (chronically, not acutely) of glucose. hPL is elevated with hypoglycemia and depressed with hyperglycemia. This response in placental hPL may be secondary to the glucose-mediated changes in insulin levels; in vitro experiments with placental tissue indicated a decrease in hPL with a decrease in glucose, followed by an increase in hPL after exposure to insulin (**Figure 7.9**).<sup>160</sup> This information and studies in fasted pregnant women have led to the following formulation for the physiologic function of hPL.<sup>161,162,163,164,165,166,167</sup>

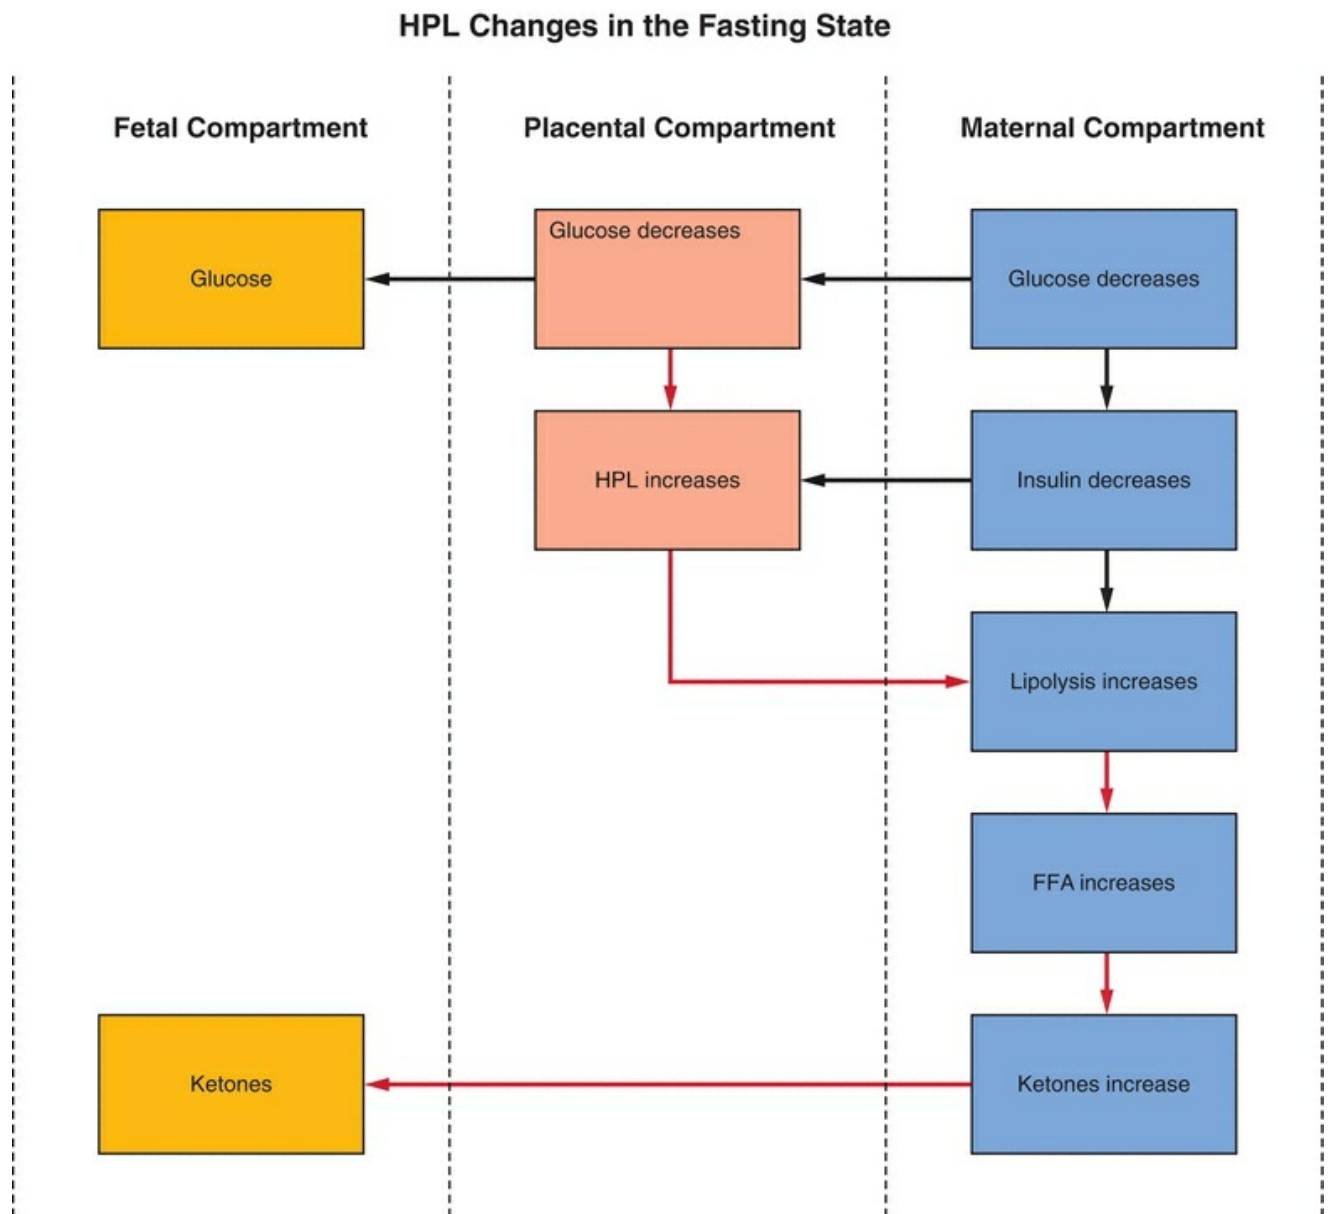

## FIGURE 7.9

The metabolic role of hPL is to mobilize lipids as free fatty acids. In the fed state, there is abundant glucose available, leading to increased insulin levels, lipogenesis, and glucose utilization. This is associated with decreased gluconeogenesis and a decrease in the circulating free fatty acid levels, because the free fatty acids are utilized in the process of lipogenesis to deposit storage packets of triglycerides (see [Chapter 19, Obesity](#)).

Pregnancy has been likened to a state of “accelerated starvation,” characterized by a relative hypoglycemia in the fasting state.<sup>164</sup> This state is due to two major influences:

- 1. Glucose provides the major, although not the entire, fuel requirement for the fetus. A difference in gradient causes a constant transfer of glucose from the mother to the fetus.**
- 2. Placental hormones, specifically estrogen and progesterone, and especially hPL, interfere with the action of maternal insulin. In the second half of pregnancy when hPL levels rise approximately 10-fold, hPL is a major force in the diabetogenic effects of pregnancy. The latter is characterized by increased levels of insulin associated with decreased cellular response (hyperinsulinemia and peripheral insulin resistance).**

As glucose decreases in the fasting state, hPL levels rise. This stimulates lipolysis leading to an increase in circulating free fatty acids. Thus, a different fuel is provided for the mother so that glucose and amino acids can be conserved for the fetus. With sustained fasting, maternal fat is utilized for fuel to such an extent that maternal ketone levels rise. There is limited transport of free fatty acids across the placenta. Therefore, when glucose becomes scarce for the fetus, fetal tissues utilize the ketones that do cross the placenta. Thus, decreased glucose levels lead to decreased insulin and increased hPL, increasing lipolysis and ketone levels. hPL also may enhance the fetal uptake of ketones and amino acids. The mechanism for the insulin antagonism by hPL may be the hPL-stimulated increase in free fatty acid levels, which, in turn, directly interfere with insulin-directed entry of glucose into cells. These interactions significantly involve growth factors, particularly insulin-like growth factor, at the cellular level ([Figure 7.10](#)).

**FIGURE 7.10**

This mechanism can be viewed as an important means to provide fuel for the fetus between maternal meals. However, with a sustained state of inadequate glucose intake, the subsequent ketosis may impair fetal brain development and function. Pregnancy is not the time to severely restrict caloric intake. Indeed, impaired fetal growth and development are now recognized to correlate with adverse cardiovascular risk factors and disease in adult life as well as diabetes mellitus.<sup>50,168,169</sup>

The lipid, lipoprotein, and apolipoprotein changes during pregnancy are positively correlated with changes in estradiol, progesterone, and hPL.<sup>170</sup> The lipolytic activity of hPL is an important factor because hPL is also linked to the maternal blood levels of cholesterol, triglycerides, phospholipids, and insulin-like growth factor-I.

When glucose is abundant, as in pregnant women with diabetes mellitus, the flow of nutritional substrates (in this case, glucose and amino acids) is in the direction of the fetus. The subsequent hyperinsulinemia in the fetus becomes a strong stimulus to growth, perhaps compounded by maternal hyperinsulinemia caused by obesity as well as the hyperinsulinemia due to the peripheral resistance produced by the hormones of pregnancy.<sup>171</sup> Fetal undernutrition lowers fetal IGF-I levels, and this is associated with a high prevalence of insulin resistance later as adults.<sup>172</sup> In vitro studies indicate that hPL, despite its lower levels in the fetus, directly affects fetal tissue metabolism, including synergistic actions with insulin, especially on glycogen synthesis in the liver. The failure of fetal growth hormone to affect fetal growth (e.g., normal growth in anencephalics) further indicates that hPL may be the fetal growth hormone.

## **hPL Clinical Uses**

Blood levels of hPL are related to placental function. Some studies indicated that hPL was valuable in screening patients for potential fetal complications, but others did not support the use of hPL measurements. Although use of the hPL assay can have an impact on perinatal care, fetal heart rate-monitoring techniques are more reliably predictive and sensitive for assessing fetal well-being. Furthermore, totally uneventful pregnancies have been reported, despite undetectable hPL.<sup>173,174</sup>

Previous suggestions that a low or declining level of hPL and a high level of hCG are characteristic of trophoblastic disease were not accurate. Because of the rapid clearance of hPL (half-life of about 20 minutes), aborting molar pregnancies is likely to have low levels of hPL, whereas the level of hCG is still high. However, intact molar pregnancies can have elevated levels of both hPL and hCG.<sup>175</sup>

# Human Chorionic Thyrotropin

The human placenta contains two thyrotropic substances. One is called human chorionic thyrotropin (hCT), which is similar in size and action to pituitary TSH. The content in the normal placenta is very small, and it is unlikely that it has any physiologic importance. hCT differs from the other glycoproteins in that it does not appear to share the common  $\alpha$  subunit. Antiserum generated to  $\alpha$ -hCG does not neutralize the biologic activities of hCT, but it does neutralize that of hCG and pituitary TSH.

Rarely, patients with trophoblastic disease have hyperthyroidism and, even more rarely, thyroid storm.<sup>176</sup> hCG has intrinsic thyrotropic activity, indicating that hCG is the second placental thyrotropic substance.<sup>177,178,179</sup> It has been calculated that hCG contains approximately 1/4,000th of the thyrotropic activity of human TSH. In conditions with very elevated hCG levels, such as hydatidiform mole, the thyrotropic activity can be sufficient to produce hyperthyroidism (with elevated free thyroxine, FT4, but suppressed levels of TSH), and this can even be encountered in normal pregnancy.<sup>180</sup> Another very rare cause of hyperthyroidism in pregnancy is an inherited mutation of the thyrotropin receptor that makes it hypersensitive to hCG.<sup>181</sup>

There is a correlation between elevated thyroid function and hyperemesis gravidarum.<sup>182,183</sup> Hyperemesis gravidarum is usually associated with very high hCG levels, and some of these patients develop hyperthyroidism as well.<sup>184</sup> Although free T4 will be elevated and TSH suppressed, patients with gestational hyperthyroidism do not develop the clinical signs of Graves disease and TSH-receptor antibodies, TRAb, will not be detectable. These hyperthyroid manifestations in normal pregnancies may be linked to a specific subpopulation of hCG molecules with greater thyrotropic bioactivity (because highly purified, standard hCG has only trivial TSH-like activity).<sup>185</sup> Specifically, hCG with reduced sialic acid content is increased in pregnant patients with hyperemesis and hyperthyroidism.<sup>186</sup> The thyroid hormone changes in pregnancy and the role of hCG as a thyroid stimulator are also discussed in [Chapter 20](#).

# Human Chorionic Adrenocorticotropin

The rise in maternal free cortisol and aldosterone that takes place throughout pregnancy is due to placental ACTH and CRH production and secretion into the maternal circulation and due to the effects of estrogen and progesterone on the maternal hypothalamic-pituitary axis.<sup>187,188,189</sup> The placental content of ACTH is higher than can be accounted for by the contribution of sequestered blood. In addition, cortisol levels in pregnant women are resistant to dexamethasone suppression, indicating that there is a component of maternal ACTH and CRH that does not originate in the maternal hypothalamus and pituitary gland. The placental production of ACTH in the syncytiotrophoblast (and the increase in maternal ACTH levels) is probably due to stimulation by the locally produced CRH in the cytotrophoblast.<sup>190</sup> Placental pro-opiomelanocortin (POMC) gene expression and ACTH content are present throughout pregnancy and increase in the weeks before term.<sup>191</sup> One can speculate that placental ACTH and CRH raise maternal adrenal activity in order to provide the basic building blocks (cholesterol and pregnenolone) for placental steroidogenesis. The increased activity of the maternal adrenal gland is also necessary for the expansion of maternal blood volume during pregnancy.

The maternal ACTH response to the administration of CRH during pregnancy is blunted, reflecting a high level of endogenous CRH and ACTH activity. Vasopressin stimulates ACTH secretion in the pituitary, both directly and indirectly by potentiating the action of CRH. In contrast to the blunted response to CRH during pregnancy, the ACTH response to vasopressin is increased.<sup>192</sup> This is further evidence that placental CRH produces a state of chronic stimulation for the maternal pituitary-adrenal axis. Thus, in contrast to nonpregnant women, CRH levels in maternal plasma are relatively high, rising in the second trimester to peak values at term.<sup>193,194</sup> In contrast to the hypothalamic-pituitary axis, placental CRH and ACTH are not suppressed by glucocorticoids, and, therefore, maternal ACTH levels are little affected by corticosteroid administration to the mother. Oxytocin is a potent stimulator of CRH and ACTH placental production, a logical mechanism to meet the stress of labor and delivery. Binding of CRH with the CRH-binding protein blunts physiologic response, but the binding protein capacity is reached late in pregnancy, increasing the biologic activity of CRH and further increasing cortisol availability during labor and delivery.<sup>195</sup>

Both maternal and fetal levels of CRH are further elevated in pathologic states such as premature labor, hypertension, fetal asphyxia, and intrauterine growth retardation.<sup>196</sup> Because CRH also stimulates prostaglandin synthesis in the placenta and fetal membranes, it is implicated in the premature labor that accompanies pathologic conditions.<sup>197</sup>

# Growth Hormone, Growth Hormone–Releasing Hormone, and Somatostatin

One of the two growth hormone genes on chromosome 17 is expressed only in the syncytiotrophoblast of the placenta; the other is expressed in the pituitary.<sup>158,198</sup> The placental growth hormone is not identical to pituitary growth hormone, differing in 13 amino acids, and after 15–20 weeks of pregnancy, placental growth hormone gradually replaces pituitary growth hormone in the maternal circulation.<sup>158,199</sup> Indeed, by term, maternal pituitary growth hormone is undetectable. Placental growth hormone is not present in fetal blood. The changes in maternal levels of insulin-like growth factors and insulin-like growth factor–binding proteins reflect regulation by this placental growth hormone.<sup>200</sup> Maternal IGF-I levels in the circulation increase during pregnancy in a pattern similar to that of placental growth hormone. Placental growth hormone is not regulated by placental growth hormone–releasing hormone but responds inversely to maternal glucose and insulin levels, protecting glucose availability for the fetus.<sup>158,201</sup>

Placental growth hormone can also stimulate gluconeogenesis and lipolysis in maternal organs. **It is believed, therefore, that placental growth hormone influences fetal growth by affecting maternal metabolism.** Placental growth hormone and maternal IGF-1 levels are lower in pregnancies with intrauterine growth retardation and higher in women with female fetuses.<sup>200,202</sup> Maternal circulating levels of placental growth hormone are higher at midgestation in pregnancies with fetal Down syndrome.<sup>203</sup>

# **$\alpha$ -Fetoprotein**

$\alpha$ -fetoprotein (AFP) is a relatively unique glycoprotein (590 amino acids and 4% carbohydrate) derived largely from fetal liver and partially from the yolk sac until it degenerates at about 12 weeks. In early pregnancy (5–12 weeks), amniotic fluid AFP is mainly from yolk sac origin, whereas maternal circulating AFP is mainly from the fetal liver.<sup>204</sup> Its function is unknown, but it is comparable in size to albumin and contains 39% sequence homology; it may serve as a protein carrier of steroid hormones in fetal blood. AFP may also be a modulator of cell proliferation, synergizing with various growth factors.<sup>205</sup>

Peak levels of AFP in the fetal blood are reached at the end of the first trimester; then levels decrease gradually until a rapid decrease begins at 32 weeks. Maternal blood levels are much lower than fetal levels, rising until week 32 (probably because of the great increase in trophoblast villous surface area during this time period) and then declining. Because AFP is highly concentrated in the fetal central nervous system, abnormal direct contact of CNS with the amniotic fluid (as with neural tube and abdominal wall defects) results in elevated amniotic fluid and maternal blood levels. Other fetal abnormalities, such as intestinal obstruction, omphalocele, and congenital nephrosis, are also associated with high levels of AFP in the amniotic fluid. Besides indicating a variety of fetal anomalies, elevated maternal AFP levels are also present with multiple pregnancies and associated with an increased risk of spontaneous miscarriage, stillbirth, preterm birth, pre-eclampsia, neonatal death, and low birth weight (probably reflecting an increase in villous surface area in response to an adverse intrauterine environment).<sup>206,207,208</sup> Conversely, very low maternal AFP levels are associated with large birth weight infants, miscarriage, and stillbirth.<sup>208,209</sup>

## **Multiple Marker Screening and Cell-Free DNA**

Down syndrome is a very common genetic cause of abnormal development. The majority of cases are due to trisomy 21, an extra chromosome usually due to nondisjunction in maternal meiosis. A low maternal level of AFP is associated with trisomy 21. However, there is extensive overlap between normal and affected pregnancies responsible for a significant false-positive rate. Several placental products are secreted in increased amounts in pregnancies with trisomy 21, including hCG and hPL, whereas the maternal circulating level of unconjugated estriol is lower in affected pregnancies. The free  $\beta$  subunit of hCG usually circulates in low concentrations, but in the presence of a fetus with Down syndrome, the levels are high. With trisomy 18, all markers are decreased. Until recently, screening for fetal aneuploidy combined three markers: AFP,  $\beta$ -hCG, and unconjugated estriol.<sup>210,211,212</sup> This protocol detected 85% of

open neural tube defects and 80% of Down syndrome, if gestational age is determined by ultrasonography.<sup>213</sup> However, Down syndrome represents only about 50% of the chromosomal abnormalities that can be detected.

The multiple marker screening protocol measures AFP, unconjugated estriol, and hCG in maternal serum at 16–18 weeks of gestation, the optimal time for neural tube defect detection. Using the patient’s age and the laboratory results, patients are provided a statistical estimation of risks for both neural tube defects and Down syndrome. Corrections are applied for race and weight. A pattern similar to that of Down syndrome has also been reported to be associated with hydropic fetal Turner syndrome.<sup>214</sup>

The most critical factor for correct risk assessment is accurate gestational dating. A 2-week error in dating can change the calculated risk for Down syndrome 10-fold (Table 7.2).

## **TABLE 7.2 Triple Test Values**

	<b>AFP</b>	<b>Estriol</b>	<b>hCG</b>
Down syndrome	Low	Low	High
Trisomy 13	Normal	No data	Low
Trisomy 18	Low	Low	Low
Open neural tube defects	High	Normal	Normal
IUGR, preterm birth, stillbirth	High	No data	No data
Multiple gestation	High	High	High

Therefore, ultrasound confirmation of gestational dating is essential. In addition, ultrasonography will indicate fetal number (multiple pregnancies are associated with higher marker values) and assess the fetus and placenta for anomalies. Indeed, protocols are in current operation that include ultrasonography for biometric measurements (nuchal translucency, absence of a nose bone) combined with hormone markers as well as substances such as inhibin-A and pregnancy-associated plasma protein A (PAPP-A).<sup>215,216</sup> Protocols are also being developed that use these markers to predict fetal loss.<sup>217</sup> The combination of hormonal measurements with ultrasonography allows earlier antenatal screening, even in the first trimester, and multiple tests reduce the false-positive rate.<sup>218,219</sup> Assessment of uterine artery pulsatility by Doppler ultrasonography further adds to evaluation accuracy. The technology that allows one to measure fetal cfDNA has been rapidly transforming the field of prenatal screening as aneuploidy screening for trisomy 21 (Down syndrome), trisomy 18, trisomy 13, and sex chromosome aneuploidies can be performed using next-generation sequencing. The sources of cfDNA are both maternal and fetal. The primary source of so-called “fetal” cfDNA in the maternal circulation is thought to be apoptosis of placental cells (syncytiotrophoblast), which gets cleared from the maternal circulation soon after delivery.<sup>220</sup> The maternal contribution to most cfDNA is circulating hematopoietic

cells.<sup>221</sup> While the fetal DNA is not isolated, in the setting of a fetal chromosomal trisomy or monosomy, the differences in the fetal contribution are immense and can be detected as small differences in the total complement of DNA representative of each chromosome in the combined sample of circulating maternal and fetal cfDNA. cfDNA is the most sensitive screening option for detecting trisomy 21, 18, and 13,<sup>222</sup> and it is commonly used as a secondary screening test in women found to be screen-positive (high risk) as a result of a previous screening test. It is also increasingly being offered as a primary screening test for fetal aneuploidy in an increasing number of countries including the United States.<sup>223</sup> It is likely that further advances in this noninvasive technology will make it possible to expand screening to include other genetic conditions including monogenic disorders as well as make the test more affordable and accessible to a wider population.

The multiple marker protocol is for screening a low-risk population regardless of age, and similarly, the cfDNA testing is for initial screening or alternatively for further screening of a population deemed to be of higher risk based on prior screening. It is important to remember that amniocentesis or chorionic villus sampling is necessary for final diagnosis. Genetic amniocentesis or chorionic villus sampling has been the standard recommendation for older women; however, although multiple marker screening does not detect all chromosomal abnormalities, it is now strongly argued that the detection rate is so high that multiple marker screening or cfDNA testing with ultrasonography should be offered even to younger women, and a decision for amniocentesis or chorionic villus sampling is then based on the estimated risk for an abnormal fetus.<sup>211,224</sup>

# Relaxin

Relaxin is a peptide hormone produced by the corpus luteum of pregnancy, which is not detected in the circulation of men or nonpregnant women. A collection of related peptides compose the relaxin family, encoded by three relaxin genes and four insulin-like peptide genes. These peptides are similar in structure to insulin, composed of two short peptide chains (24 and 29 amino acids, respectively) linked by disulfide bridges. Although it has been argued that the human corpus luteum is the sole source of relaxin in pregnancy, it has also been identified in human placenta, decidua, and chorion.<sup>225,226,227</sup> The maternal serum concentration rises during the first trimester when the corpus luteum is dominant and declines in the second trimester.<sup>228</sup> This suggests a role in maintaining early pregnancy, but its function is not really known. In animals, relaxin softens the cervix (ripening), inhibits uterine contractions, and relaxes the pubic symphysis; however, relaxin levels do not correlate with changes in peripheral joint laxity in human pregnancy.<sup>229</sup> The animal cervical changes are comparable to those seen with human labor, and in in vitro studies of human cervical stromal cells, relaxin induces changes consistent with clinical ripening.<sup>230,231</sup> Human relaxin binds primarily to relaxin receptors in the decidua and chorionic cytotrophoblast.<sup>232</sup> Expression of the relaxin receptors is greatest before term and reduced after labor.<sup>233,234</sup> Relaxin, originating in the decidua and binding to its receptors in the fetal membranes, increases cytokine levels that can activate matrix metalloproteinases and lead to rupture of the membranes and labor.<sup>235</sup> A search for important roles of relaxin in human pregnancy continues, but these roles appear to be facilitatory, not mandatory.

To examine the contribution of the corpus luteum, normally, pregnant women who conceived naturally were compared with women pregnant with donated oocytes (and therefore without corpora lutea).<sup>236</sup> Circulating relaxin was undetectable in the women without functioning ovaries, confirming that its major source is the corpus luteum. No effect on prolactin secretion was observed, but it did appear that relaxin enhanced growth hormone secretion by the pituitary. Obviously, relaxin is not necessary for the maintenance of pregnancy and labor because the rest of pregnancy and the outcomes did not differ between those women with circulating levels of relaxin and those with undetectable levels. However, recombinant relaxin and drugs targeted to the relaxin receptors are being tested for clinical applications.<sup>237,238</sup> Thus far, potential uses include a decrease in collagen formation, an increase in vasodilation, an increase in vascular endothelial growth factor, and the release of histamine. In monkey studies, relaxin treatment combined with estrogen is effective for cervical ripening.<sup>239</sup>

# Prolactin

Following ovulation, the endometrium becomes a secretory organ and remains so throughout pregnancy. Decidualized endometrium secretes renin, which may be involved in the regulation of water and electrolytes in the amniotic fluid, and relaxin, which may influence prostaglandin production in the membranes. One of the best studied special endocrine functions of the decidual endometrium is the secretion of prolactin. Prolactin is synthesized by the endometrium during a normal menstrual cycle, but this synthesis is not initiated until histologic decidualization begins about day 23.<sup>240,241</sup> The control of prolactin secretion by decidual tissue has not been definitively established. Some argue that once decidualization (**Figure 7.11**) is established, prolactin secretion continues in the absence of either progesterone or estradiol, although there is evidence for an inhibitory feedback by decidual proteins (perhaps prolactin itself).<sup>240,242</sup> Others indicate that endometrial prolactin production requires the combined effects of progestin and estrogen hormones plus the presence of other placental and decidual factors, including relaxin, IGF-I, and specific stimulatory and inhibitory proteins.<sup>243</sup> Indeed, human decidual cells express a prolactin-releasing peptide that stimulates prolactin secretion.<sup>244</sup> It is recognized, however, that transcriptional regulation of the prolactin gene in the decidua is not identical to that in the pituitary and that unique transcription factors are involved.<sup>245</sup> Prolactin, hPL, and growth hormone bind to the same receptor that activates the JAK/Stat signaling pathway resulting in tyrosine phosphorylation and activation of transcription factors.

## FIGURE 7.11

During pregnancy, prolactin secretion is limited to the fetal pituitary, the maternal pituitary, and the uterus. Neither trophoblast nor fetal membranes synthesize prolactin, but both the myometrium and endometrium can produce prolactin. The endometrium requires the presence of progesterone to initiate prolactin, whereas progesterone suppresses prolactin synthesis in the myometrium. Prolactin derived from the decidua is the source of prolactin found in the amniotic fluid.<sup>246</sup> The prolactin in the fetal circulation is derived from the fetal pituitary. Decidual prolactin is transcribed by a gene with an additional exon compared with the pituitary, accounting for a different system of regulation.<sup>247</sup>

During pregnancy, prolactin maternal blood levels rise from the normal level of 10–25 ng/mL to high concentrations, beginning about 8 weeks and reaching a peak of 200–400 ng/mL at term.<sup>248,249</sup> The increase in prolactin parallels the increase in estrogen beginning at 7–8 weeks of gestation, and the mechanism for increasing prolactin secretion is believed to be estrogen suppression of the hypothalamic prolactin-inhibiting factor, dopamine, and direct stimulation of prolactin gene transcription in the pituitary.<sup>250,251</sup> There is marked variability in maternal prolactin levels in pregnancy, with a diurnal variation similar to that found in nonpregnant persons. The increase in maternal levels of prolactin represents maternal pituitary secretion in response to estrogen as the fetus prepares the mother for breastfeeding. The mechanisms for pituitary secretion of prolactin are discussed in [Chapters 2, 5, and 16](#).

Amniotic fluid concentrations of prolactin parallel maternal serum concentrations until the tenth week of pregnancy, rise markedly until the 20th week, and then undergo a decrease until delivery. The maternal and fetal blood levels of prolactin are derived from the respective pituitary glands, and, therefore, dopamine agonist suppression of pituitary secretion of prolactin throughout pregnancy produces low maternal and fetal blood levels, yet there is normal fetal growth and development, and amniotic fluid levels are unchanged.<sup>252</sup> Fortunately, decidual secretion of prolactin is unaffected by dopamine agonist treatment because decidual prolactin is important for fluid and electrolyte regulation of the amniotic fluid. This decidual prolactin is transported across the membranes in a process that requires the intact state of amnion and chorion with adherent decidua. The prolactin receptor is expressed in fetal and maternal tissues in the following descending order of intensity: chorionic cytotrophoblast, decidua, amnion, and syncytiotrophoblast.<sup>253</sup> This molecular expression is consistent with local actions.

No clinical significance can be attached to maternal and fetal blood levels of prolactin in abnormal pregnancies. Decidual and amniotic fluid prolactin levels are

lower, however, in hypertensive pregnancies and in patients with polyhydramnios.<sup>254,255</sup> Prolactin receptors are present in the chorion laeve, and their concentration is lower in patients with polyhydramnios.<sup>256</sup> Prolactin reduces the permeability of the human amnion in the fetal to maternal direction. This receptor-mediated action takes place on the epithelium lining the fetal surface.<sup>257</sup> There is also evidence that prolactin derived from the fetal pituitary contributes to the regulation of fetal water and electrolyte balance by acting as an antidiuretic hormone.<sup>258</sup>

# Cytokines and Growth Factors

The placenta synthesizes many proteins that are part of the normal composition of cells throughout the body. Local placental cytokine production is believed to be important for embryonic growth and in the maternal immune response essential for survival of the pregnancy.<sup>259</sup> Interleukin-1 $\beta$  is produced in the decidualized endometrium during pregnancy, and colony-stimulating factor-1 (CSF-1) is produced by both decidua and placenta. CSF-1 gene expression in response to interleukin-1 $\beta$  has been localized to mesenchymal fibroblasts from the core of placental villi.<sup>260</sup> Thus, a system of communication is present between maternal decidual and fetal tissue to provide growth factor support for the placenta that would include fetal hematopoiesis, a known response to CSF-1. The placenta also produces interleukin-6, and both interleukins stimulate hCG release by activation of the interleukin-6 receptor.<sup>261</sup> Thus, the interleukin-1 influence on hCG secretion is mediated by the interleukin-6 system. Both trophoblast-derived interleukin-1 and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) synergistically release interleukin-6 and activate the interleukin-6 system to secrete hCG.<sup>262</sup> Interferons and their receptors are present in virtually all cells, and thus, it is not surprising that they are found in the tissues of pregnancy.

The insulin-like growth factors, IGF-I and IGF-II, are involved in prenatal and postnatal growth and development. These growth factors do not cross the placenta into the fetal circulation; however, they may be involved in placental growth.<sup>263</sup> The maternal levels of IGF-I, which exerts lipolytic effects during pregnancy,<sup>264,265</sup> are significantly regulated by growth hormone-dependent liver synthesis. The fetus can influence maternal IGF-I levels by means of the placental secretion of hPL. An increase in maternal IGF-I levels during pregnancy with a rapid decrease after delivery indicates a significant placental influence. There is no major change in maternal IGF-II levels throughout pregnancy. There is evidence that IGF-II secreted by the placenta is also important for modulating the sensitivity of pancreatic  $\beta$  cells to glucose<sup>266</sup> and maternal insulin and glucose concentrations during pregnancy.<sup>267,268</sup> The six IGF-binding proteins transport IGFs in the circulation, protect IGFs against metabolism and clearance, and, importantly, affect the biologic activity of IGFs by modulating IGF availability at the cellular level. Pregnancy is marked by a rise in maternal levels of insulin-like growth factor-binding protein-1 (IGFBP-1), beginning at the end of the first trimester and reaching a peak at term.<sup>269,270</sup> IGFBP-1 is now recognized to be the same as placental protein-12, a decidual protein. Thus, IGFBP-1 originates in the decidua, regulated by progesterone, as well as in the liver. The prominence of IGFBP-1 in the pregnant state is in contrast to the nonpregnant state when IGFBP-3 is the main circulating IGFBP. During pregnancy, the levels of IGFBP-3 and IGFBP-2 decrease, apparently due to the

activity of a pregnancy-associated serum protease (IGFBP-3 protease).<sup>269</sup> These changes would promote the bioavailability of IGF-I in maternal tissues, and this may be important in enhancing nutrient transfer from the mother to the placenta. There is evidence to indicate that the mother can alter IGFBP-3 proteolytic activity according to her nutritional state; thus, increased proteolysis would decrease IGFBP-3 levels increasing the bioavailability of maternal IGF-I.<sup>271</sup>

In the pregnant ewe and fetal lamb, glucose and other nutritional factors regulate the gene expression and, therefore, the circulating levels of IGF-binding proteins.<sup>272</sup> Fasting and feeding increased and decreased, respectively, the IGFBP concentrations, perhaps partly a response to insulin levels and the effect of insulin on liver synthesis of IGFBPs. These changes are consistent with IGF and IGFBP involvement in the responses to nutrition and stress. Because IGFBP-1 appears to be the principal binding protein in pregnancy, attention is focused on the changes in IGF-I and IGFBP-1. IGF-I, produced in the placenta, regulates transfer of nutrients across the placenta to the fetus and, thus, enhances fetal growth; IGFBP-1, produced in the decidua, interferes with IGF-I action and inhibits fetal growth.<sup>273</sup> Thus, newborn birth weight correlates directly with maternal levels of IGF-I and inversely with levels of IGFBP-1.

Intrauterine growth restriction is associated with reduced fetal blood levels of IGF-I and IGFBP-3 and increased levels of IGFBP-1 and IGFBP-2.<sup>274</sup> In view of the strong relationship between the IGF system and fetal nutrition, it is logical that fetal glucose availability and insulin are the principal regulating agents. In experimental animals, an increase in fetal insulin or glucose elevates IGF-I levels, whereas nutritional restriction causes an increase in IGFBP-1 and IGFBP-2 and a decrease in IGFBP-3.<sup>275</sup> Insulin is believed to influence growth by promoting cellular uptake of nutrients and by increasing IGF-I production. The fetal blood levels of IGF-II parallel those of IGF-I, and IGF-II promotes fetal growth by means of the IGF-I receptor. IGF-II appears to be important early in embryonic growth, and then after organ development is complete, IGF-I becomes the dominant factor.

EGF is present in both cytotrophoblast and syncytiotrophoblast, but more intensely in syncytiotrophoblast, and probably is involved in the differentiation of cytotrophoblast into syncytiotrophoblast. EGF is well known as a mitogen. Other growth factors isolated from human placenta include platelet-derived growth factor, nerve growth factor, fibroblast growth factor, and transforming growth factors. These factors are probably all involved in the proliferation and growth associated with pregnancy.

# Inhibin, Activin, and Follistatin

The placenta produces inhibin, which is responsible for the marked increase in maternal inhibin levels throughout pregnancy.<sup>276,277</sup> Inhibin-A is the principal bioactive inhibin secreted during pregnancy, rising in the maternal circulation at the time of the emergence of placental function, peaking at 8 weeks of gestation, and then decreasing before increasing again in the third trimester to reach a level at term that is 100 times greater than that during the normal menstrual cycle.<sup>278,279,280,281</sup> Undoubtedly, the high levels of inhibin and estrogen during pregnancy account for the profound suppression of maternal gonadotropins. Trophoblastic inhibin synthesis is inhibited by activin-A and stimulated by hCG, GnRH, EGF, transforming growth factor- $\alpha$ , and PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub> , the major placental prostaglandins.<sup>277</sup> Activin-A, the major trophoblastic activin product, also increases in the maternal circulation, with elevated but stable levels from 8 to 24 weeks, and then increasing to reach a level at term that is also 100 times greater than that during the normal menstrual cycle.<sup>282</sup>

Similar to their action in the ovarian follicle, inhibin and activin are regulators within the placenta for the production of GnRH, hCG, and steroids; as expected, activin is stimulatory, and inhibin is inhibitory.<sup>128</sup> GnRH and the subunits for inhibin and activin can be found in the same placental cells, in both cytotrophoblast and syncytiotrophoblast.<sup>283</sup> The maternal levels of inhibin-B are very low throughout pregnancy; however, inhibin-B is significantly expressed in the amnion where it is believed to influence prostaglandin synthesis.<sup>284</sup> Trophoblast synthesis and release of inhibin and activin are part of the complex placental story, involving many hormones and locally produced factors. The placental and decidual appearance of inhibin and activin occurs early in pregnancy in time for possible roles in embryogenesis and local immune responses. Higher levels of activin-A are found at midgestation in women who subsequently develop pre-eclampsia.<sup>208,285</sup>

Follistatin is the activin-binding protein expressed in placenta, membranes, and decidua.<sup>286</sup> Because follistatin binds activin, it antagonizes the stimulatory effects of activin on placental steroid and peptide production.

# Endogenous Opiates

Fetal and maternal endogenous opiates originate from the pituitary glands and are secreted in parallel with ACTH, in response to CRH, which is, in part, derived from the placenta.<sup>287</sup> There is reason to believe that in pregnancy, the intermediate lobe of the maternal pituitary gland is a major source of elevated circulating endorphin levels. However, the syncytiotrophoblast in response to CRH produces all of the products of POMC metabolism, including  $\beta$ -endorphin, enkephalins, and dynorphins. The placenta and membranes are richly endowed with G protein opioid receptors.<sup>288</sup> The presence of CRH in the placenta and placental opiate production in response to CRH and oxytocin indicate an interaction similar to that in the hypothalamic-pituitary axis.<sup>289</sup>

It is not certain whether maternal blood levels of endogenous opiates increase with advancing gestation.<sup>92</sup> However, a marked increase in maternal values is reached during labor, coinciding with full cervical dilation. The maternal levels also correlate with the degree of pain perception and use of analgesia. On the fetal side, hypoxia is a potent stimulus for endorphin release.

There are many hypotheses surrounding the function of endogenous opiates in pregnancy. These include roles related to stress; inhibition of oxytocin, vasopressin, and gonadotropins; the promotion of prolactin secretion; and, of course, a natural analgesic agent during labor and delivery.

# The Renin-Angiotensin System

The maternal circulating levels of prorenin, the inactive precursor of renin, increase 10-fold during early pregnancy, the result of ovarian stimulation by hCG.<sup>290,291</sup> This increase in prorenin from the ovary is not associated with any significant change in the blood levels of the active form, renin. Possible roles for this ovarian prorenin-renin-angiotensin system include the following: stimulation of steroidogenesis to provide androgen substrate for estrogen production, regulation of calcium and prostaglandin metabolism, and stimulation of angiogenesis. This system may affect vascular and tissue functions both in and outside the ovary. Prorenin also originates in chorionic tissues and is highly concentrated in the amniotic fluid. The highest biologic levels of prorenin are found in gestational sacs in early pregnancy; its possible roles in embryonic growth and development remain speculative.<sup>291</sup> Renin and angiotensinogen (the renin substrate) are expressed by the following fetal tissues: chorion, amnion, and placenta.<sup>292</sup> This system responds to a variety of factors, affecting vascular resistance and blood volume.<sup>293</sup> Maternal renin activity is increased fourfold by midgestation, partly a response to an estrogen-induced increase in angiotensinogen but largely a compensatory response to maintain blood pressure in the presence of vasodilation.<sup>294</sup> There is no evidence that fetal or uterine prorenin or renin contributes to the maternal circulation.

# Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is derived from human atrial tissue and the placenta.<sup>295</sup> It is a potent natriuretic, diuretic, and smooth muscle–relaxant peptide that circulates as a hormone. Maternal ANP increases in the third trimester and during labor, and cord levels on the arterial side suggest that ANP is a circulating hormone in the fetus.<sup>296</sup> In the mother, ANP release is stimulated by atrial stretch, and this is another mechanism for regulating the volume and electrolyte changes associated with pregnancy and delivery.<sup>297</sup> ANP regulates water and electrolyte balance in the fetus as well, and increased amniotic fluid and maternal blood second-trimester levels of ANP have been reported in the presence of fetal cardiac malformations.<sup>298</sup> In mice with a targeted deletion of the natriuretic peptide receptor, hearts are enlarged, and surviving adults have hypertension and cardiac hypertrophy.<sup>299</sup> ANP belongs to a family of natriuretic peptides that have been found in the human uterus. ANP is secreted by myometrial cells and exerts a suppressive effect on myometrial contractions; it is speculated that the expanding uterus may release ANP just as the heart does when the atrium is stretched.<sup>300</sup>

## Other Proteins

The mother responds to a pregnancy even before implantation. Remarkably, early pregnancy factor (EPF) can be detected in the maternal circulation within 1–2 days after coitus results in a pregnancy.<sup>301</sup> It remains throughout pregnancy but, interestingly, disappears before parturition. EPF prior to implantation is apparently produced by the ovary in response to a signal from the embryo. After implantation, EPF is no longer secreted by the ovary but now is derived from the embryo. EPF is a protein associated with cell proliferation and growth and, therefore, is present in many nonpregnant tissues such as neoplasms. EPF has immunosuppressive properties and is abundant in platelets.

Pregnancy-specific  $\gamma_1$ -glycoprotein (PSG) was previously known as Schwangerschaftsprotein 1. The physiologic function of PSG produced by the placenta is unknown, but it has been used as a test for pregnancy and a marker for malignancies, including choriocarcinoma. Molecular studies have revealed that PSG consists of a family of glycoproteins encoded by genes on chromosome 19.<sup>302</sup> The PSG family is closely related to the carcinoembryonic antigen (CEA) proteins.

Placental soluble fms-like tyrosine kinase (sFlt-1) and soluble endoglin (sENG) are circulating receptors for VEGF and PLGF and transforming growth factor- $\beta$  (TGF- $\beta$ ), respectively.<sup>303,304</sup> Soluble Flt-1 and sENG are secreted in large quantities by the placenta resulting in marked elevation in their circulating levels during pregnancy, which steadily rise until term.<sup>303,304</sup> They are almost undetectable in the circulation of nonpregnant individuals. Both sFlt-1 and sENG are found to be increased in sera and placentae of women with pre-eclampsia, and their abnormal elevation predates the development of the syndrome. There is experimental animal evidence that sENG cooperates with sFlt-1 to induce endothelial dysfunction in vitro and pre-eclampsia in vivo.<sup>305</sup> It is thought that sFlt-1 and sENG elevation results in angiogenic imbalance, which in turn leads to endothelial damage and the clinical onset of the syndrome. However, large prospective studies have failed to show sufficient accuracy of these biomarkers for clinical utility in prediction of pre-eclampsia.<sup>306,307,308</sup>

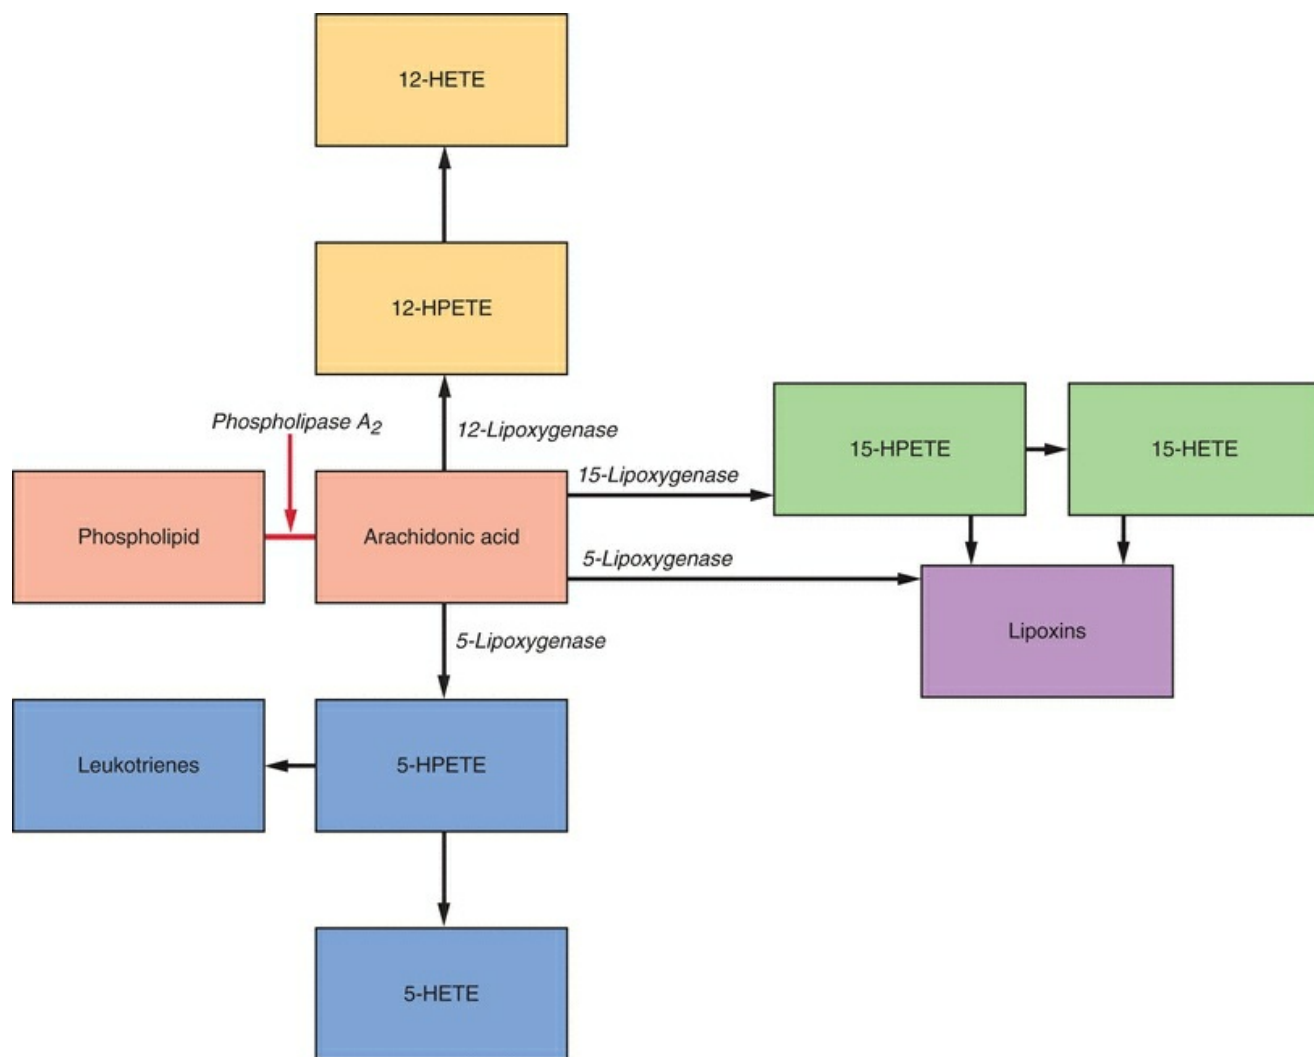

Pregnancy-associated plasma protein-A is a placental protein that is similar to a macroglobulin in the serum, and investigators are still in search of specific functions. Low levels of PAPP-A in the first trimester are associated with adverse obstetrical outcomes.<sup>208</sup> Progesterone-associated endometrial protein, previously called placental protein 14, is now recognized to originate in secretory endometrium and decidua. No role for this protein has been described thus far. Neuropeptide Y, a peptide extensively distributed in the brain, is found in trophoblast, membranes, and decidua, with higher but nonchanging maternal blood levels during pregnancy.<sup>92</sup>

# PROSTAGLANDINS

---

# Prostaglandin Biosynthesis

Prostaglandins are autocrine and paracrine factors produced in almost all cells in the human body. The family of prostaglandins with the greatest biologic activity is that having two double bonds, derived from arachidonic acid.<sup>309,310</sup> Arachidonic acid can be obtained from two sources, directly from the diet (from meats) or by formation from its precursor linoleic acid, which is found in vegetables. In the plasma, 1–2% of the total free fatty acid content is free arachidonic acid. The majority of arachidonic acid is covalently bound in esterified form as a significant proportion of the fatty acids in phospholipids and in esterified cholesterol. Arachidonic acid is only a minor fatty acid in the triglycerides packaged in adipose tissue (**Figure 7.12**).

**FIGURE 7.12**

The rate-limiting step in the formation of the prostaglandin family is the release of free

arachidonic acid. A variety of hydrolases may be involved in arachidonic acid release, but phospholipase A<sub>2</sub> activation is an important initiator of prostaglandin synthesis because of the abundance of arachidonate in the 2 position of phospholipids. In addition, phospholipase C activity can provide arachidonic acid. Types of stimuli that activate such lipases include burns, infusions of hypertonic and hypotonic solutions, thrombi and small particles, endotoxin, snake venom, mechanical stretching, catecholamines, bradykinin, angiotensin, and the sex steroids.

“Eicosanoids” refer to all the 20-carbon derivatives, whereas “prostanoids” indicate only those containing a structural ring. After the release of arachidonic acid, the synthetic path can go in two different directions: the lipoxygenase pathway or the cyclo-oxygenase (prostaglandin endoperoxide H synthase) pathway, depending on the local cellular context. There are three lipoxygenase enzymes that lead to active compounds, predominantly in inflammatory white blood cells. Arachidonic acid is first converted to hydroperoxyeicosatetraenoic acids (HPETEs) and then to hydroxyeicosatetraenoic acids (HETEs), lipoxins, or leukotrienes. The leukotrienes are formed by 5-lipoxygenase oxygenation of arachidonic acid at C-5, forming an unstable intermediate, LTA<sub>4</sub>.<sup>311</sup> LTB<sub>4</sub> is formed by hydration and LTC<sub>4</sub> by the addition of glutathione. The remaining leukotrienes are metabolites of LTC<sub>4</sub>. The previously known “slow-reacting substance of anaphylaxis” consists of a mixture of LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub>. The leukotrienes are involved in the defense reactions of white cells and participate in hypersensitivity and inflammatory responses. LTB<sub>4</sub> acts primarily on leukocytes (stimulation of leukocyte emigration from the bloodstream), whereas LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub> affect smooth muscle cells (bronchoconstriction in the lungs and reduced contractility in the heart). All leukotrienes increase microvascular permeability. Thus, the leukotrienes are major agonists, synthesized in response to antigens provoking asthma and airway obstruction. Leukotrienes are 100–1,000 times more potent than histamine in the pulmonary airway. Asthma is now treated with specific leukotriene receptor antagonists.

The 12-lipoxygenase pathway leads to 12-hydroxyeicosatetraenoic acid (12-HETE). Little is known about 12-HETE other than its function as a leukostatic agent. The lipoxins (LXA and LXB), products of the 5- and 15-lipoxygenase pathways, inhibit natural killer cell cytotoxicity and are vasodilators.<sup>311</sup>

The cyclo-oxygenase pathway leads to the prostaglandins. The first true prostaglandin (PG) compounds formed are PGG<sub>2</sub> and PGH<sub>2</sub> (half-life of about 5 minutes), the mothers of all other prostaglandins. The numerical subscript refers to the number of double bonds. This number depends on which of the three precursor fatty acids has been utilized. Besides arachidonic acid, the other two precursor fatty acids

are linoleic acid, which gives rise to the PG<sub>1</sub> series, and pentanoic acid, the PG<sub>3</sub> series. The latter two series are of less importance in physiology, hence the significance of the arachidonic acid family. The prostaglandins of original and continuing relevance to reproduction are PGE<sub>2</sub> and PGF<sub>2α</sub> and possibly PGD<sub>2</sub>. The α in PGF<sub>2α</sub> indicates the α steric configuration of the hydroxyl group at the C-9 position. The A, B, and C prostaglandins either have little biologic activity or do not exist in significant concentrations in biologic tissues. In the original work, the prostaglandin more soluble in ether was named PGE, and the one more soluble in phosphate (spelled with an F in Swedish) buffer was named PGF. Later, naming became alphabetical.

The cyclo-oxygenase enzyme (prostaglandin synthase) exists in two forms, COX-1 and COX-2, products of separate genes.<sup>312,313,314</sup> Prostacyclin is produced by COX-1, the constitutive form of the enzyme found in virtually all tissues, whereas COX-2 is induced in responses to inflammatory stimuli. COX-2 is expressed only after stimulation by various growth factors, cytokines, hormones, and endotoxins; therefore, it is called the inducible form. Thus, selective inhibition of COX-2 would possibly be therapeutically advantageous, avoiding the side effects associated with inhibition of COX-1 (**Figure 7.13**).

**FIGURE 7.13**

# Thromboxane and Prostacyclin

Thromboxanes are not true prostaglandins because of the absence of the pentane ring, but prostacyclin ( $\text{PGI}_2$ ) is a legitimate prostaglandin. Thromboxane (TX) (half-life about 30 seconds) and  $\text{PGI}_2$  (half-life about 2–3 minutes) can be viewed as opponents, each having powerful biologic activity that counters or balances the other.  $\text{TXA}_2$  is the most powerful vasoconstrictor known, whereas  $\text{PGI}_2$  is a potent vasodilator. These two agents also have opposing effects on platelet function. Platelets, lungs, and the spleen predominately synthesize  $\text{TXA}_2$ , whereas the heart, stomach, and blood vessels throughout the body synthesize  $\text{PGI}_2$ . The lungs are a major source of prostacyclin. Normal pulmonary endothelium makes prostacyclin, whereas  $\text{TXA}_2$  appears in response to pathologic stimuli.<sup>315</sup> The pulmonary release of prostacyclin may contribute to the body's defense against platelet aggregation (**Figure 7.14**).

**FIGURE 7.14**

Let us take a closer look at platelets. The primary function of platelets is the preservation of the vascular system. Blood platelets stick to foreign surfaces or other tissues, a process called adhesion. They also stick to each other and form clumps; this process is called aggregation. Because platelets synthesize  $\text{TXA}_2$ , a potent stimulator of

platelet aggregation, the natural tendency of platelets is to clump and plug defects and damaged spots. The endothelium, on the other hand, produces PGI<sub>2</sub>, and its constant presence inhibits platelet aggregation and adherence, keeping blood vessels free of platelet aggregates and ultimately clots. Thus, prostacyclin has a defensive role in the body. It is 4–8 times more potent a vasodilator than the E prostaglandins, and it prevents the adherence of platelets to healthy vascular endothelium. However, when the endothelium is damaged, platelets gather, beginning the process of thrombus formation. Even in this abnormal situation, prostacyclin strives to fulfill its protective role because increased PGI<sub>2</sub> can be measured in injured endothelium, in thrombosed vessels, and in the vascular tissues of hypertensive animals.

It is believed that endothelial production of prostacyclin plays an important role in the impressive vasodilation that is associated with pregnancy. The placenta is a major source of thromboxane, and pre-eclampsia may, in part, reflect an imbalance between the vasodilator, prostacyclin, and the vasoconstrictor, thromboxane.<sup>316</sup>

Conditions associated with vascular disease can be understood through the prostacyclin-thromboxane mechanism. For example, atheromatous plaques and nicotine inhibit prostacyclin synthesis. Increasing the cholesterol content of human platelets increases the sensitivity to stimuli that cause platelet aggregation due to increased thromboxane production. The well-known association between low-density and high-density lipoproteins (HDLs) (LDL cholesterol and HDL cholesterol) and cardiovascular disease may also be partly explained in terms of PGI<sub>2</sub>. LDL from men and postmenopausal women inhibits, and HDL stimulates prostacyclin production.<sup>317</sup> Platelets from diabetic pregnant women make more TXA<sub>2</sub> than platelets from normal pregnant women. Smokers who use oral contraceptives have increased platelet aggregation and an inhibition of prostacyclin formation.<sup>318</sup> Incidentally, onion and garlic inhibit platelet aggregation and TXA<sub>2</sub> synthesis.<sup>319</sup> Perhaps the perfect contraceptive pill is a combination of progestin, estrogen, and some onion or garlic.

In some areas of the world, there is a low incidence of cardiovascular disease. This can be directly attributed to diet and the protective action of prostacyclin.<sup>320</sup> The diet of Eskimos and Japanese has a high content of pentanoic acid and low levels of linoleic and arachidonic acids. Pentanoic acid is the precursor of prostaglandin products with three double bonds, and, as it happens, PGI<sub>3</sub> is an active agent, whereas TXA<sub>3</sub> is either not formed or inactive. The fat content of most common fish is 8–12% pentanoic acid and more than 20% in the more exotic (and expensive) seafoods such as scallops, oysters, and caviar.

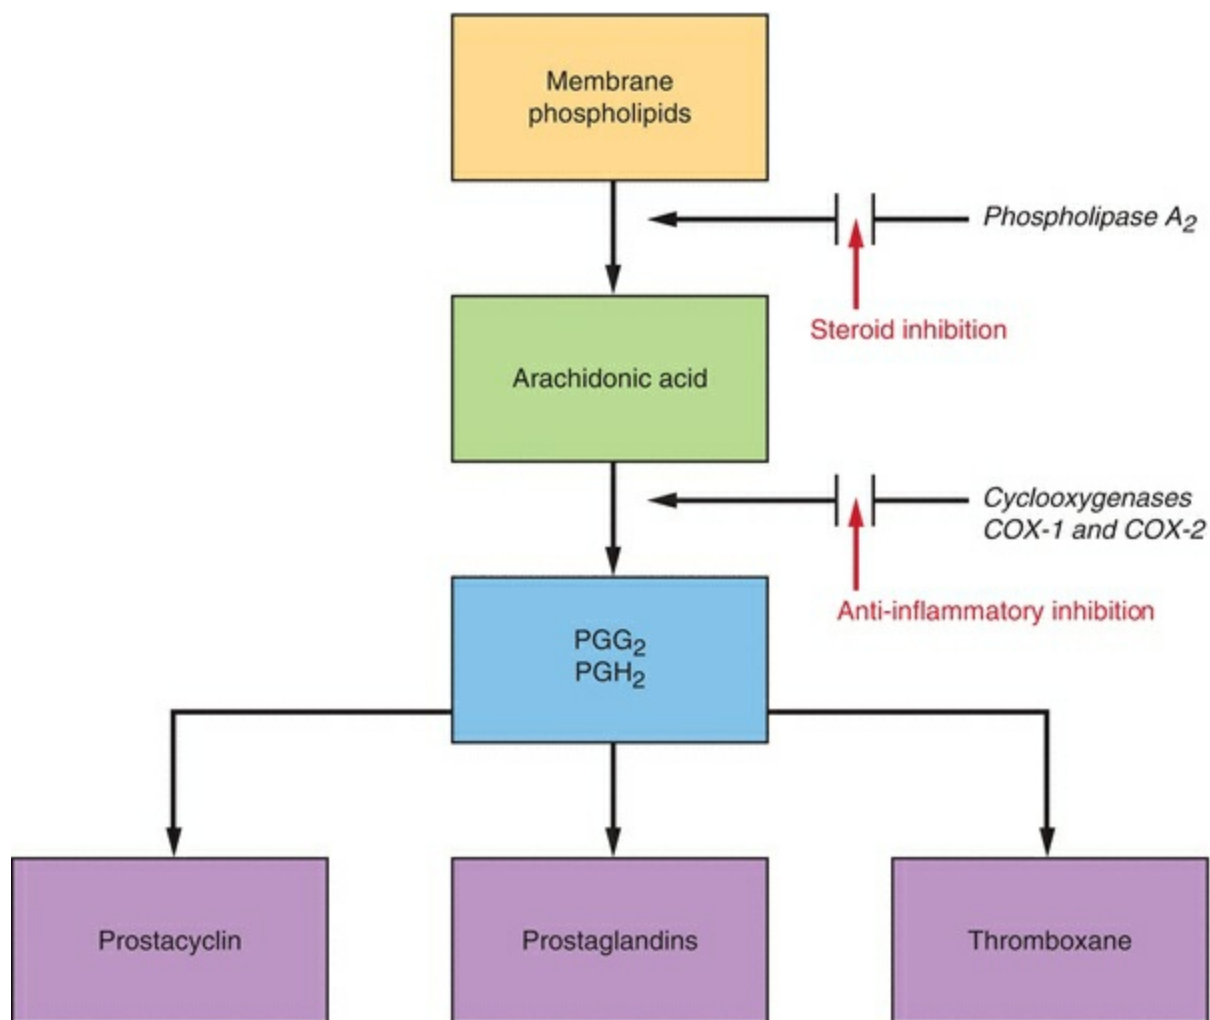

# Metabolism

Prostaglandin metabolism is initiated by 15-hydroxyprostaglandin dehydrogenase. The metabolism of prostaglandins occurs primarily in the lungs, kidneys, and liver. The lungs are important in the metabolism of E and F prostaglandins. Indeed, there is an active transport mechanism that specifically carries E and F prostaglandins from the circulation into the lungs. Nearly all active prostaglandins in the circulation are metabolized during one passage through the lungs. Therefore, members of the prostaglandin family have a short half-life and, in most instances, exert autocrine/paracrine actions at the site of their synthesis. Because of the rapid half-lives, studies are often performed by measuring the inactive end products, for example, 6-keto-PGF<sub>1α</sub>, the metabolite of prostacyclin, and TXB<sub>2</sub>, the metabolite of thromboxane A<sub>2</sub>.

# Prostaglandin Inhibition

A review of prostaglandin biochemistry is not complete without a look at the inhibition of the biosynthetic cascade of products. Corticosteroids were thought to inhibit the prostaglandin family by stabilizing membranes and preventing the release of phospholipase. It is now proposed that corticosteroids induce the synthesis of proteins called lipocortins (or annexins), which block the action of phospholipase.<sup>321</sup> Thus far, corticosteroids and some local anesthetic agents are the only substances known to work at this step. Because corticosteroids reduce the availability of arachidonic acid for both the lipoxygenase and cyclo-oxygenase pathways, they are very effective anti-inflammatory agents and antihypersensitivity agents, especially for the treatment of asthma.

Aspirin is an irreversible inhibitor, selectively acetylating the cyclo-oxygenase involved in prostaglandin synthesis. The other inhibiting agents, nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin and naproxen, are reversible agents, forming a reversible bond with the active site of the enzyme. Acetaminophen inhibits cyclo-oxygenase in the central nervous system, accounting for its analgesic and antipyretic properties, but it has no anti-inflammatory properties and does not affect platelets. However, acetaminophen does reduce prostacyclin synthesis; the reason for this preferential effect is unknown.<sup>322</sup> The analgesic, antipyretic, and anti-inflammatory actions of these agents are mediated by inhibition of the cyclo-oxygenase enzymes, COX-1 and COX-2. Aspirin, indomethacin, and ibuprofen are more potent inhibitors of COX-1 than COX-2.<sup>323</sup> Diclofenac, acetaminophen, and naproxen inhibit both enzymes equally. The side effects associated with each agent are a reflection of the degree of selectivity toward the two enzymes; inhibition of COX-1, the constitutive form, is associated with significant side effects, and inhibition of COX-2, the inducible form, is potentially therapeutic for pain and inflammation. Part of the anti-inflammatory activity of glucocorticoids is due to inhibition of COX-2 formation. The well-known gastric ulcerogenic side effect of anti-inflammatory drugs is due to the fact that PGE<sub>2</sub> protects the gastric mucosa by inhibiting gastric acid secretion, and COX-1 is the predominant enzyme in the gastric mucosa. The specific inhibitors of COX-2 are effective analgesics with a better gastrointestinal side effect profile (**Figure 7.15**).

**FIGURE 7.15**

Efficacy in treating dysmenorrhea is similar compared to the older agents with the newer specific COX-2 inhibitors. Theoretically, the COX-2 inhibitors should avoid the unwanted inhibition of prostaglandin activity in the process of ovulation; however, in the mouse, it is the COX-2 enzyme that is involved in ovulation, and rofecoxib delayed ovulation in a small trial of women.<sup>324,325</sup>

Because of the irreversible nature of the inhibition by aspirin, aspirin exerts a long-lasting effect on platelets, maintaining inhibition in the platelet for its life span (8–10 days). Prostacyclin synthesis in the endothelium recovers more quickly because the endothelial cells can resynthesize new cyclo-oxygenase. Platelets, lacking nuclei, cannot produce new enzyme, probably exclusively COX-1. The sensitivity of the platelets to aspirin may explain the puzzling results in the early studies in which aspirin was given to prevent subsequent morbidity and mortality following thrombotic events. It takes only a little aspirin to effectively inhibit thromboxane synthesis in platelets. Going beyond this dose will not only inhibit thromboxane synthesis in platelets but also inhibit

the protective prostacyclin production in blood vessel walls. Some suggest that a dose of 3.5 mg/kg (about half an aspirin tablet) given at 3-day intervals effectively induces maximal inhibition of platelet aggregation without affecting prostacyclin production by the vessel walls.<sup>326</sup> Others indicate that the dose that effectively and selectively inhibits platelet cyclo-oxygenase is 20–40 mg daily.<sup>327,328</sup> The major handicap with the use of inhibitors of PG synthesis is that they strike blindly and with variable effects from tissue to tissue. Obviously, drugs that selectively inhibit TXA<sub>2</sub> synthesis would be superior to aspirin in terms of antithrombotic effects.

A concern with the specific COX-2 inhibitors is their inhibition of prostacyclin formation, whereas COX-1 generation of TXA<sub>2</sub> is unaffected. Unfortunately, arterial thrombotic events, including myocardial infarction and stroke, are about twofold increased in users of COX-2 inhibitors, raising appropriate caution, especially in individuals at high risk for cardiovascular disease.<sup>329</sup> It is not certain that nonselective, traditional NSAIDs don't share this cardiovascular risk.

# THE ENDOCRINOLOGY OF PARTURITION

---

The timing of birth is a crucial determinant of perinatal outcome. Both preterm birth (defined as delivery before 37 weeks of gestation) and postterm pregnancy (failure to deliver before 42 weeks) are linked to higher risk of adverse pregnancy events. It has long been thought that the fetoplacental unit is in charge of the timing of parturition.<sup>330,331</sup> While this appears to be true in some species, despite intensive investigations spanning many decades, a precise mechanism of such a “placental clock” has yet to crystallize in humans. It has now become apparent that the endometrium/decidua also plays a central role in initiating the cascade of events culminating in human birth.<sup>332</sup>

Perhaps the best example of the interplay among fetus, placenta, and mother is the initiation and maintenance of parturition. Hormonal changes in the uteroplacental environment are the principal governing factors accounting for the eventual development of uterine contractions. The sequence of events has been repeatedly reviewed in detail, where references to the original work are available.<sup>333,334,335,336,337,338,339</sup>

Extensive work in sheep has implicated the fetal pituitary-adrenal axis in normal parturition. The sequence of events in the ewe begins about 10 days prior to labor with elevation of fetal cortisol in response to fetal pituitary ACTH, in turn a response to increased release of hypothalamic CRH. Fetal adrenalectomy or hypophysectomy prolongs pregnancy, whereas infusion of ACTH or glucocorticoids into the sheep fetus stimulates premature labor. Maternal stimulation of the fetal adrenal is not a factor because in sheep (and in women) there is little or no placental transfer of maternal ACTH into the fetal circulation. Thus, parturition in the ewe is initiated by a signal in the fetal brain activating ACTH secretion.

Increased cortisol secretion by the fetal adrenal gland starts a chain of events associated with labor. The sequence of events continues in the ewe with a decline in progesterone. This change is brought about by the induction of 17 $\alpha$ -hydroxylase, 17,20-lyase enzyme activity (P450c17) in the placenta (**Figure 7.16**). The up-regulation of P450c17 may be mediated by PGE<sub>2</sub>. COX-2 activity is stimulated by cortisol, while at the same time, cortisol inhibits the activity of 15-hydroxyprostaglandin dehydrogenase. An increase in PGE<sub>2</sub> correlates with the increasing activity of P450c17.

## Changes in Sheep Pregnancy

**FIGURE 7.16**

Glucocorticoid treatment of sheep placental tissue specifically increases the rate of production of 17 $\alpha$ ,20 $\alpha$ -dihydroxypreg-4-en-3-one. This dihydroxyprogesterone compound also has been identified in sheep placental tissue obtained after spontaneous labor. Thus, direct synthesis of progesterone does not decline, but increased metabolism to a 17 $\alpha$ -hydroxylated product results in less available progesterone. Progesterone withdrawal is associated with a decrease in the resting potential of myometrium, that is, an increased response to electric and oxytocic stimuli. Conduction of action potential through the muscle is increased, and the myometrial excitability is increased.

Dihydroxyprogesterone also serves as a precursor for the rise in estrogen levels, which occurs a few days prior to parturition. Estrogens enhance rhythmic contractions, as well as increase vascularity and permeability and the oxytocin response. Thus, progesterone withdrawal and estrogen increase lead to an enhancement of conduction and excitation.

The final event in the ewe is a rise in PGF<sub>2 $\alpha$</sub>  production hours before the onset of uterine activity. A cause-and-effect relationship between the rise in estrogen and the

appearance of  $\text{PGF}_{2\alpha}$  has been demonstrated in sheep. These events indicate that the decline in progesterone, the rise in estrogen, and the increase in  $\text{PGF}_{2\alpha}$  are all secondary to direct induction of a placental enzyme by fetal cortisol.

# Human Parturition

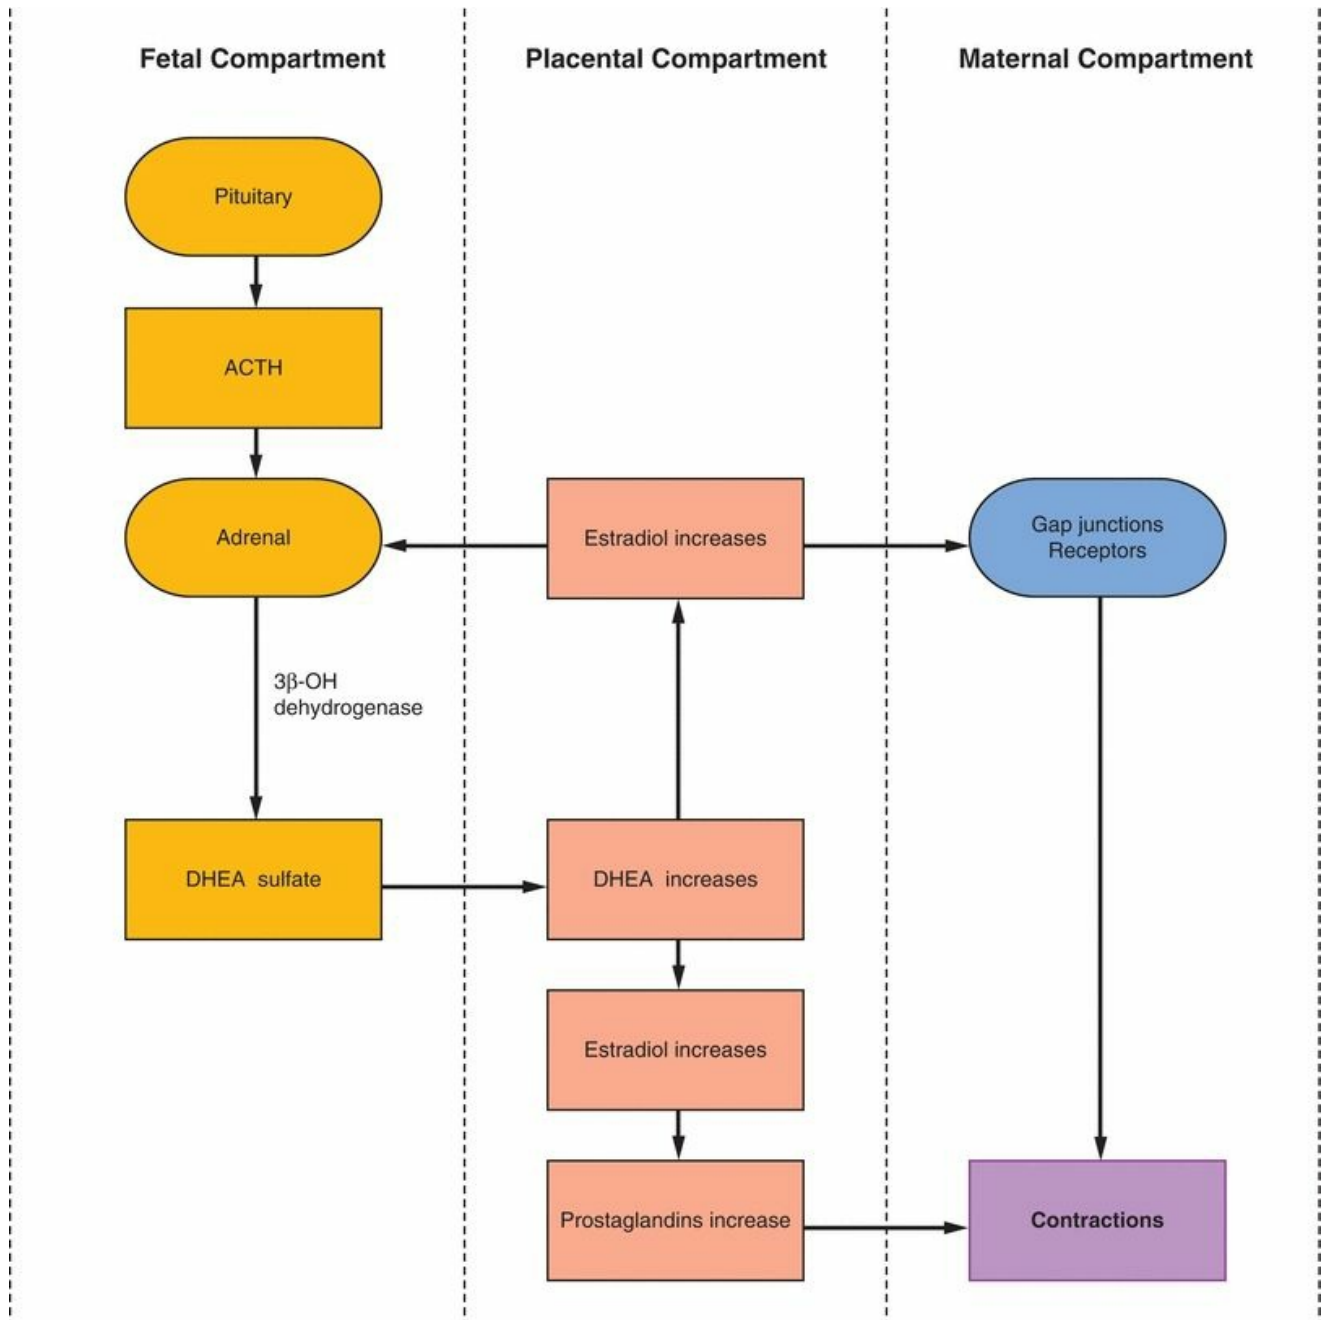

The control of pregnancy and parturition is very species specific. The mechanisms involved in human pregnancy maintenance and parturition are highly complex and involve both maternal and fetal systems. There is no simple chain of events as there are in other species. The steroid events in human pregnancy are not identical to events in the ewe, chiefly because placental P450c17 enzyme activity is absent. In addition, there is a more extended time scale. Steroid changes in the ewe occur over the course of several days, whereas in human pregnancy the changes begin at approximately 34–36 weeks and occur over the last 5 weeks of pregnancy. However, if the time course is expressed as a percentage of gestational length, the percentages in sheep and primates are impressively comparable.

Cortisol rises dramatically in amniotic fluid, beginning at 34–36 weeks, and correlates with pulmonary maturation. Cord blood cortisol concentrations are high in infants born vaginally or by cesarean section following spontaneous onset of labor. In contrast, cord blood cortisol levels are lower in infants born without spontaneous labor, whether delivery is vaginal (induced labor) or by cesarean section (elective repeat section). In keeping with the extended time scale of events, administration of glucocorticoids is not followed acutely by the onset of labor in pregnant women (unless the pregnancy is past due).

It is unlikely that the cortisol increments in the fetus represent changes due to increased adrenal activity in the mother in response to stress. Although maternal cortisol crosses the placenta readily, it is largely (85%) metabolized to cortisone in the process. This, in fact, may be the mechanism by which suppression of the fetal adrenal gland by maternal cortisol is avoided. In contrast to the maternal liver, the fetal liver has a limited capacity for transforming the biologically inactive cortisone to the active cortisol. On the other hand, the fetal lung does possess the capability of changing cortisone to cortisol, and this may be an important source of cortisol for lung maturation. Cortisol itself induces this conversion in lung tissue. Increased fetal adrenal activity is followed by changes in steroid levels, as well as important developmental accomplishments (e.g., increased pulmonary surfactant production and the accumulation of liver glycogen). In human parturition, an important contribution of the fetal adrenal, in addition to cortisol, is its effect on placental estrogen production. The common theme in human pregnancies associated with failure to begin labor on time is decreased estrogen production, for example, delayed parturition in anencephaly or placental sulfatase deficiency.<sup>340</sup>

Progesterone maintenance of uterine quiescence and increased myometrial excitability associated with progesterone withdrawal are firmly established as mechanisms of parturition in lower species (**Figure 7.17**). In primates, the role of

progesterone has been less certain, largely because of the inability to demonstrate a definite decline in peripheral blood levels of progesterone prior to parturition.<sup>341</sup> Nevertheless, pharmacologic treatment with progesterone or synthetic progestational agents has some effect in preventing premature labor, although not labor at term.<sup>342,343,344,345</sup> There is also reason to believe that progesterone concentration is regulated locally, especially in the fetal membranes, and progesterone withdrawal can be accomplished by a combination of binding, metabolism, and changes in receptor isoform levels, as well as changes in coactivating and corepressing proteins.<sup>346</sup>

**FIGURE 7.17**

In the myometrium, during advancing gestation and with parturition, overall progesterone receptor concentration does not change with the onset of labor; however, a shift in receptor isoforms occurs with a dominance of progesterone receptor-A and other isoforms of the progesterone receptor other than receptor-B (progesterone receptor-C, another truncated isoform, is expressed in the myometrium, decidua, and membranes).<sup>347,348,349,350,351</sup> **Because progesterone receptor-A mainly suppresses progesterone receptor-B activity (the principal mediator of genomic progestational action), this change is consistent with a local withdrawal of progesterone in the myometrium. Therefore, there is growing reason to believe that a functional progesterone withdrawal occurs in primates, keeping the mechanism of parturition evolutionarily consistent. This withdrawal of progesterone occurs not only in the myometrium but also in the decidua and the fetal membranes.**

Because progesterone receptor-B activity suppresses estrogen receptor expression, a shift to progesterone receptor-A would simultaneously allow both progesterone withdrawal and an increase in estrogen activity.<sup>348</sup> This further indicates that the process of parturition begins before the onset of contractions. Prostaglandin involvement continues to be an integral part of this process; prostaglandin F<sub>2α</sub> stimulates progesterone receptor-A expression in myometrial cells studied in vitro, a response consistent with the emerging dominance of progesterone receptor-A before parturition.<sup>352</sup>

Progesterone receptor concentrations in the monkey amnion change in the presence of labor, consistent with activation of prostaglandin and cytokine production in the membranes following functional progesterone withdrawal.<sup>347</sup> In a fashion similar to human myometrium, progesterone receptor-A levels in monkey myometrium increase in late gestation and during labor. Interruption of exposure to progesterone (e.g., with the antiprogesterone, RU-486) leads to uterine contractions.<sup>353</sup> Furthermore, inhibition of progesterone production in the second trimester of human or the third trimester of monkey pregnancies is followed by a decrease in maternal, fetal, and amniotic fluid progesterone concentrations and preterm labor and delivery.<sup>354,355</sup> Perhaps, multiple mechanisms exist, which affect in a subtle fashion the local concentration and actions of progesterone and the production of progesterone in fetal membranes allowing redundant pathways to compensate when a specific pathway is compromised.<sup>356</sup> Coactivator and corepressor proteins are known to modulate the responsiveness of steroid hormone target tissues. Appropriate changes in intracellular regulatory proteins would be another potential method to modulate progesterone activity in pregnant tissues.<sup>357</sup>

An increase in estrogen levels in maternal blood begins at 34–35 weeks of gestation, but a late increase just before parturition (as occurs in the ewe) has not been

observed in human pregnancy. Perhaps, a critical concentration is the signal in human pregnancy rather than a triggering increase. Or the changes are taking place at a local level and are not reflected in the maternal circulation.<sup>358</sup> Although it has not been definitely demonstrated, increased or elevated estrogen levels, as well as a local withdrawal of progesterone production, are thought to play a key role in increasing prostaglandin. As with progesterone, the change in estrogen may be a functional increase at the local tissue level, such as an increase in estrogen receptor concentration and/or activity. Given the central role in parturition for progesterone withdrawal in all species, the local estrogen change could be secondary to the functional progesterone withdrawal, such as the change in progesterone receptor-A expression, allowing estrogen receptor gene expression to escape progesterone inhibition.<sup>348</sup>

The concept of a functional progesterone withdrawal in primate parturition and the obvious importance of progesterone withdrawal in other species prompted extensive study of the administration of progestational drugs to prevent preterm labor. There is some effect with progesterone itself, 100 mg/daily administered vaginally, but there is a one-third reduction in preterm birth with 17 $\alpha$ -hydroxyprogesterone caproate given as a weekly 250-mg injection.<sup>359,360</sup> These results have been obtained in women at high risk for preterm birth by virtue of a previous preterm birth. Progestational therapy is ineffective once labor has begun, and the impact on pregnancies complicated by conditions associated with premature labor is unknown, although studies have indicated no reduction in preterm birth in women with twin or triplet gestations.<sup>361,362,363</sup> Multiple clinical trials are ongoing.

## Key Points: Evidence for a Role of Prostaglandin in Parturition

- Prostaglandin levels in maternal blood and amniotic fluid increase in association with labor.
- Arachidonic acid levels in the amniotic fluid rise in labor, and arachidonate injected into the amniotic sac initiates parturition.
- Patients taking high doses of aspirin have a highly significant increase in the average length of gestation, incidence of postmaturity, and duration of labor.
- Indomethacin prevents the normal onset of labor in monkeys and stops premature labor in human pregnancies.
- Stimuli known to cause the release of prostaglandins (cervical manipulation, stripping of membranes, and rupture of membranes) augment or induce uterine contractions.

- The process of cervical ripening and softening is mediated by prostaglandins.
- Exogenously administered prostaglandins induce labor.

The precursor fatty acid for prostaglandin production in part may be derived from storage pools in the fetal membranes, the decidua, or both.<sup>321</sup> Phospholipase A<sub>2</sub> has been demonstrated in both human chorioamnion and uterine decidua. The availability of arachidonic acid for prostaglandin production during parturition follows the stimulation of hydrolysis of phosphatidylethanolamine and phosphatidylinositol in decidual, amnion, and chorion laeve tissues.<sup>364,365,366</sup> Microsomes from amnion, chorion laeve, and decidua vera tissues contain lipases that hydrolyze fatty acids esterified in the 2 position. Specific phospholipase activity (phospholipase A<sub>2</sub> acting on phosphatidylethanolamine and phospholipase C acting on phosphatidylinositol) combined with a DAG lipase that also has a specificity for arachidonic acid provides a mechanism for the release of arachidonic acid. The activity of these enzymes in fetal membranes and decidua vera tissue increases with increasing length of gestation.

The key may be the increasing levels of estrogen (both estradiol and estriol) in the maternal circulation as well as in the amniotic fluid or, more importantly, locally within the uterus. The marked rise in estrogen near term may affect the activity of the lipase enzymes, leading to the liberation of arachidonic acid. The activity of these phospholipases is increased by increasing concentrations of calcium; and, therefore, the regulation of intracellular calcium is an important mechanism. Nevertheless, a role for local progesterone withdrawal in the activation of prostaglandin production remains a likely mechanism.<sup>355</sup>

Cervical ripening is the process by which the cervix becomes soft and distensible and easily dilated. This change is associated with a decrease in collagen and proteoglycans, and an increase in water, brought about by enzymes and cytokines in response to prostaglandins. Progesterone is believed to exert a stabilizing influence on the cervix during pregnancy, a state that is antagonized by estrogen. Studies of enzyme activity within human cervical tissue indicate that prior to the initiation of labor, progesterone levels are maintained in the cervix, whereas estrogen becomes inactivated.<sup>367</sup> With the onset of parturition, 17 $\beta$ -hydroxysteroid dehydrogenase is decreased, resulting in an increase in the local concentrations of estradiol and a metabolite of progesterone, 20 $\alpha$ -hydroxyprogesterone (in effect, a local cervical withdrawal of progesterone). These changes are consistent with local responses to increasing estrogen levels and support the general mechanism of progesterone withdrawal occurring at localized tissue sites.

The human fetal membranes and decidua are incredibly active. Human chorion and

decidua produce estrogen utilizing a variety of substrates, especially estrone sulfate and DHEAS, and this activity is increased around the time of parturition.<sup>368,369</sup> In addition, the human fetal membranes synthesize and metabolize progesterone.<sup>16</sup> The membranes contain a 17,20-hydroxysteroid dehydrogenase system. One active site converts 20 $\alpha$ -dihydroxyprogesterone to progesterone, while another active site on this enzyme converts estrone to estradiol. Thus, this enzyme can play an important role in altering the estrogen/progesterone ratio. The membranes and the decidua contain distinct cell populations with different biochemical activities (which change with labor).<sup>370</sup> Steroidogenic and prostaglandin interactions among these cells could produce the changes necessary for parturition without affecting the concentrations of circulating hormones. In addition, relaxin derived from decidua and/or chorion may exert a paracrine action on amnion prostaglandin production.<sup>227</sup> Throughout most of pregnancy, the amnion and chorion may exert an inhibitory influence over the myometrium by suppressing calcium channel activity.<sup>371</sup> Finally, the fetus may take a very direct role in this scenario by secreting substances into the amniotic fluid, which interact with the fetal membranes to signal the initiation of parturition.

## Key Points: Observations of Placental Corticotropin-Releasing Hormone (CRH)

- CRH is produced in trophoblast, the fetal membranes, and decidua.<sup>92</sup>
- During pregnancy, CRH levels in the amniotic fluid and the maternal circulation progressively increase, and although amniotic fluid levels do not further increase with labor, the highest maternal levels are found at labor and delivery.
- Levels of the CRH-binding protein are decreased in trophoblast, membranes, decidua, the amniotic fluid, and maternal circulation prior to labor.<sup>370,372,373</sup> This decrease in the CRH-binding protein would allow an increase in CRH activity.
- CRH directly stimulates DHEA and DHEAS biosynthesis in cells derived from the fetal zone of the adrenal.<sup>57</sup>
- CRH stimulates prostaglandin release in fetal membranes, decidua, and myometrium.<sup>108,374</sup>
- Increased CRH and decreased CRH-binding protein have been measured in women with preterm labor and in women with threatened preterm labor who subsequently deliver within 24 hours.<sup>330,375,376,377</sup>
- Cortisol, in the presence of progesterone, stimulates (probably by blocking progesterone inhibition) trophoblastic CRH synthesis.<sup>55,378</sup>
- CRH, activin A, vasopressin, and prostaglandin F<sub>2 $\alpha$</sub>  stimulate oxytocin release

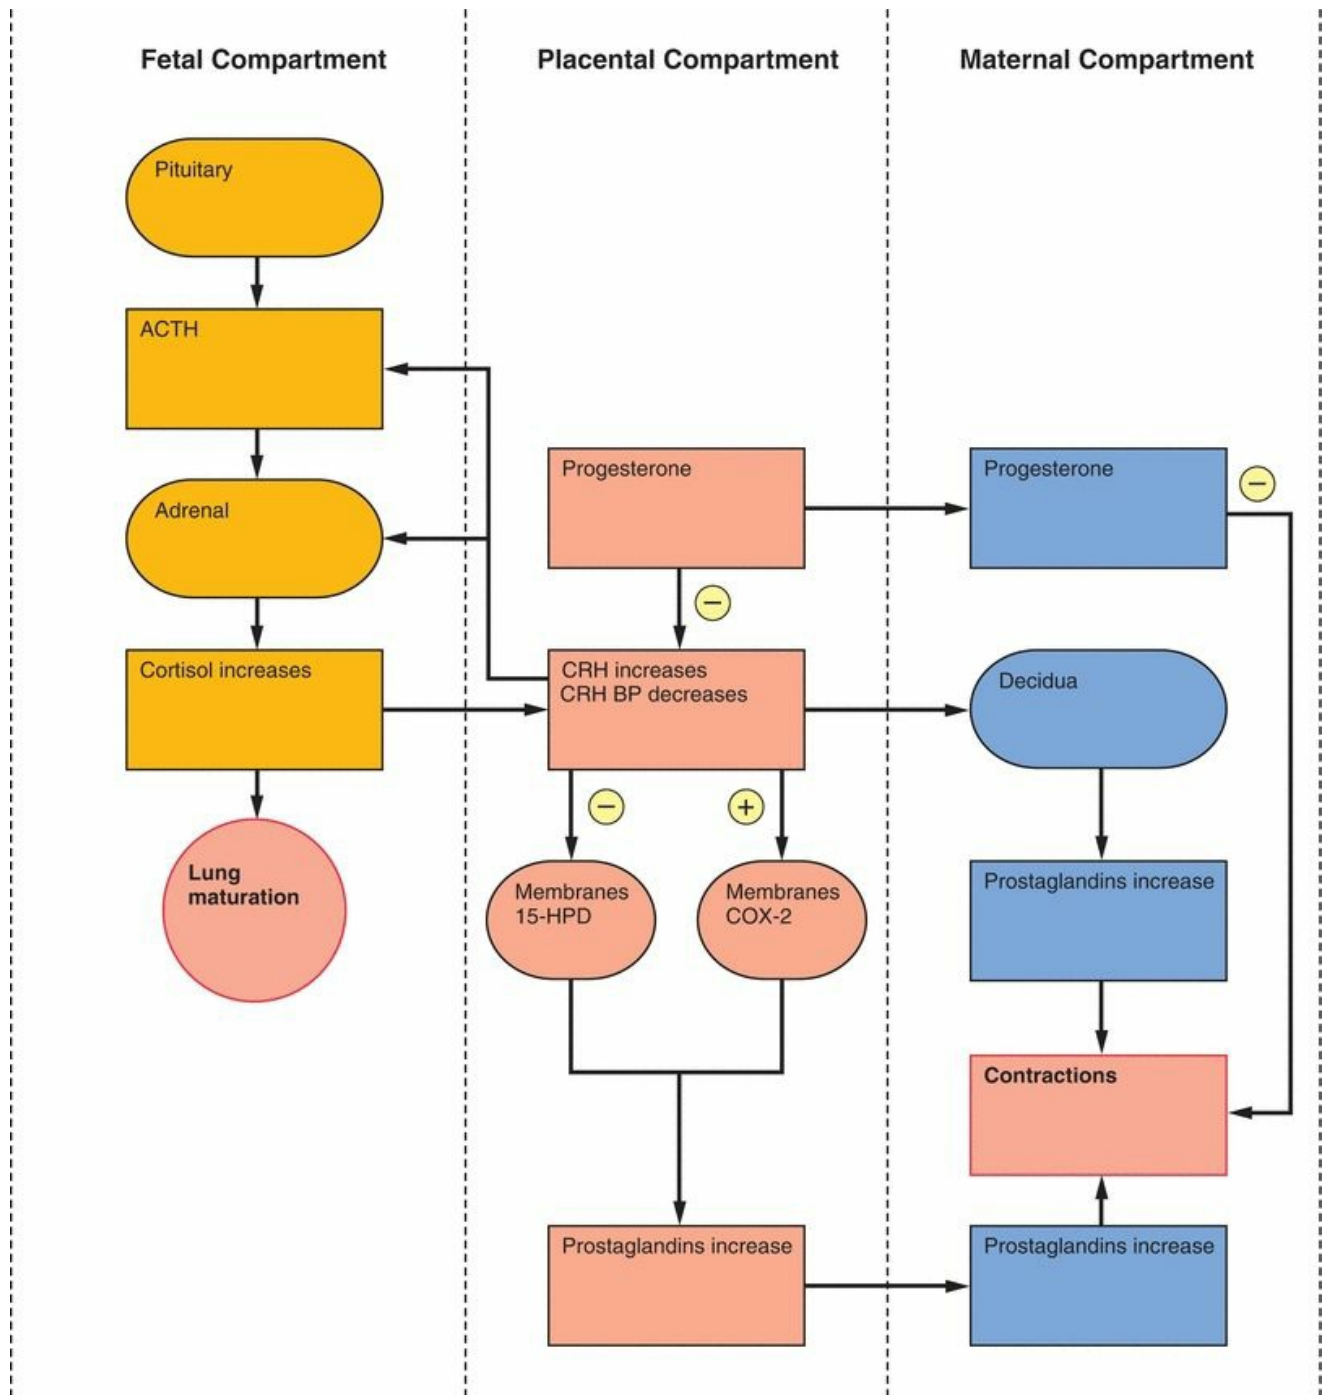

from placental tissues, to augment myometrial contractions.<sup>379</sup>

- CRH increases the secretion of matrix metalloproteinases in placental cells and fetal membranes, a prelude to the rupture of membranes.<sup>110</sup>

These observations are consistent with a key mechanism involving CRH activity in the initial triggering events of parturition. Although in the ewe the CRH signal begins in the fetal brain, in women, it appears to begin in the uterus. Indeed, placental CRH is expressed in primate placentas.<sup>380</sup> Progesterone and estrogen are major inhibiting factors for CRH production in placental tissue.<sup>381</sup> It has been hypothesized that rising fetal cortisol levels (e.g., in response to stress, especially hypoxia) compete with progesterone for the glucocorticoid receptor in the placenta, thus blocking the inhibitory action of progesterone on CRH synthesis, leading to an increase in CRH.<sup>55</sup>

**Cortisol directly stimulates CRH gene expression in the placenta, providing a mechanism for a specific link between cortisol and CRH.**<sup>382</sup> Because CRH directly stimulates steroidogenesis in the fetal zone of the adrenal, the increase in CRH would increase DHEAS to serve as precursor for the increase in estrogen that occurs prior to parturition. The sequence of events could be started by an increase in CRH or a decrease in CRH-binding protein, or both, associated with the estrogen and progesterone changes in late pregnancy (estrogen and progesterone receptor-A repress and progesterone receptor-B increases CRH gene expression).<sup>383,384</sup> On the other hand, consistent with the sheep studies, the initiating step in this sequence of events could be an increase in fetal ACTH secretion, for example, in response to stress and relative hypoxemia and an increase in placental CRH (**Figure 7.18**). Although CRH plays a central role, various pathways can lead to its increase, another example of multiple pathways to parturition. Regardless of the specific triggering event, it is increasingly clear that the fetus plays a pivotal, if not controlling, role in parturition.

**FIGURE 7.18**

## Regulation of Prostaglandins

It is clear that suppression of prostaglandin production in the uterus is required for pregnancy maintenance and eventual success. The levels of prostaglandins in the decidua are 200-fold lower in pregnancy than in the endometrium at any stage of the menstrual cycle, persisting throughout most of pregnancy. This appears to be caused by a decrease in prostaglandin synthesis and not an increase in prostaglandin

breakdown.<sup>385</sup> Moreover, in all species examined and at any gestational age, exogenous prostaglandin administration has the ability to induce abortion,<sup>386,387</sup> and failure to suppress prostaglandin production in the endometrium at the time of implantation is associated with spontaneous abortion.<sup>388</sup>

With labor, the arachidonic acid pathway in the fetal membranes shifts toward the cyclo-oxygenase direction with a large increase in the production of PGE<sub>2</sub> due to the induction of COX-2 activity. This COX-2 activity is a response to the increase in cortisol that in turn is a response to CRH. In addition, CRH can directly stimulate prostaglandin production in the membranes.

Specific protein inhibitors of prostaglandin synthase have been demonstrated in placenta, amnion, and chorion, and these proteins cannot be found in tissue from patients who have established labor.<sup>321,389</sup> The link between infection and the onset of labor (especially preterm labor) may be due to the conversion by bacterial medium (with inflammatory factors such as the interleukins) of arachidonic metabolism in the membranes and decidua to a condition associated with labor marked by the production of PGE<sub>2</sub>.<sup>321,390,391</sup> In this case, prostaglandin production may be a consequence of inflammatory induction of the second cyclo-oxygenase enzyme COX-2.<sup>392</sup> In addition, intra-amniotic infection is associated with a loss of the chorionic high concentration of 15-hydroxyprostaglandin dehydrogenase that inactivates prostaglandins, resulting in a shift that favors biosynthesis and activity.<sup>393</sup> These changes are modulated by the cytokines involved in the inflammatory response.

Prostaglandin production during pregnancy reflects the usual complex interaction of a host of autocrine/paracrine factors. Platelet-activating factor, EGF, and transforming growth factor- $\alpha$  stimulate prostaglandin production by the fetal membranes apparently by regulating intracellular calcium concentrations.<sup>394,395</sup> Secretory products of the fetal membranes themselves are active stimulators of membrane prostaglandin production, including renin derived from chorion prorenin.<sup>396</sup> Decidual PGF<sub>2 $\alpha$</sub>  production is enhanced by bradykinin, EGF, and transforming growth factor- $\alpha$ , and these responses are further increased by interleukin-1 $\beta$ .<sup>397,398</sup> Prostaglandin production by amnion, chorion, and decidual cells is stimulated by CRH and modulated by progesterone.<sup>107</sup> The ubiquitous substances, activin and inhibin, are involved here as well. Amnion and chorion produce the activin and inhibin subunits, and activin stimulates prostaglandin PGE<sub>2</sub> release from amnion cells.<sup>284</sup>

During labor, the maternal circulating levels of PGE<sub>2</sub>, PGF<sub>2 $\alpha$</sub> , and the PGF<sub>2 $\alpha$</sub>  metabolite are increased, a change that can be directly attributed to uterine production because the gradient across the uterus for these substances is also increased. This

increase in production of prostaglandins within the uterus must be the key factor, because the concentration and affinity of prostaglandin receptors do not change at parturition.<sup>399</sup> Prostacyclin is produced (at least in vitro) by a variety of tissues involved in pregnancy: endometrium, myometrium, placenta, amnion, chorion, and decidua. Prostacyclin and thromboxane are probably more important in the vascular responses of mother and fetus and in all likelihood do not play a role in initiating or maintaining uterine contractions; however, prostacyclin does inhibit myometrial contractility.<sup>400</sup> PGI synthase expression appropriately decreases in myometrium with increasing gestational age.<sup>401</sup>

Decidua produces both PGE<sub>2</sub> and PGF<sub>2α</sub>, but the amnion and chorion produce primarily PGE<sub>2</sub>.<sup>402</sup> The inducible cyclo-oxygenase, COX-2, is expressed at a high level at term in the amnion and chorion.<sup>403</sup> As in sheep, prostaglandin synthesis in membranes and decidua is probably stimulated by cortisol; glucocorticoid receptors are present in the same cells that contain cyclo-oxygenase.<sup>404</sup>

There is evidence for the transfer of prostaglandin E<sub>2</sub> across the membranes to the decidua and possibly the myometrium.<sup>405</sup> The paradox of PGE<sub>2</sub> production in the amnion being matched not by a PGE metabolite in the maternal circulation but by a PGF<sub>2α</sub> metabolite was explained by transfer across the membranes and conversion of PGE<sub>2</sub> to PGF<sub>2α</sub> in the decidua.<sup>406</sup> However, continued study of this issue strongly indicates that prostaglandins produced on one side of the membranes do not contribute to the prostaglandins on the other side, arguing that uterine contractions must be primarily influenced by decidual or myometrial prostaglandins.<sup>407</sup> Indeed, COX-2 expression in the myometrium increases at term before the onset of labor and is correlated with estrogen receptor-α activity.<sup>348</sup> There is reason to believe that the myometrial exposure to prostaglandins is also influenced by the activity of a catabolic enzyme in the chorion.

At term, prostaglandin synthesis occurs in the amnion and decidua, and throughout pregnancy, the chorion forms a barrier preventing passage of bioactive prostaglandins to the myometrium because of a large capacity to catabolize prostaglandins via 15-hydroxyprostaglandin dehydrogenase.<sup>393,408</sup> The activity of this enzyme is decreased in the presence of labor, including preterm labor, and after premature rupture of membranes or when infection is present.<sup>393,409,410</sup>

**Because the activity of 15-hydroxyprostaglandin dehydrogenase decreases in the myometrium and the chorion during labor, a combination of increased biosynthesis of prostaglandins and a decrease in 15-hydroxyprostaglandin dehydrogenase achieves the increase in prostaglandins associated with parturition,**

**probably mediated by the local changes in estrogen and progesterone bioavailability and activity, with key roles also played by CRH and cortisol.** Cortisol decreases and progesterone increases 15-hydroxyprostaglandin dehydrogenase activity in placental tissues.<sup>411,412</sup> A functional withdrawal of progesterone would allow a greater effect of cortisol resulting in an increase in prostaglandins. Regulation of intracellular calcium ions contributes to this mechanism; an influx of calcium ions increases prostaglandin synthase expression, whereas prostaglandin dehydrogenase expression is suppressed.<sup>413</sup> This is a potential pathway for the input of locally produced peptides involved in parturition.

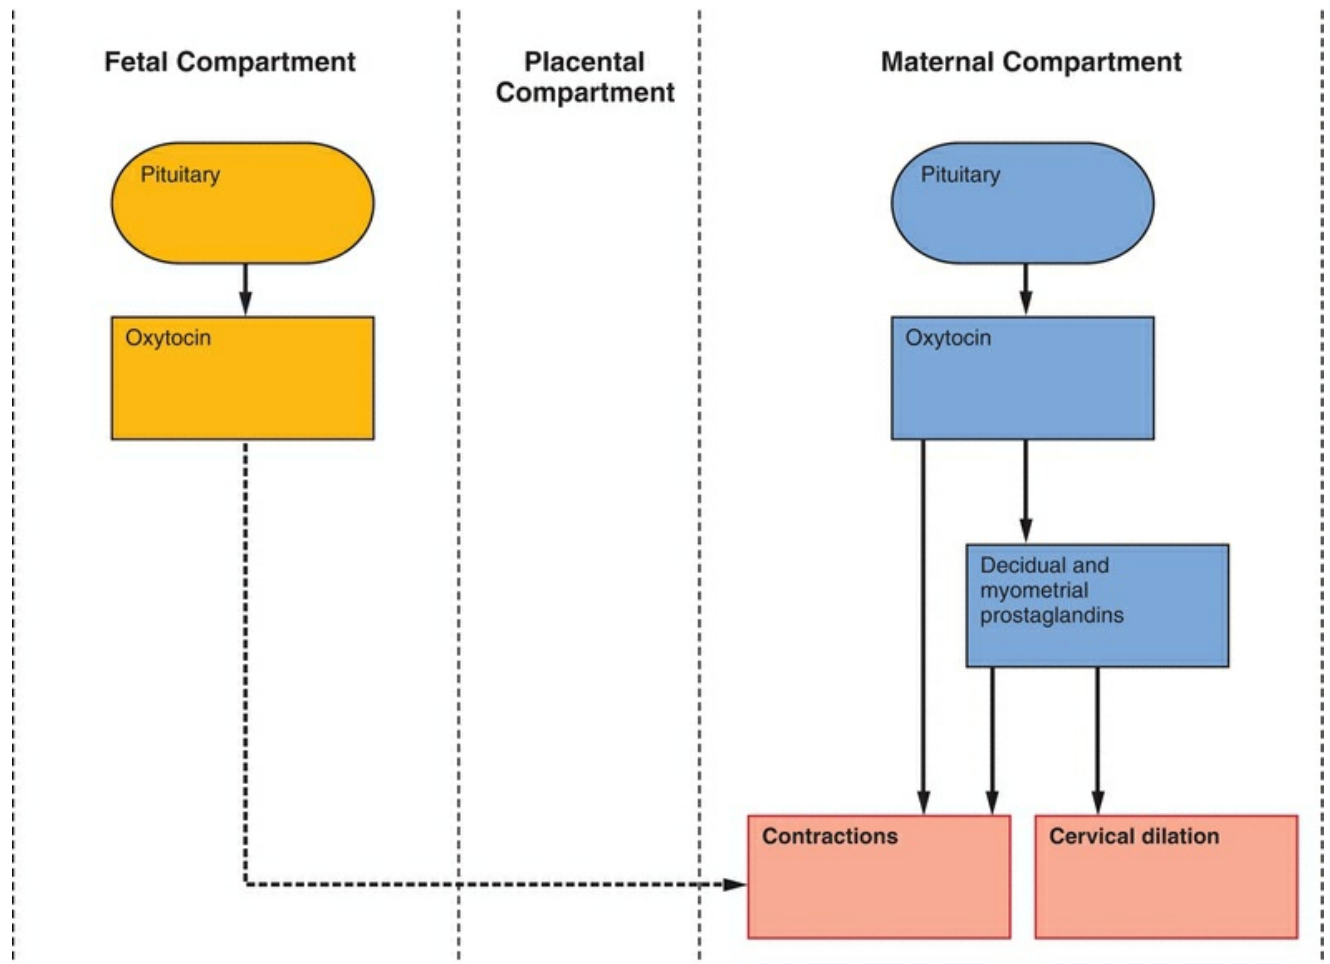

## **Metalloproteinases**

Disruption and remodeling of the extracellular matrix are part of the process of parturition just as it is in implantation and placentation. Cervical ripening, rupture of the fetal membranes, and detachment of the placenta all involve activity of the matrix metalloproteinases in the decidua and the membranes.<sup>414</sup> A balance between these enzymes and their inhibitors is necessary to maintain the integrity of fetal membranes and uterine structure and function. With the change in function associated with parturition, one would expect this balance to shift toward metalloproteinase expression and activity, and, indeed, this is the case.<sup>415</sup> An early event in premature labor and premature rupture of membranes is the activation of the metalloproteinases. There is evidence to indicate that metalloproteinases are activated by prostaglandins and cytokines and inhibition is maintained by down-regulation of the conversion of plasminogen to plasmin by progesterone.<sup>416</sup>

## **Oxytocin and Myometrial Responses**

Using sensitive assays, an increase in maternal levels of oxytocin can be detected prior to parturition, occurring at first only at night.<sup>417,418</sup> Activation of oxytocin secretion is linked to progesterone withdrawal because brainstem oxytocin neurons are suppressed by brain metabolites of progesterone.<sup>419</sup> Once labor has begun, oxytocin levels rise significantly, especially during the second stage (**Figure 7.19**). Thus, maternal oxytocin may be most important for developing the later, more intense uterine contractions. Extremely high concentrations of oxytocin can be measured in the cord blood at delivery, and release of oxytocin from the fetal pituitary may also be involved in labor. However, this is controversial, and studies in monkeys fail to indicate a role for fetal oxytocin in parturition.<sup>418</sup> Part of the contribution of oxytocin to parturition is the stimulation of prostaglandin synthesis in decidua and myometrium.<sup>420</sup> Cervical dilation appears to be dependent on oxytocin stimulation of prostaglandin production, probably

in the decidua. The greater frequency of labor and delivery at night may be due to greater nocturnal oxytocin secretion. In addition, oxytocin is synthesized in the amnion, in the chorion, and, significantly, in the decidua.<sup>417,421,422</sup> This locally produced oxytocin, in response to CRH, may be a significant stimulus for myometrial and membrane production of prostaglandins.

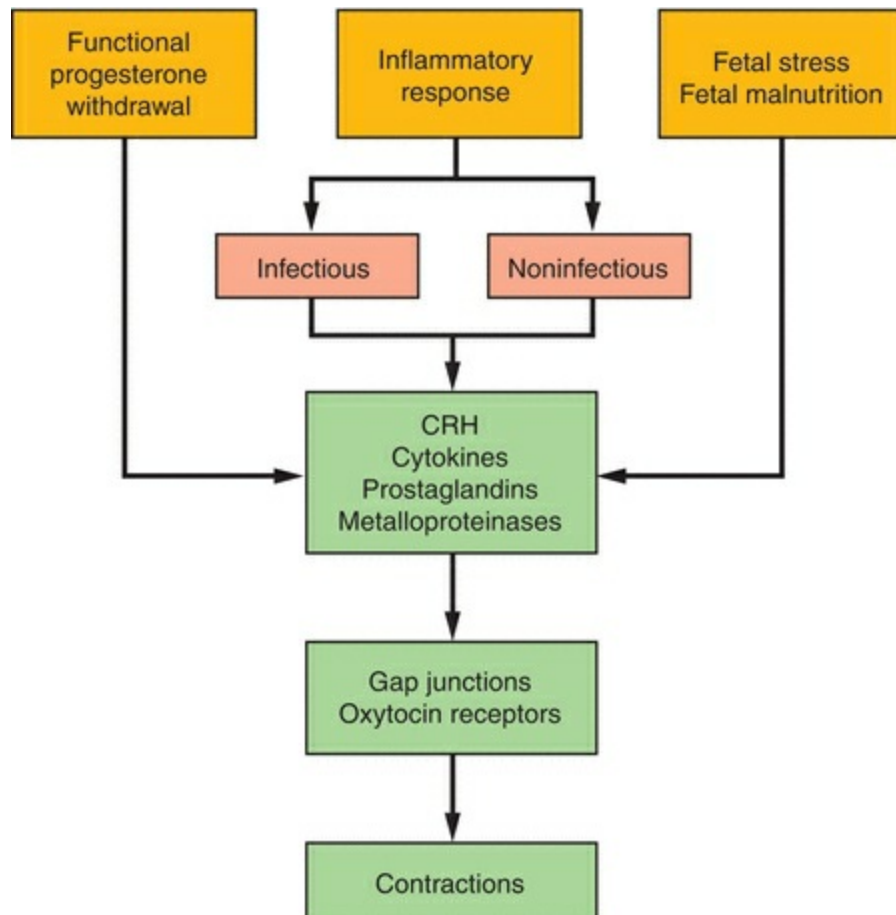

**FIGURE 7.19**

It is likely that oxytocin action during the initial stages of labor may depend on myometrial sensitivity to oxytocin in addition to the levels of oxytocin in the blood. The concentration of oxytocin receptors in the myometrium is low in the nonpregnant state and increases steadily throughout gestation (an 80-fold increase), and during labor, the concentration doubles.<sup>423</sup> The mechanism for the increase is unknown, but it likely is due to a change in the prostaglandin and hormonal milieu of the uterus, especially functional progesterone withdrawal. The local production and effects of oxytocin, estrogen, and progesterone combine in a complicated process of autocrine, paracrine,

and endocrine actions to result in parturition.

Animal studies have implicated the formation of low-resistance pathways in the myometrium, called **gap junctions**, as an important action of steroids and prostaglandins during labor.<sup>424</sup> In the gap junction, a pore forms, which allows communication from cytoplasm to cytoplasm between two cells (**Figure 7.20**). The pore is a cylinder-shaped channel formed of six special proteins called **connexins**. Either substances or electrical current (ions) can follow this pathway without leakage into extracellular space. Thus, gap junctions provide a means of communication between myometrial cells, allowing enhancement of electrical conductivity and synchronization of activity. Gap junction formation is related to the estrogen/progesterone ratio (estrogen up-regulates connexin-43, the gap junction protein, which is down-regulated by progesterone) and to the presence of the stimulating prostaglandins PGE<sub>2</sub> and PGF<sub>2α</sub>. Therefore, it is not surprising that the number of gap junctions increases in the final weeks of pregnancy, especially just before labor. The modulation of the number and the permeability of gap junctions are another contributing factors in the control of uterine contractility.

**FIGURE 7.20**

The final contraction of the uterine muscle results from increased free calcium concentrations in the myofibril, the result of prostaglandin action and functional progesterone withdrawal, an effect opposed to the promotion of calcium binding in the sarcoplasmic reticulum by the presence of progesterone.<sup>425,426</sup> Thus, prostaglandins and oxytocin increase, while progesterone decreases intracellular calcium levels. The intracellular calcium concentration is affected by cellular entry and exit of calcium as well as binding in the sarcoplasmic reticulum. It is the intracellular concentration of calcium that determines the rate of myosin phosphorylation and the contractile state of the myometrium. Tocolytic therapy (the use of  $\beta$ -adrenergic agents) stimulates adenylate cyclase activity, which increases the levels of cellular cyclic AMP, which, in turn, decreases intracellular calcium concentration and inhibits actin-myosin interaction by modulating kinase phosphorylation.

Ducsay and colleagues propose that the coordination of this complex relationship of physiologic, endocrine, and molecular mechanisms is expressed in rhythms.<sup>75,427</sup> Both mother and fetus experience 24-hour rhythms in hormone secretions, and uterine activity is correlated with day and night (photoperiod regulation). The coordination and enhancement of this rhythmicity play a role in parturition. Improved detection and measurement of this activity could contribute to better prevention and treatment of preterm labor.

Molecular biology is now assessing the activity of genes in the uterus and fetal membranes.<sup>428</sup> Some of this activity is predictable, correlating with autocrine and paracrine substances known to be involved in parturition. The identification of other genes differentially regulated during parturition will open new areas for research. Ultimately, we will come to understand the mechanisms of normal parturition and to be more effective in managing premature and abnormal labor.

## Concluding Thought

Imagine yourself as a fetus within a pregnant uterus. Your growth, development, and survival require keeping the uterus quiescent for most of the pregnancy. This is accomplished by maintaining progesterone inhibitory dominance of the myometrium. When ready to begin extrauterine life or when your environment becomes inhospitable, you are able to prepare or “activate” the parturition mechanisms by means of hormonal and autocrine/paracrine messengers. Ultimately, uterine contractions and cervical ripening are stimulated, and amazingly, even if you are incapable of initiating these events, the sequence will eventually begin, and delivery will ensue. The extraordinary experience and wonder of labor and birth, as perceived by parents and birth assistants, are matched by your ability and the complexity of the systems you influence.

# Treatment of Labor with Prostaglandin Inhibition

The key role for prostaglandins in parturition raises the potential for treatment of premature labor with inhibitors of prostaglandin synthesis. The concern has been that such treatment would result in intrauterine closure of the ductus arteriosus causing pulmonary hypertension. Clinical studies, however, indicate that use of the nonsteroidal anti-inflammatory agents for short periods of time (3 days) yields good results and does not result in this complication.<sup>429</sup> Beyond 34 weeks, the fetus is more sensitive to this pulmonary action, and treatment should be limited to pregnancies less than 32 weeks and with caution from 32 to 34 weeks. If the drug is failing, it should not be maintained because increased blood loss can occur at delivery. Because indomethacin inhibits the synthesis of all members of the prostaglandin family, including the vasodilating prostacyclin, it should be used with caution in hypertensive patients.<sup>430</sup> Sulindac is just as effective as a tocolytic but does not affect urine output and amniotic fluid, and it has a lesser impact on the fetal ductus arteriosus.<sup>431,432</sup> A specific COX-2 inhibitor, celecoxib, was as effective as indomethacin in treating preterm labor, but importantly, there was no adverse impact on the ductus arteriosus and there was a lesser transient decrease in amniotic fluid volume.<sup>433,434</sup>

Treatment of pregnant women with indomethacin reduces the amniotic fluid volume due to a decrease in fetal urine output. This is reversible with a decrease in dose. This treatment has been used for polyhydramnios with good response and no effect on the newborn despite treatment for 2–11 weeks.<sup>435,436,437</sup>

# Induction of Labor and Cervical Ripening

Pharmacologically and physiologically, prostaglandins have two direct actions associated with labor: ripening of the cervix and myometrial stimulation. Successful parturition requires organized changes in both the upper uterus and in the cervix. The cervical changes are in response to the estrogen/progesterone ratio and the local release of prostaglandins. Whether relaxin plays a role in human parturition is not established; however, recombinant relaxin is being tested for cervical ripening.

Ripening of the cervix is the result of a change that includes an increase in hyaluronic acid and water and a decrease in dermatan sulfate and chondroitin sulfate (these compounds hold the collagen fibers in a rigid structure). How prostaglandins operate in this change is unknown, but enzyme activation must be involved. For ripening of the cervix, PGE<sub>2</sub> is very effective, whereas PGF<sub>2α</sub> has little effect. The purpose of pharmacologically achieving ripening of the cervix is to increase the success rate with induction of labor and lower the proportion of cesarean sections. Intravaginal prostaglandin E<sub>2</sub> (dinoprostone) administered as tablets and suppositories and mixed in gels has been very effective for cervical ripening. A synthetic PGE<sub>1</sub> analogue, misoprostol, is also effective when used intravaginally or orally for cervical ripening and labor induction, although there can be a problem of uterine tachysystole (rapid contractions).<sup>438,439,440,441</sup>

A major clinical application for the induction of labor in the United States is the use of intravaginal PGE<sub>2</sub> in cases of fetal demise and anencephalic fetuses. The patient should be well hydrated with an electrolyte solution to counteract the induced vasodilation and decreased peripheral resistance. If satisfactory uterine activity is established, the next application should be withheld. And, finally, because there is a synergistic effect when oxytocin is used shortly after prostaglandin administration, there should be a minimum of 6 hours between the last prostaglandin dose and beginning of oxytocin augmentation.

Prostaglandins are used to induce term labor. Intravenous prostaglandins are not an acceptable method due to the side effects achieved by the high dosage necessary to reach the uterus. The intravaginal and oral administration of PGE<sub>2</sub> is as effective as intravenous oxytocin, with good results initially reported even in patients with previous cesarean sections.<sup>442,443</sup> Later, concern was raised that uterine rupture may be more frequent with prostaglandin use in women with previous cesareans.<sup>444</sup> The intravaginal administration of misoprostol, the synthetic prostaglandin E<sub>1</sub> analogue, is safe, effective, and relatively inexpensive for the routine induction of labor.<sup>445</sup> These methods, plus intracervical administration, are in routine use in many parts of the world.

# Induced Abortion

Prostaglandins are effective for postcoital contraception and first-trimester abortion but impractical because of the high incidence of side effects, including an unacceptable rate of incomplete abortions. For midtrimester abortions, intra-amniotic prostaglandin, intramuscular methyl esters, and vaginal PGE suppositories are available. Again, the major clinical problems have been the efficacy in accomplishing complete expulsion and the high level of systemic side effects. Overall, there is a higher risk of hemorrhage, fever, infection, antibiotic administration, readmission to the hospital, and more operative procedures when compared with saline abortions.

The combination of prostaglandin's oxytocic action with the antiprogestosterone effect of RU 486 (mifepristone) has proved to be a safe and effective medical treatment for the induction of therapeutic abortion in both the first and second trimesters.<sup>446,447,448,449</sup> Combining a prostaglandin analogue, misoprostol, with mifepristone inexpensively and safely achieves greater than 95% efficacy ([Chapter 21](#)).

# Prostaglandins and Postpartum Hemorrhage

When routine methods of management for postpartum hemorrhage caused by uterine atony have failed, an analogue of prostaglandin  $F_{2\alpha}$  gives excellent results (80–90% successful).<sup>450</sup> Prostin 15 M is 15(S)-15-methyl prostaglandin  $F_{2\alpha}$ -tromethamine. The dose is 0.25–0.5 mg, repeated up to 4 times and given with equal efficacy either intramuscularly or directly into the myometrium. It can also be used after the replacement of an inverted uterus. Failures are usually associated with infections or magnesium sulfate therapy. However, clinical trials with injectable prostaglandins have indicated that regular methods are as effective and that the modest reduction in blood loss does not warrant routine use to prevent postpartum hemorrhage.<sup>451</sup> When used after delivery for the prevention of postpartum hemorrhage, misoprostol, the  $PGE_1$  analogue, 600 mg given orally, is less effective with more side effects than the standard use of oxytocin.<sup>451,452</sup> However, misoprostol can be a lifesaver when delivery and hemorrhage occur in parts of the world where parenteral drugs are not available.

# PROSTAGLANDINS AND THE FETAL CIRCULATION

---

The predominant effect of prostaglandins on the fetal and maternal cardiovascular system is to maintain the ductus arteriosus and the renal, mesenteric, uterine, placental, and probably the cerebral and coronary arteries in a relaxed or dilated state. The importance of the ductus arteriosus can be appreciated by considering that 59% of the cardiac output flows through this connection between the pulmonary artery and the descending aorta.

Control of ductal patency and closure is mediated through prostaglandins. The arterial concentration of oxygen is the key to the caliber of the ductus. With increasing gestational age, the ductus becomes increasingly responsive to increased oxygen. In this area, too, attention has turned to PGI<sub>2</sub> and TXA<sub>2</sub>.

Fetal lamb ductus homogenates produce mainly PGI<sub>2</sub> when incubated with arachidonic acid. PGE<sub>2</sub> and PGF<sub>2α</sub> are formed in small amounts and TXA<sub>2</sub> not at all. Although PGE<sub>2</sub> is less abundant than PGI<sub>2</sub> in the ductus, it is a more potent vasodilator of the ductus and is more responsive to oxygen (decreasing vasodilation with increasing oxygen).<sup>453</sup> Thus, PGE<sub>2</sub> appears to be the most important prostaglandin in the ductus from a functional point of view, whereas PGI<sub>2</sub>, the major product in the main pulmonary artery, appears to be the major factor in maintaining vasodilation in the pulmonary bed. The ductus is dilated maximally in utero by production of prostaglandins, and a positive vasoconstrictor process is required to close it. The source of the vasoconstrictor is probably the lung. With increasing maturation, the lung shifts to TXA<sub>2</sub> formation. This fits with the association of ductal patency with prematurity. With the onset of pulmonary ventilation at birth leading to vascular changes that deliver blood to the duct directly from the lungs, TXA<sub>2</sub> can now serve as the vasoconstrictor stimulus. The major drawback to this hypothesis is the failure of inhibitors to affect the constriction response to oxygen.

Administration of vasodilating prostaglandins can maintain ductal patency after birth while preparing an infant for surgery to correct a congenital lesion causing pulmonary hypertension.<sup>454</sup> Infants with persistent ductus patency may be spared from thoracotomy by treatment with an inhibitor of prostaglandin synthesis. The use of indomethacin to close a persistent ductus in the premature infant is successful about 40% of the time.<sup>453,455</sup> Ibuprofen is equally effective and reduces blood flow to critical organs less than that observed with indomethacin.<sup>456</sup> An important factor is early diagnosis and treatment because with increasing postnatal age the ductus becomes less

sensitive to prostaglandin inhibitors, probably because of more efficient clearance of the drug.<sup>457</sup> The highest incidence of successful ductus closure has been with infants younger than 30 weeks of gestation and younger than 10 days old.

This aspect of the use of prostaglandin inhibitors is of concern in considering the use of agents to inhibit premature labor. The drug half-life in the fetus and newborn is prolonged because the metabolic pathways are limited, and there is reduced drug clearance because of immature renal function. In utero constriction of the ductus can cause congestive heart failure and fetal pulmonary hypertension.<sup>458</sup> Prolonged ductus constriction leads to subendocardial ischemia and fibrotic lesions in the tricuspid valve muscles. Infants with persistent pulmonary hypertension have hypoxemia, cardiomegaly, and right-to-left shunting through the foramen ovale or the ductus. Infants of mothers given either indomethacin or salicylates chronically have been reported to have this syndrome. Duration of exposure and dosage are critical. It takes occlusion of the ductus for more than 2 weeks to produce fetal pulmonary hypertension and cardiac hypertrophy. This side effect is rare in pregnancies less than 27 weeks of gestation; the ductus arteriosus usually begins to respond at 27–30 weeks, and after 30 weeks, this is an important side effect that can be minimized if long-term use is avoided.<sup>459</sup>

# PROSTAGLANDINS AND FETAL BREATHING

---

Prior to parturition, fetal breathing is very shallow. It is proposed that placental PGE<sub>2</sub> suppresses breathing by acting in the fetal brain.<sup>460</sup> Occlusion of the umbilical cord is rapidly followed by a loss of this PGE<sub>2</sub> influence and the onset of air breathing. The administration of indomethacin to fetal sheep increases, whereas infusion of PGE suppresses, fetal breathing movements. This may be the explanation for the decrease in fetal breathing movements observed during human labor (associated with an increase in prostaglandin levels).

# FETAL LUNG MATURATION

---

The pulmonary alveoli are lined with a surface-active phospholipid-protein complex called pulmonary surfactant, which is synthesized in the type II pneumocyte of mature lungs. It is this surfactant that decreases surface tension, thereby facilitating lung expansion and preventing atelectasis. In full-term fetuses, surfactant is present at birth in sufficient amounts to permit adequate lung expansion and normal breathing. In premature fetuses, however, surfactant is present in lesser amounts, and, when insufficient, postnatal lung expansion and ventilation are frequently impaired, resulting in progressive atelectasis, the clinical syndrome of respiratory distress.

Phosphatidylcholine (lecithin) has been identified as the most active and most abundant lipid of the surfactant complex. The second most active and abundant material is phosphatidylglycerol (PG), which significantly enhances surfactant function. Both are present in only small concentrations until the last 5 weeks of pregnancy. Beginning at 20–22 weeks of pregnancy, a less stable and less active lecithin, palmitoyl-myristoyl lecithin, is formed. Hence, a premature infant does not always develop respiratory distress syndrome; however, in addition to being less active, synthesis of this lecithin is decreased by stress and acidosis, making the premature infant more susceptible to respiratory distress. At about the 35th week of gestation, there is a sudden surge of dipalmitoyl lecithin, the major surfactant lecithin, which is stable and very active. Because secretion by the fetal lungs contributes to the formation of amniotic fluid and the sphingomyelin concentration of amniotic fluid changes relatively little throughout pregnancy, assessment of the lecithin/sphingomyelin (L/S) ratio in amniotic fluid at approximately 34–36 weeks of pregnancy can determine the amount of dipalmitoyl lecithin available and thus the degree to which the lungs will adapt to newborn life.

Gluck and colleagues, in 1971, were the first to demonstrate that the L/S ratio correlates with pulmonary maturity of the fetal lung.<sup>461</sup> In normal development, sphingomyelin concentrations are greater than those of lecithin until about gestational week 26. Prior to 34 weeks, the L/S ratio is approximately 1:1. At 34–36 weeks, with the sudden increase in lecithin, the ratio rises acutely. In general, a ratio of 2.0 or greater indicates pulmonary maturity and that respiratory distress syndrome will not develop in the newborn.<sup>462</sup> Respiratory distress syndrome associated with a ratio greater than 2.0 usually follows a difficult delivery with a low 5-minute Apgar score, suggesting that severe acidosis can inhibit surfactant production. A ratio in the transitional range (1.0–1.9) indicates that respiratory distress syndrome may develop but that the fetal lung has entered the period of lecithin production, and a repeat amniocentesis in 1 or 2 weeks usually reveals a mature L/S ratio. The rise from low to high ratios can occur within 3–4 days.

An increase in the surfactant content of PG at 34–36 weeks marks the final maturation of the fetal lung. When the L/S ratio is greater than 2.0 and PG is present, the incidence of respiratory distress syndrome is virtually zero. The assessment of PG is especially helpful when the amniotic fluid is contaminated because the analysis is not affected by meconium, blood, or vaginal secretions. The L/S ratio has been replaced in many centers by a method that uses fluorescence polarization with a fluorescent probe that binds to surfactant. The fluorescent method is simple, automated, rapid, and less costly.

Abnormalities of pregnancy may affect the rate of maturation of the fetal lung, resulting either in an early mature L/S ratio or a delayed rise in the ratio. Accelerated maturation of the ratio is associated with hypertension, advanced diabetes, hemoglobinopathies, heroin addiction, and poor maternal nutrition. Delayed maturation is seen with diabetes (without hypertension) and Rh sensitization. In general, accelerated maturation is associated with reductions in uteroplacental blood flow (and presumably increased fetal stress). With vigorous and effective control of maternal diabetes, the risk of respiratory distress syndrome in the newborns is not significantly different from infants born to nondiabetics.

Since Graham Liggins observed survival of premature lambs following the administration of cortisol to the fetus,<sup>463</sup> it has become recognized that fetal cortisol is the principal requisite for surfactant biosynthesis. This is true despite the fact that no increase in fetal cortisol can be demonstrated to correlate with the increases in fetal lung maturation. For this reason, fetal lung maturation can be best viewed as the result of not only cortisol but also the synergistic action of prolactin, thyroxine, estrogens, prostaglandins, growth factors, and perhaps other yet unidentified agents.<sup>464</sup> Insulin directly inhibits surfactant protein expression in fetal lung tissue, which explains the increase in respiratory distress syndrome associated with hyperglycemia in pregnancy (although this effect can be overcome by the stress associated with advanced diabetes).<sup>465</sup>

Corticosteroid therapy of pregnant women threatened with preterm delivery reduces neonatal mortality, respiratory distress syndrome, and intraventricular hemorrhage.<sup>466</sup> In general, maximal benefit in terms of enhanced fetal pulmonic maturity has been demonstrated with glucocorticoid administration from 24 to 34 weeks of gestational age, with some benefit between 34 weeks and 36 6/7 weeks.<sup>466,467</sup> The optimal effect requires that 48 hours elapse after initiation of therapy although some benefit is achieved within hours after administration. The current recommendation in the United States is to administer two doses of betamethasone, 12 mg intramuscularly 24 hours apart, or four doses of dexamethasone, 6 mg intramuscularly every 12 hours for pregnant women between 24 0/7 weeks and 36 6/7 weeks of gestation who are at risk of preterm

delivery within 7 days.<sup>466,467</sup> Multiple weekly treatments or serial courses are no longer recommended, but a single repeat course of antenatal corticosteroids should be considered in women who are less than 34 0/7 weeks of gestation who are at risk of preterm delivery within 7 days and require consultation with a maternal-fetal medicine specialist. Although every case of respiratory distress syndrome and subsequent chronic lung disease cannot be prevented, a significant impact can be achieved on infant mortality and the incidence and severity of respiratory distress syndrome. Additional treatment with TRH was initially believed to be beneficial; however, clinical trials indicate that TRH does not further reduce the incidence of chronic lung disease in glucocorticoid-treated very low birth weight infants.<sup>468,469,470</sup>

# THE POSTPARTUM PERIOD

---

The immediate postpartum period is a time of rapid readjustment to the nonpregnant endocrine state. About 10–15% of women become clinically depressed during this time, and an endocrine mechanism has been suggested.<sup>471</sup> The clinician should always have a high index of suspicion for thyroid dysfunction because of the 5–10% incidence of postpartum thyroiditis in the 3–6 months after delivery. Because of the relative hypercortisolism in the last trimester of pregnancy, it has been suggested that persistent suppression of hypothalamic CRH secretion (and thus the pituitary-adrenal axis) in the postpartum period is a characteristic finding in women with postpartum depression and that this suppression also contributes to a greater vulnerability to autoimmune diseases, such as thyroiditis.<sup>472</sup>

# Normal and Abnormal Sexual Development

Abnormalities of sexual differentiation are seen infrequently in an individual clinician's practice. However, few physicians have not been challenged at least once by a newborn with ambiguous genitalia or by a young woman with primary amenorrhea. Traditional classifications for disorders of sexual differentiation have been confusing, but advances in reproductive science have helped to define their causes and to provide the foundation for a logical and efficient approach to diagnosis.

This chapter first considers the processes involved in normal sexual differentiation, to provide a basis for understanding the various types and causes of abnormal development. Some subjects are discussed in other chapters, but also are included here, for clarity and completeness. The fundamental theme is that disorders of sexual development (DSD) result primarily from abnormalities in the amount or action of androgens—from excess androgen in females and from too little androgen in males.

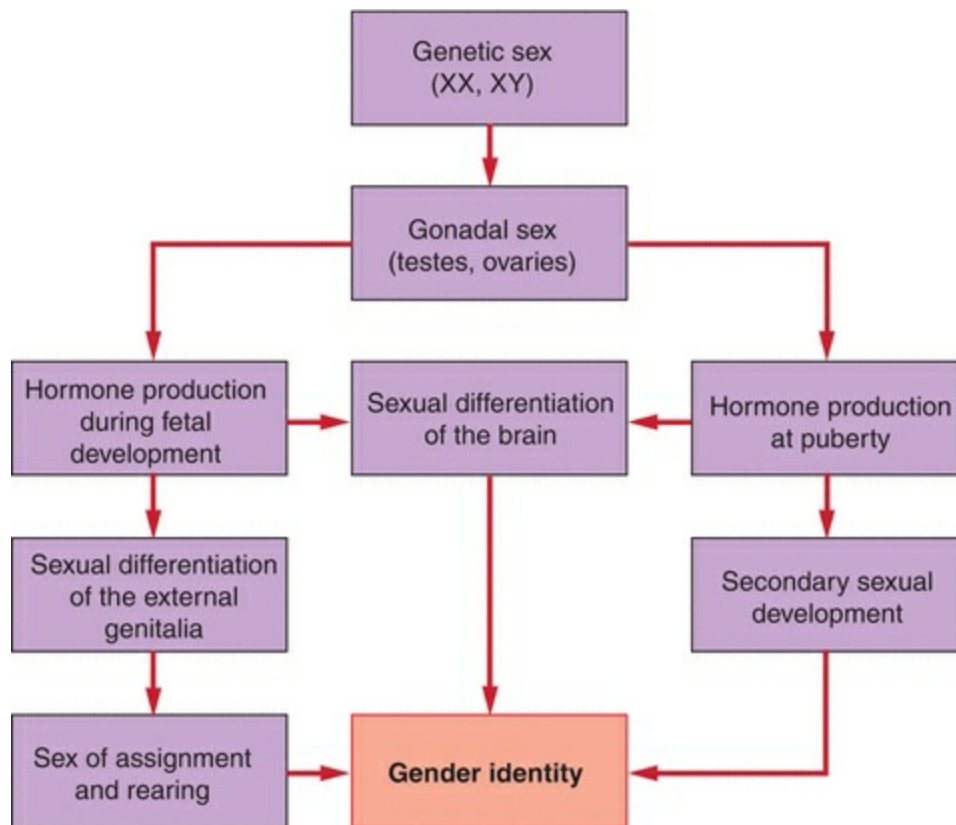

# NORMAL SEXUAL DIFFERENTIATION

---

The gender identity of a person (whether an individual identifies as a male or a female) is determined by their genetic, gonadal, and phenotypic sex and also is influenced by their environment. Genetic or chromosomal sex is defined by the sex chromosomes, typically XX or XY. Gonadal sex is defined by the direction of gonadal differentiation, into ovaries or testes. Phenotypic sex is defined primarily by the appearance of the external genitalia and the secondary sexual characteristics that develop at puberty. Gender identity includes all behavior having any sexual connotation, such as body gestures and mannerisms, habits of speech, recreational preferences, and content of dreams. Sexual expression, both homosexual and heterosexual, reflects the sum of all sexual influences on the individual, both prenatal and postnatal, the latter referring to the role assigned by society in accordance with the individual's phenotype and behavior.

Normal sexual differentiation involves a sequence of related processes that begins with genetic or chromosomal sex, as established at the time of fertilization.<sup>1</sup> Gonadal sex is determined next; directed by the genetic sex, the indifferent gonads differentiate into ovaries or testes. In turn, gonadal sex controls the hormonal environment of the embryo, which directs the development of the internal and external genitalia. The processes involved in sexual differentiation of the embryonic brain are less clear, but may involve mechanisms similar to those controlling differentiation of the external genitalia. The inductive influences of hormones on the developing central nervous system (CNS) ultimately may determine the patterns of hormone secretion and sexual behavior in the adult.<sup>2,3,4,5,6,7</sup>

Although the mechanisms that govern sex differentiation are not yet entirely clear, our understanding of the molecular processes involved has advanced significantly in recent years. Current concepts are summarized here, beginning with the genetics of sex determination, followed by germ cell sex differentiation, gonadal differentiation, and development of the internal and external genitalia (**Figure 8.1**).

**FIGURE 8.1**

# Genetics of Sex Determination

Both the X and the Y chromosomes appear to have evolved from autosomal ancestors over a period of 300 million years.<sup>8</sup> Most of the ancestral genes on the Y chromosome have been lost in the process, leaving only a limited number of currently active genes. A great many genes are involved in translating the sex chromosome composition of the embryo and in directing the differentiation of the gonadal somatic cells,<sup>9,10,11</sup> but sex determination depends primarily on the presence or absence of a Y chromosome.

In females, the identical pair of X chromosomes aligns and recombines along its entire length during meiosis, like the autosomes. In males, homology between the X and Y chromosomes is limited to two small regions located at the very distal ends of the short and long arms of the Y. The “pseudoautosomal” region constitutes only approximately 5% of the entire Y chromosome and is the only region that normally pairs and recombines during meiosis.<sup>10,12</sup> Most of the remaining 95% of the Y chromosome is unique to the male, containing multiple copies of genes expressed specifically in the testis and encoding proteins with specialized functions.<sup>8</sup> A single copy of the one gene most critical to testis differentiation, SRY (Sex-determining Region on Y), is located on the distal short arm of the Y (Yp11.3), immediately adjacent to the pseudoautosomal region.<sup>13</sup>

Most of what is known about the genetic basis for sexual differentiation derives from studies of mutations in the mouse and human associated with varying degrees of “sex reversal,” conditions in which the chromosomal sex does not correlate with the gonadal or phenotypic sex. **In humans, 46,XX male sex reversal occurs when pairing between the X and Y chromosomes during male meiosis extends abnormally into adjacent nonhomologous regions, allowing inappropriate recombination and transfer of Y-specific DNA onto the X chromosome.** Careful analysis of four XX males having a very small piece of translocated Y DNA (60 kb)<sup>14</sup> prompted a search for highly conserved sequences within that region, which led to discovery of the SRY gene.<sup>13</sup> The identification of SRY mutations in three XY females supported the hypothesis that SRY was the critical and long-sought “testis-determining factor,”<sup>15,16</sup> but proof derived ultimately from studies in the mouse. First, a deletion in Sry (by convention, mouse gene symbols are italicized and the first letter is in uppercase with all the rest in lowercase, human gene symbols are italicized and all letters are in uppercase, mouse and human protein designations are the same as the gene symbol, but not italicized and all in uppercase) was identified in a line of XY female mice.<sup>17</sup> Second, Sry gene expression in the genital ridge was observed just at the time of testis differentiation.<sup>18</sup> Third, transgenic XX mice carrying Sry develop as males.<sup>19</sup> **SRY now is generally established as the primary genetic signal determining the direction of**

**gonadal differentiation in mammals.**<sup>10,20</sup> However, XX hermaphrodites having ovotestes but not SRY have been described, and only a small proportion of phenotypic females with XY gonadal dysgenesis (Swyer syndrome) harbor SRY mutations. These observations indicate clearly that sex determination and sex reversal involve genes other than SRY.<sup>21</sup>

Although the mechanisms that regulate SRY expression are still unclear, the nuclear receptor SF1 (Steroidogenic Factor 1) has emerged as a likely and important activator. In the mouse, SF1 binds to and activates the Sry promoter,<sup>22</sup> and heterozygous mutations in the Sfl gene (resulting in haploinsufficiency) produce XY female sex reversal.<sup>23,24,25</sup> In humans, SF1 haploinsufficiency is a known cause of XY female sex reversal,<sup>26</sup> and an SF1 polymorphism that reduces transactivation function by approximately 20% is recognized as a susceptibility factor for the development of micropenis and cryptorchidism.<sup>27,28</sup> Evidence indicates that splice variants of WT1 (Wilms tumor 1) and GATA4 (GATA-binding protein 4) also may be involved in the regulation of Sry expression; both are transcription factors containing zinc-finger motifs that can interact and synergistically activate the promoter of human SRY.<sup>29</sup> WT1 mutations are associated with gonadal dysgenesis and ambiguous genitalia in males.<sup>30</sup>

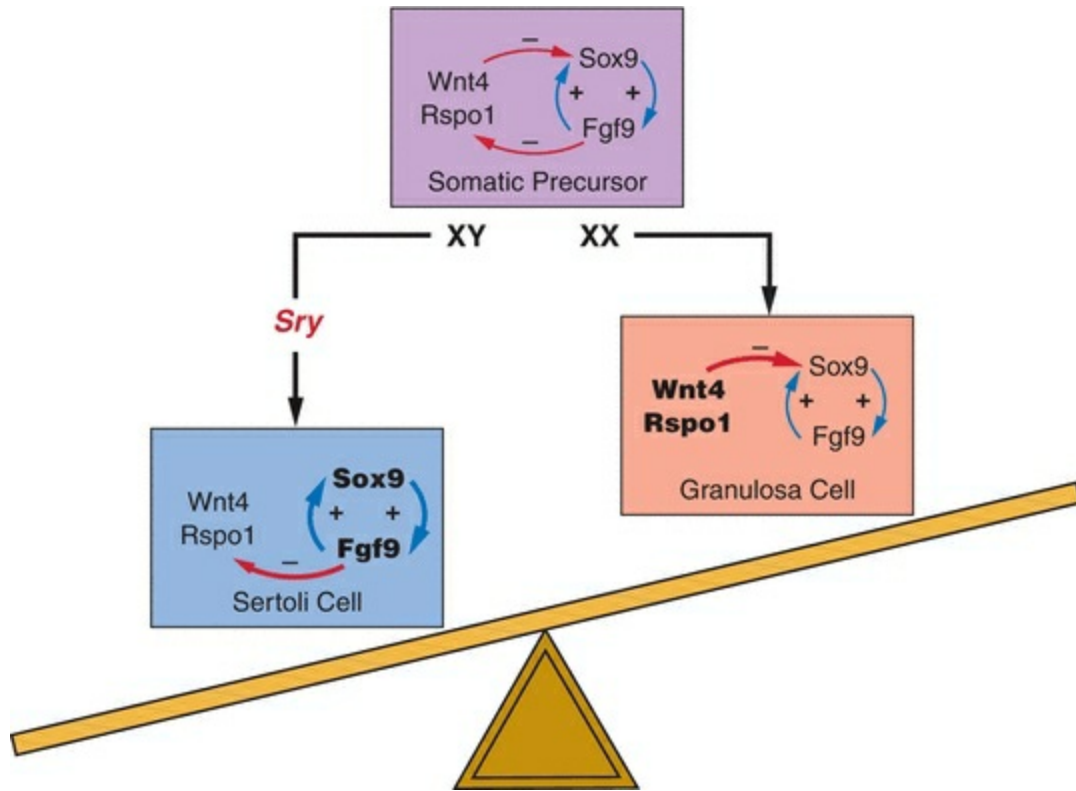

**The sequence of molecular events involved in testis differentiation is not completely understood, but SRY appears to activate a number of other genes that promote testis development.**<sup>31</sup> The 204 amino acid protein product of SRY (SRY) contains a 79 amino acid domain very similar to that in a recognized family of transcription factors known as the high mobility group (HMG), which bind to DNA and regulate gene transcription. Members of the related SRY HMG box (SOX) protein family of transcription factors play a crucial role in the cascade of events that drives testis differentiation, and most of the SRY point mutations identified in sex-reversed patients translate to abnormalities in the amino acid sequence of SOX proteins.<sup>32</sup>

**Substantial evidence now indicates that SOX9 is the most likely SRY target gene.** In mice, Sox9 expression is dramatically up-regulated soon after Sry expression begins in XY gonads but down-regulated in XX gonads,<sup>33</sup> and cell fate mapping experiments have found that SOX9-positive Sertoli cells derive exclusively from SRY-positive gonadal somatic cells.<sup>34</sup> XY mouse embryos having a targeted deletion of Sox9 develop ovaries,<sup>35,36</sup> and transgenic activation of Sox9 expression induces male development in XX embryos.<sup>10</sup> In humans, heterozygous mutations in SOX9 (resulting in haploinsufficiency) cause a skeletal malformation syndrome (campomelic dysplasia) in which most affected XY patients exhibit female sex reversal, and SOX9 duplication (resulting in overexpression) is the only known autosomal cause of XX male sex reversal.<sup>32</sup>

The developmental consequences of activating and inactivating mutations in Sox9 resemble those of similar mutations in Sry, implying not only that Sox9 is required for testis differentiation, but also that Sry activation of Sox9 may be all that is necessary to activate other genes important to testis development, such as Fgf9 (fibroblast growth factor 9), and to repress genes that induce ovary development, such as Wnt4 (a member of the wingless family of genes), Rspo1 (Respondin 1), Dax1 (dosage-sensitive sex reversal, adrenal hypoplasia critical region, on chromosome X, gene 1), and Foxl2 (forkhead box L2).<sup>32</sup> DAX1 is a nuclear transcription factor normally up-regulated in the ovary and repressed by SOX9, but DAX1 duplication (resulting in overexpression) can repress SRY (directly, or indirectly by inhibiting SF1) and cause XY female sex reversal.<sup>37,38</sup> SOX9 probably is the one most important factor regulating the activity of genes involved in Sertoli cell differentiation, and evidence suggests that SOX9 drives the process via feed-forward loops that up-regulate its own expression. SOX9 stimulates Sfl expression, binds to the same enhancer as SRY (after Sry expression has ended), and also stimulates Fgf9 expression in nascent Sertoli cells, all of which up-regulate Sox9 expression and combine to maintain high levels of SOX9 activity.<sup>10,31,32</sup> **Although a great many genes are involved in testis differentiation, virtually all male-to-female sex reversal in mice and in humans can be explained ultimately, directly or indirectly, by the failure to generate sufficient levels of SOX9 to promote the positive-feedback loops that maintain its expression.**

FGF9 appears particularly critical for maintaining the levels of Sox9 expression required to induce testis differentiation. Both Fgf9 and Sox9 are expressed at low levels in bipotential XX and XY gonads (**Figure 8.2**), but Fgf9 expression is lost in XX and amplified in XY gonads soon after Sry is expressed.<sup>39</sup> Deletion of Fgf9 does not prevent initial expression of Sry or Sox9 in Sertoli cell precursors, but Sox9 expression is a prerequisite for Fgf9 expression, and without it, Sox9 expression cannot be sustained.<sup>40</sup> FGF9 also appears to actively repress genes that promote ovary differentiation, such as Wnt4.<sup>39</sup>

**FIGURE 8.2**

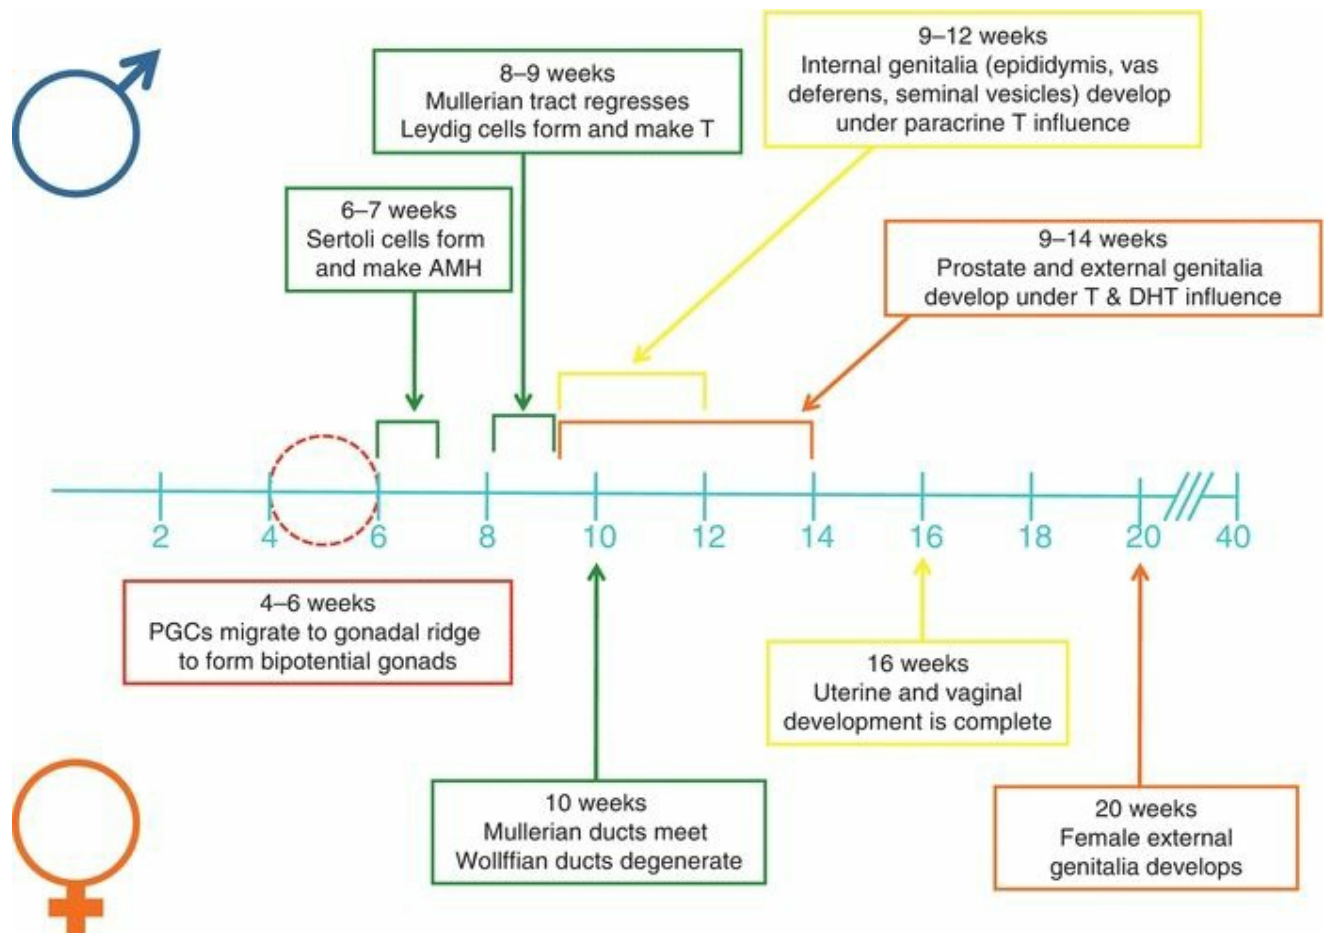

Whereas ovarian differentiation has long been considered the “default” pathway of sex determination—the automatic result in the absence of a testis-determining factor—recent evidence challenges that traditional concept. In mice, inactivating mutations in genes such as *Wnt4*,<sup>39,41</sup> *Rspo1*,<sup>42,43,44</sup> and *Foxl2*<sup>45,46,47</sup> result in partial or complete XX male sex reversal, and activating mutations in  $\beta$ -catenin or *Dax1* result in XY female sex reversal.<sup>32,48,49</sup> *Rspo1* is required for *Wnt4* expression and activates  $\beta$ -catenin, which, like *Foxl2*, down-regulates *Sox9* expression.<sup>21</sup> *Dax1* acts as a dominant-negative regulator of transcription of other nuclear receptors, including SF1, and thus may repress *Sry* expression.<sup>32</sup> Taken together, these observations suggest strongly that ovarian development results from the active repression of one or more genes in the testis pathway, rather than from a developmental default mechanism.

**It now appears that both testis and ovary differentiation require dominantly acting genes, with SRY inducing testis development via up-regulation of SOX9 and with other genes, primarily WNT4 and RSP01, teaming to promote ovary development via repression of SOX9. The new concept views the fate of the bipotential gonad as balanced between opposing forces and SRY as the key factor. In XY gonads, SRY induces SOX9 and tips differentiation toward testis development, and in XX gonads lacking SRY, other genes combine to repress SOX9**

**and promote ovary development.**<sup>21,50</sup>

# Germ Cell Sex Differentiation

In human embryos, gonadal development begins during the 5th week of gestation as a protuberance overlying the mesonephric ducts, known as the genital or gonadal ridge. The primordial germ cells do not arise within but migrate into the developing gonads between 4 and 6 weeks of gestation, proliferating as they go (**Figure 8.3**). At least in the mouse, their survival during migration appears to depend on an interaction between the cell surface tyrosine kinase receptor, c-KIT, and a ligand produced by surrounding tissues, called stem cell factor.<sup>51</sup> At this stage of development, the gonads are identical in males and females, indifferent and bipotential, capable of differentiating into either testes or ovaries in response to inductive signals. Although germ cells do not induce gonadal development, they play a more active role in females than in males. In the genetic or pharmacologically induced absence of germ cells, testis cords (the embryonic precursor to seminiferous tubules in the adult testis) can develop, but in females, ovary differentiation fails altogether<sup>52,53</sup>; somatic cells aggregate but deteriorate, leaving only stromal tissue and, ultimately, a fibrous streak. **After arrival in the nascent gonads, germ cell differentiation into male (prospermatogonia) or female (oogonia) depends on the sex of the gonadal somatic cells and on signals in the surrounding environment rather than on the chromosomal sex of the germ cells themselves.** In XY/XX mouse chimeras, XY primordial germ cells can develop as oogonia in female embryos, and XX germ cells as prospermatogonia in male embryos.<sup>54</sup>

**FIGURE 8.3**

It is not yet clear whether the signaling molecules that mediate germ cell sex determination act in the developing testis to inhibit meiosis or in the developing ovary to induce meiosis, what those signaling molecules may be, and whether they act directly on the germ cells themselves or indirectly via actions on gonadal somatic cells.<sup>31</sup> Recent studies in mice aimed at identifying molecular candidates for the putative meiosis-inducing or meiosis-inhibiting factors have focused attention on retinoic acid, which is produced in the mesonephros. Whereas retinoic acid treatment induces primordial germ cells in male gonadal explant cultures to express *Stra8*, *Scp3*, and *Dmc1* (meiosis marker genes), germ cells in female gonadal explants treated with a retinoic acid inhibitor continue to express *Oct4* (a marker for pluripotent cells).<sup>55</sup> Moreover, Sertoli cells, which surround the germ cells in the developing testis cords, express *Cyp26B1*, a gene encoding an enzyme (CYP26B1) that metabolizes retinoic acid.<sup>56</sup> **Taken together, these observations suggest that local levels of retinoic acid may regulate germ cell differentiation in the developing gonad, with retinoic acid diffusing from the adjacent mesonephros acting as the functional meiosis-inducing factor in female germ cells and with CYP26B1 produced by Sertoli cells in the**

**developing testis cords acting as the functional meiosis-inhibiting factor in male germ cells.**<sup>10</sup> Alternatively, or in addition, Sertoli cells may secrete a specific meiosis-inhibiting factor, with one likely downstream target being Nanos2, a gene expressed exclusively in male germ cells.<sup>31,57</sup>

In the male, the primordial germ cells become incorporated into the developing testis cords and enter mitotic arrest as prospermatogonia, resuming proliferation soon after birth. In the female, the primordial germ cells (oogonia) continue to proliferate by mitosis somewhat longer, reaching a peak of 5–7 million by 20 weeks of gestation. However, only some enter meiosis and become primary oocytes, arresting in diplotene of the first meiotic prophase, and become surrounded by a single layer of flattened pregranulosa cells, forming primordial follicles. Those that are not incorporated into primordial follicles degenerate via apoptosis, and, by birth, only approximately 1–2 million germ cells remain. The signals for programmed cell death are unknown but seem likely to involve some form of intercellular communication between the primary oocyte and surrounding pregranulosa cells.

Whereas male germ cells proliferate continuously, the traditional dogma has held that female germ cells proliferate only during embryogenesis and, therefore, that females are born with a finite number of primordial follicles that are steadily depleted and cannot be replenished. However, that dogma has been challenged by studies suggesting that germ-line stem cells reside within the bone marrow and may replenish the ovary with new oocytes,<sup>58,59</sup> stimulating a vigorous scientific debate,<sup>60,61,62,63,64,65,66</sup> which continues.<sup>67,68,69</sup>

# Testis Differentiation and Development

The current model for testis differentiation and development, based primarily on studies in mice, envisions a sequence of events that begins with the formation of the genital ridge, first recognized as a thickening underlying the coelomic epithelium adjacent to the mesonephros. Primordial germ cells migrate into the genital ridge, along with proliferating coelomic epithelial cells, which express SF1. A portion of the epithelial daughter cells expresses Sry to become Sertoli cell precursors, the first cell type to differentiate and the only cell type in the developing testis that expresses Sry. The subset of somatic cells expressing Sry immediately also begins to express Sox9, a reliable marker for developing Sertoli cells. In turn, Sox9-positive Sertoli cell precursors secrete other paracrine signaling molecules such as Fgf9 and prostaglandin D<sub>2</sub> (PGD<sub>2</sub>), which also play important roles in testis differentiation. FGF9 reinforces Sox9 expression and induces neighboring cells to proliferate, thereby increasing the generation of supporting cell precursors that are able to express Sry. PGD<sub>2</sub> can induce even Sry-negative cells to express SOX9 and to differentiate into Sertoli cells.<sup>34</sup> Together, FGF9 and PGD<sub>2</sub> help to maintain SOX9 levels and to ensure a sufficient number of Sertoli cells to form a testis. Once the number of SOX9-positive cells reaches a critical threshold, SOX9 represses Sry expression.

Under the control of Sry, Sertoli cells also secrete a factor that induces a migration of cells from the adjacent mesonephros. The developing testis enlarges rapidly with the influx of migrating cells, which differentiate into endothelial cells and Leydig cells upon their arrival in the developing gonad.<sup>10</sup> Male-specific peritubular myoid cells appear to differentiate from cells already within the gonad, flattening and surrounding aggregates of Sertoli cells that organize in layers around clusters of primordial germ cells.<sup>50</sup> The peritubular myoid cells thus help to form the testis cords, later serving to promote the movement of sperms through the seminiferous tubules in the adult testis. Together, the Sertoli cells and peritubular myoid cells induce the development of a basal lamina between them, separating the testis cords from the interstitial tissue. The steroidogenic Leydig cells differentiate within the interstitium, in close proximity to developing blood vessels that derive from endothelial cell precursors. Endothelial cell migration from the mesonephros is specific to the male and required for development of an arterial network that extends throughout the interstitium but not into the testis cords<sup>50</sup> (**Figure 8.4**).

**FIGURE 8.4**

# Ovary Differentiation and Development

In females lacking a Y chromosome and SRY, the bipotential gonad begins to differentiate into an ovary about 2 weeks later than testis development begins in the male. **Normal ovarian differentiation requires the presence of germ cells; in their absence, the gonadal somatic cells fail to differentiate, indicating some form of communication between germ cells and somatic cells.**<sup>53</sup> Wnt4 and Rspo1 are two genes that play an important role in ovarian differentiation; XX mice with targeted deletions of either gene develop ovotestes containing sex cords and functional Leydig cells.<sup>43</sup> Wnt4 expression suppresses the migration of mesonephric endothelial and steroidogenic cells as occurs in the developing testis. This action of Wnt4 is dependent on Rspo1.<sup>41,43</sup> Rspo1 expression is specifically up-regulated in XX somatic cells from the earliest stages of gonadal differentiation and encodes a secreted protein that, like WNT4, activates the  $\beta$ -catenin signaling pathway in somatic cells, resulting in a loss of cell-cell adhesion between female germ cells, which is a prerequisite for their entry into meiosis.<sup>43</sup> Consequently, directly or indirectly, RSPO1 regulates female germ cell and ovarian differentiation, by promoting events required for initiation of meiosis, by inhibiting migration of mesonephric cells via Wnt4 expression, and by down-regulating Sox9, which drives testis differentiation. **Thus, whereas testis differentiation is directed by somatic cells, ovary differentiation requires communication between somatic cells and germ cells.**<sup>70</sup>

Gradually, the developing ovary becomes organized into an outer cortex and an inner medullary region, which ultimately regresses, leaving behind a compressed nest of vestigial tubules and Leydig cells in the hilar region known as the rete ovarii. By 20 weeks of gestation, the ovary achieves mature compartmentalization, consisting of an active cortex containing follicles exhibiting early stages of maturation and atresia, and a developing stroma. Within the cortex, primordial follicles are separated from the somatic cells by a surrounding basement membrane. In some primordial follicles, the pregranulosa cells become cuboidal and proliferate, the oocyte enlarges and produces a zona pellucida (an extracellular glycoprotein matrix deposited between the oocyte and the granulosa cells), and a surrounding layer of thecal cells develops. The remainder stay quiescent until sometime later.

The molecular events that regulate primordial follicle formation and that stimulate or inhibit the initiation of follicular development are understood poorly but appear to involve a variety of factors, all locally produced and regulated, including members of the transforming growth factor  $\beta$  (TGF- $\beta$ ) superfamily of proteins and another family of trophic factors called neurotrophins. Activins, inhibins, antimüllerian hormone (AMH), and bone morphogenetic proteins (BMPs) are members of the TGF- $\beta$  family of proteins.

Activins promote and inhibins retard primordial follicle development, and their relative local concentrations in the fetal ovary during the time of follicle assembly may determine the size of the ovarian follicular pool.<sup>71</sup> AMH appears to be an important inhibitor of primordial follicle growth, and BMPs exert the opposite effect.<sup>71</sup> AMH action is mediated, at least in part, by the transcription factor Osterix (Osx), which influences regression of müllerian ducts.<sup>72</sup> Neurotrophins and their receptors are essential for the differentiation and survival of various neuronal populations in the central and peripheral nervous systems, but their presence in the developing ovary suggests they also play a role in ovarian development. Four mammalian neurotrophins have been identified, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin 4/5 (NT-4/5), all of which exert their actions via binding to high-affinity transmembrane tyrosine kinase receptors encoded by members of the trk proto-oncogene family (NGF to TrkA, BDNF and NT-4/5 to TrkB, and NT-3 to TrkC).<sup>73</sup> Observations in NGF- and TrkA-null mice indicate that NGF stimulates the proliferation of ovarian mesenchymal cells during the early stages of follicular assembly and promotes differentiation and synthesis of follicle-stimulating hormone (FSH) receptors in granulosa cells. Similar experiments with TrkB-null mice suggest that TrkB signaling is required for oocyte survival after follicular assembly and for preantral follicular development.<sup>73</sup> The specific signaling mechanisms that mediate the effects of activins, inhibins, BMPs, and neurotrophins remain to be established.

Other paracrine factors mediate a bidirectional communication between oocytes and their surrounding granulosa cells. Oocytes are linked to their investment of granulosa cells via gap junctions, which allow passage of small molecules such as ions (e.g., calcium), metabolites (e.g., pyruvate, nucleic acids, inositol), amino acids (e.g., L-alanine), cholesterol, and intracellular signaling molecules (e.g., cyclic adenosine monophosphate, cAMP) between granulosa cells and oocytes. In mice, targeted deletions of gap junction proteins (known as connexins), disrupt follicular and oocyte development.<sup>70,74,75,76</sup>

Oocytes are unable to use glucose as an energy source to support meiotic maturation, cannot transport certain amino acids, and lack both the enzymes necessary for cholesterol synthesis and the receptors for its uptake from carrier-borne sources. Consequently, they are dependent on adjacent granulosa cells to metabolize glucose into a usable energy substrate, such as pyruvate, for transport of essential amino acids, such as L-alanine, and for synthesis and transfer of cholesterol.<sup>77</sup> **To meet their needs, oocytes stimulate glycolysis, amino acid transport, and cholesterol synthesis in granulosa cells via paracrine and juxtacrine signals that promote expression of transcripts involved in these metabolic processes, at least in some species.**<sup>77</sup>

Candidate signaling molecules include closely related members of the TGF- $\beta$  family, growth differentiation factor 9 (GDF9) and BMP15; both are expressed robustly in oocytes and appear crucial for normal ovarian follicle development in mammalian species.<sup>78</sup>

# Genital Duct Differentiation and Development

Caspar Wolff described the mesonephros in 1759 in his doctoral dissertation, at the age of 26.<sup>79</sup> The paired structures were named wolffian bodies by the 19th century embryologist, Rathke, in recognition of Wolff's initial discovery and description. Johannes Müller, a German physiologist, described the embryology of the genitalia in 1830. The paramesonephric ducts received his name, not because of his original contributions, but in recognition of his ability to synthesize the existing literature into a coherent concept.

The mesonephric (wolffian) and paramesonephric (müllerian) ducts are discrete primordia that coexist in all embryos during the ambisexual period of development (up to 8 weeks). Thereafter, one duct system persists, giving rise to specialized ducts and glands, and the other regresses, leaving behind only nonfunctional vestiges. **The wolffian duct develops first; differentiates into the epididymis, vas deferens, and seminal vesicles in males; and regresses in females. The müllerian duct develops later, even after the beginning of sex determination; differentiates into the fallopian tubes, uterus, and upper portion of the vagina in females; and regresses in males.**

The hormonal control of genital duct differentiation and development was established by the classic experiments of Alfred Jost.<sup>80</sup> His landmark studies demonstrated that hormones produced by the testis direct the sexual differentiation of both the internal and external genitalia in the male. Whereas testosterone stabilizes and promotes development of the wolffian ducts, AMH directs the regression of the müllerian system. In females, the wolffian ducts regress, in the absence of testosterone, and the müllerian ducts develop fully, in the absence of AMH. Although not yet clearly defined, our knowledge of the molecular mechanisms involved is growing steadily.

## Mesonephric (Wolffian) Duct Development

Testosterone is secreted by the fetal testes soon after Leydig cell formation (at 8 weeks of gestation) and rises rapidly to peak concentrations at 15–18 weeks. Fetal testosterone stimulates development of the wolffian duct system, from which the epididymis, vas deferens, and the seminal vesicles derive. Testosterone levels in the male fetus correlate with Leydig cell development, overall gonadal weight,  $3\beta$ -hydroxysteroid dehydrogenase activity, and chorionic gonadotropin (hCG) concentrations. As maternal hCG levels decline, beginning at approximately 20 weeks of gestation, Leydig cell testosterone secretion comes under the control of fetal pituitary luteinizing hormone (LH). In the absence of LH, as in males with anencephaly and other forms of congenital hypopituitarism, Leydig cells all but disappear and the internal and external genitalia do

not develop fully.<sup>81</sup>

Testosterone can reach the developing wolffian duct system via the systemic fetal circulation, but the paracrine actions of testosterone produced in nearby Leydig cells are more important for the stabilization and differentiation of the wolffian duct. **High local concentrations of testosterone stimulate the ipsilateral wolffian duct to differentiate into the epididymis, vas deferens, and seminal vesicle. Duct system differentiation proceeds, therefore, according to the nature of the adjacent gonad.** High concentrations of testosterone are required because the duct does not have the ability to convert testosterone to dihydrotestosterone (DHT).<sup>82</sup> In rodents, wolffian development can be induced in female embryos by treatment with exogenous androgens, but only to a limited extent,<sup>83</sup> because exogenous androgen treatment cannot achieve and maintain the high local concentrations required to induce duct differentiation. For the same reason, the wolffian ducts do not develop in female fetuses exposed to excess endogenous adrenal androgens, as in classical congenital adrenal hyperplasia (CAH), or to excess maternally derived androgens, as occurs in women with pregnancy luteoma. Testosterone acts via binding to androgen receptors in the wolffian duct, which are detectable in both males and females, but androgen production in females does not approach the levels required to promote wolffian duct differentiation.<sup>83</sup>

The paired wolffian ducts arise within the urogenital ridge during embryogenesis, running its length and terminating in the cloaca. The ducts form by a rearrangement of mesenchymal cells rather than by cell proliferation.<sup>84</sup> The regulatory signals involved have not been established, but evidence from studies in mice having targeted deletions of candidate genes has implicated a number of transcription factors, including PAX2, LIM1, and EMX2. All are expressed in mesenchymal condensations before duct formation and respond to opposing signals from adjacent mesoderm and overlying ectoderm, which appear to restrict their expression to the specific area in the mesoderm from which the ducts arise.<sup>84</sup> Along the axis of the forming wolffian ducts, a series of smaller tubules develop. The most anterior tubules fuse with the wolffian duct to become the precursors of the efferent ducts, ultimately connecting the testis to the epididymis; the more posterior or caudal tubules regress. In the human, parallel efferent ductules form multiple connections with the head (caput) of the epididymis.

Gradually, the straight wolffian ducts elongate and coil as a result of epithelial cell proliferation, stimulated by testosterone transported from the testes via the lumen of the duct, as well as by growth factors (e.g., epidermal growth factor, EGF; basic fibroblast growth factor, bFGF), which also are found in high concentrations in luminal fluid.<sup>85,86</sup> The structure of the developing epididymis becomes increasingly complex. Elongation and three-dimensional coiling begin at the end nearest the testis (the caput) and progress distally, except at the most caudal end of the duct, which remains straight and ultimately

gives rise to the vas deferens. The factors that stimulate or control coiling of the duct are uncertain but may involve a combination of regional signals from the surrounding mesenchyme, focal “hot spots” of epithelial cell growth, and physical space limitations.<sup>84</sup> Region-specific expression of homeobox (HOX) genes, which are transcriptional regulators of patterning, appears important for the differentiation of the duct into its morphologically and functionally distinct segments (caput, corpus, and caudal regions). For example, Hoxa10 and Hoxa11 appear to act distally to define the boundary between the epididymis and vas deferens.<sup>87</sup> Others HOX genes appear to direct differentiation of the seminal vesicle (derived from the posterior wolffian duct) and the prostate (derived from the urogenital sinus).<sup>88</sup> Evidence suggests that HOX genes may act by controlling the expression of other morphogenic factors such as inhibin beta A, which is expressed most highly in the greatly coiled caput region and to a progressively lesser extent in the mesenchyme surrounding more distal regions of the duct.<sup>89</sup> Growth factors in the testicular fluid also appear to play an important role in cellular differentiation along the length of the epididymis.<sup>90</sup>

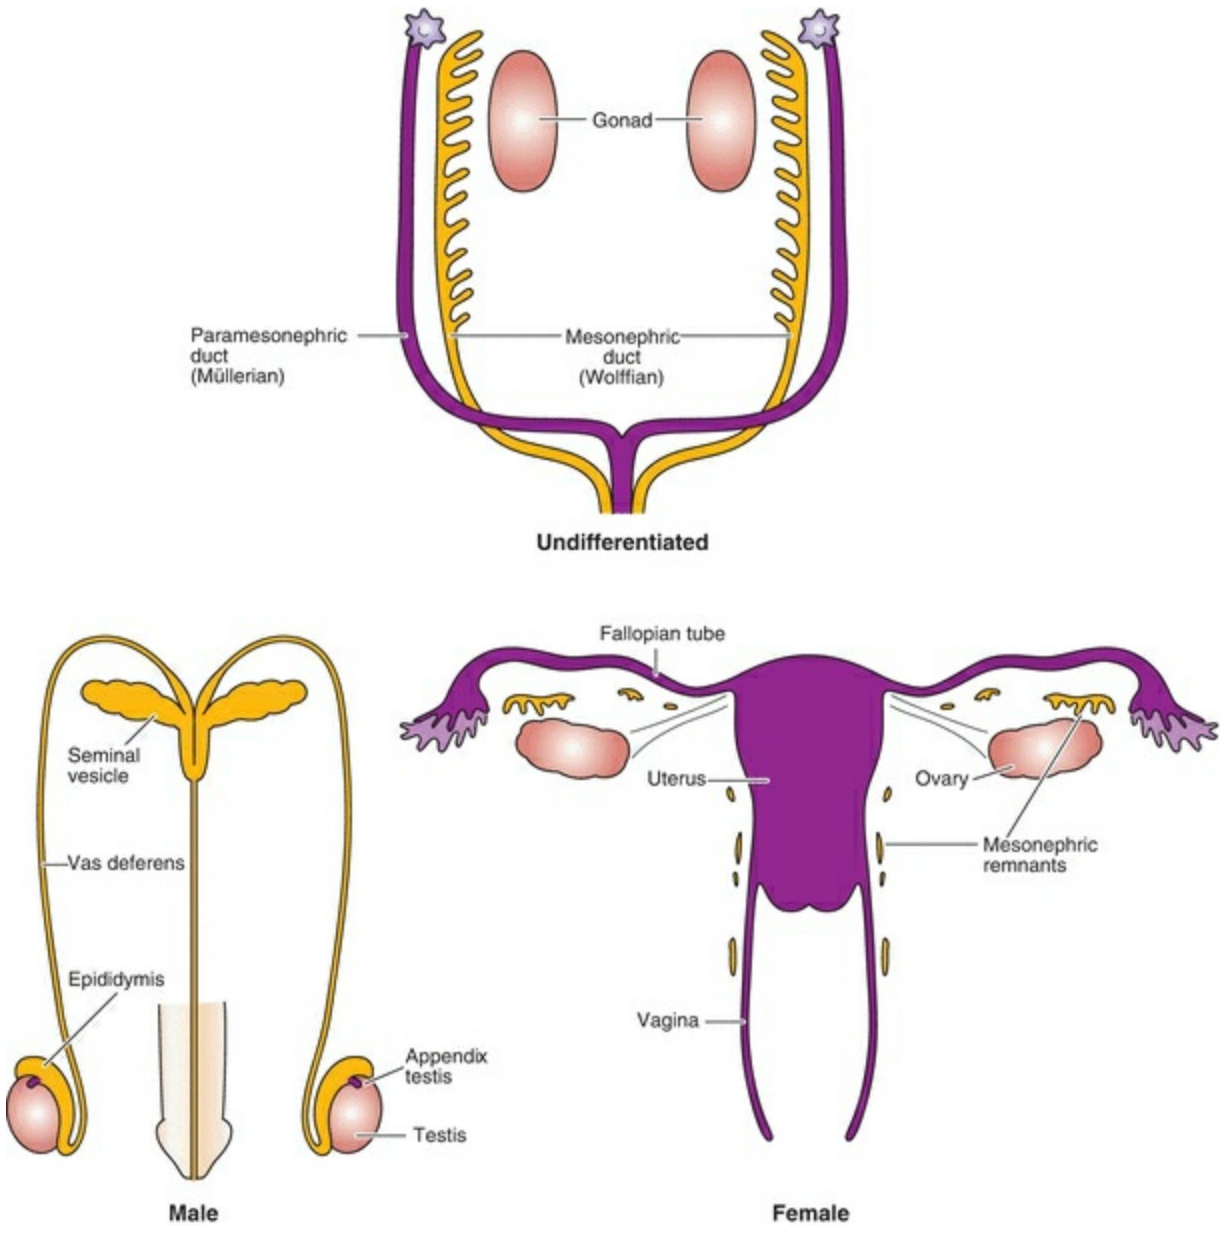

The extraordinary length of the epididymis—approximately 6 meters in the human—reflects its functional importance. **As sperms leave the testis, they are functionally immature, having neither full motility nor the ability to recognize and fertilize an oocyte.** They mature and acquire those functions as they pass through the epididymis, undergoing both biochemical and physical changes in a changing luminal environment regulated by a region-specific epididymal epithelium. The vas deferens is distinguished from the epididymis by its structure and by its function. It originates at the caudal end of the epididymis, where sperms are stored, and ends in the ejaculatory duct, which joins with the urethra. The vas deferens is surrounded by layers of smooth muscle that contract in response to sympathetic nerve stimulation, moving sperms through the vas deferens, into the ejaculatory duct (formed by the union of the vas with the duct of the seminal vesicle), and into the urethra.

## **Paramesonephric (Müllerian) Duct Development and Regression**

The müllerian ducts begin by invagination of the coelomic epithelium, which progresses until reaching the wolffian ducts, then elongate, by cellular proliferation, along the length of the wolffian ducts until reaching and fusing with the urogenital sinus.<sup>91</sup> The wolffian ducts make no direct contribution to the müllerian ducts, but are essential for normal müllerian development, serving as a guide or migrational template.<sup>92</sup> **If the wolffian ducts do not form, müllerian duct development also fails. Consequently, abnormalities in the renal system are highly associated with abnormalities in**

## **development of the fallopian tubes, uterus, and upper vagina.**

Müllerian duct development can be separated into three phases, each controlled by different genes, as demonstrated by careful analyses of mutant mice. Selection of the cells in the coelomic epithelium that will become the müllerian ducts is controlled by *Lim1*, which encodes a protein also involved in formation of the wolffian ducts.<sup>93</sup> Expression of *Wnt4* and other genes in the Wnt family (*Wnt7a*, *Wnt9b*) appears necessary for epithelial invagination.<sup>91</sup> *Pax2* is required for duct elongation<sup>94</sup> and, together with *Pax8*, also for differentiation of the duct into a uterus and vagina.<sup>95</sup> Directly or indirectly, müllerian duct development also involves other genes such as those encoding retinoic acid receptors; mice having targeted deletions of the retinoic acid receptors fail to develop müllerian ducts or to differentiate specific portions of the duct<sup>96</sup> (**Figure 8.5**).

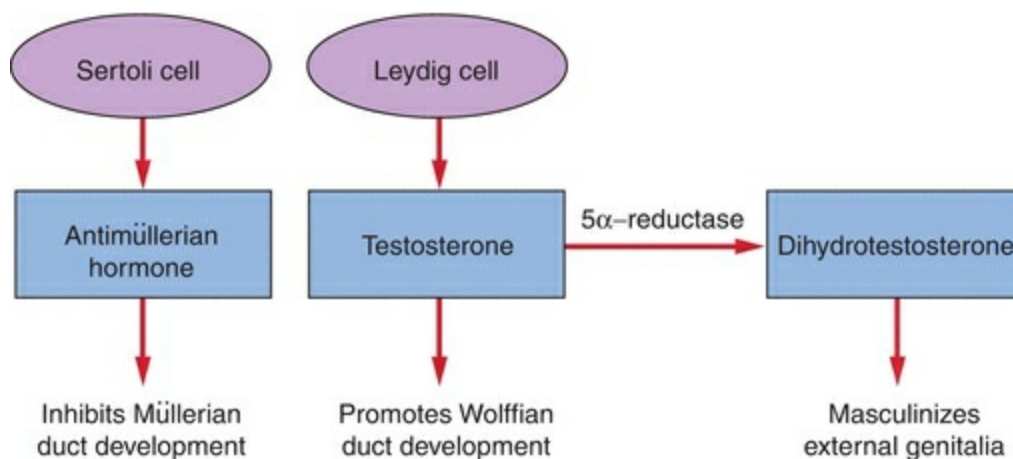

**FIGURE 8.5**

AMH is a member of the TGF- $\beta$  superfamily family of growth and differentiation factors that includes inhibin and activin.<sup>97,98</sup> The gene encoding AMH is located on the short arm of chromosome 19 (19p13.3). Like other members of the TGF- $\beta$  superfamily, AMH signaling is mediated via a heterodimeric receptor consisting of a type I and a type II serine/threonine kinase receptor; the type II part of the receptor mediates ligand specificity and the type I receptor activates a downstream signaling cascade. The specific type II receptor that binds AMH, called AMHR2, has been isolated in several mammalian species; in the human, the gene encoding AMHR2 is located on chromosome 12 (12q13). Three different type I receptors have been linked to AMH signaling—ALK2, ALK3, and ALK6; ALK2 and ALK3 appear particularly important, because

decreased expression or deletion of either disrupts müllerian duct regression.<sup>91</sup> **AMH gene expression is induced by SOX9 in Sertoli cells soon after testicular differentiation and results in the ipsilateral regression of the müllerian ducts by 8 weeks of gestation, before the emergence of testosterone and stimulation of the wolffian ducts.**<sup>99</sup> Inactivating mutations of AMH or AMHR2 result in persistent müllerian ducts in males.<sup>100</sup>

The process of müllerian duct regression involves a number of genes, but studies in mice indicate that *Wt1* and *Wnt7a* play key roles. AMH signaling induces coelomic epithelial cells expressing *Wt1*, *Amhr2*, and *Alk3* to migrate and surround the müllerian duct, transforming to mesenchymal cells in the process.<sup>101,102</sup> *Wnt7a* expression in the müllerian duct mesoepithelium promotes secretion of a signaling molecule (WNT7a) that activates AMHR2 in the neighboring mesenchymal cells via WT1, which binds and activates the *Amhr2* promoter.<sup>91</sup> At the same time,  $\beta$ -catenin gene expression increases in the mesenchymal cells surrounding the duct, and accumulation of  $\beta$ -catenin is accompanied by increased apoptosis in the müllerian ductal epithelium.<sup>101,102</sup> Whether WNT-dependent  $\beta$ -catenin activity is required to induce *Amhr2* expression or functions downstream of AMH signaling, or both, is not yet clear. Regardless, the process of müllerian duct regression appears to involve both apoptosis and the transition of ductal epithelial cells to mesenchymal cells.<sup>91</sup> The matrix metalloproteinase MMP2 also plays a role, by mediating destruction of the extracellular matrix; available evidence indicates that MMP2 activity also is AMH dependent, although the mechanism involved has not been established<sup>103</sup> (**Figure 8.6**).

**FIGURE 8.6**

# Development of the External Genitalia

In the bipotential state, which persists until 9 weeks of gestation, the external genitalia consist of a genital tubercle, a urogenital sinus, and lateral labioscrotal folds or swellings. Unlike the internal genitalia where both duct systems initially coexist, the external genitalia are neutral primordia able to develop into either male or female structures, depending on gonadal steroid hormone signals.

In the male, the Leydig cells of the fetal testis begin to secrete testosterone at 8–9 weeks of gestation, and masculinization of the external genitalia begins 1 week later, at approximately 10 weeks. **The genital tubercle grows, forming the penis, the edges of the urogenital sinus fuse to form the penile urethra, and the labioscrotal folds fuse to form a scrotum.** The process typically is completed by 12–14 weeks of gestation. Thereafter, the principal change is in the growth and length of the penis. Complete development of the male external genitalia and differentiation of the prostate requires the conversion of testosterone to DHT, via the action of the intracellular enzyme 5 $\alpha$ -reductase. The genital tubercle and the labioscrotal swellings are highly sensitive to DHT, being rich in both androgen receptors and 5 $\alpha$ -reductase activity ([Figure 8.7](#)).

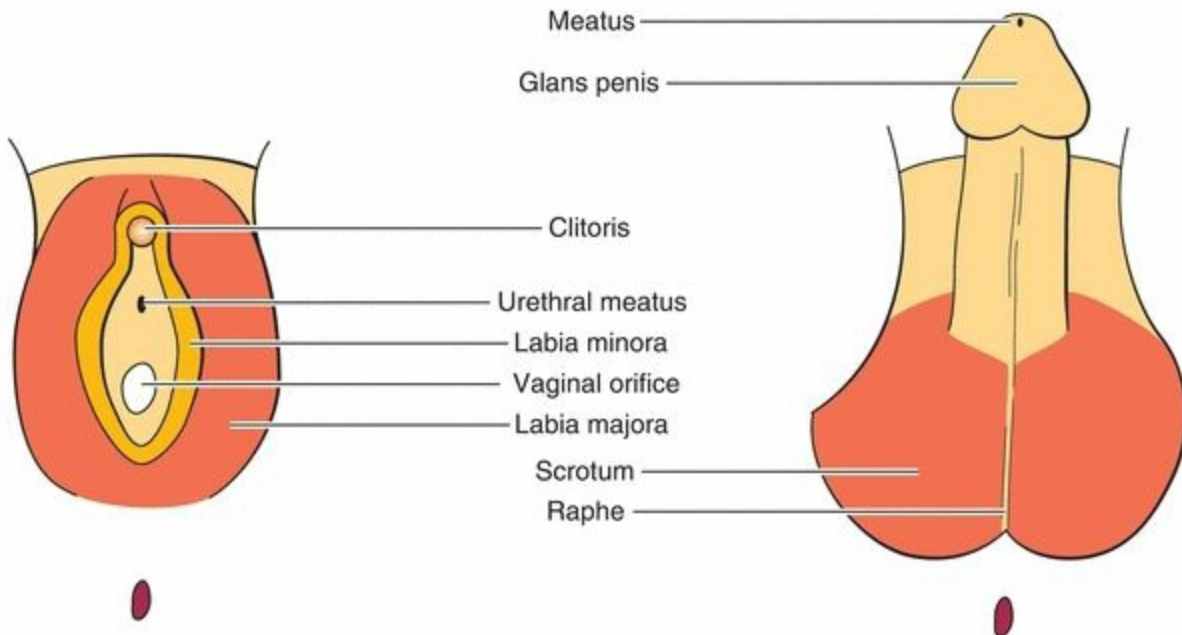

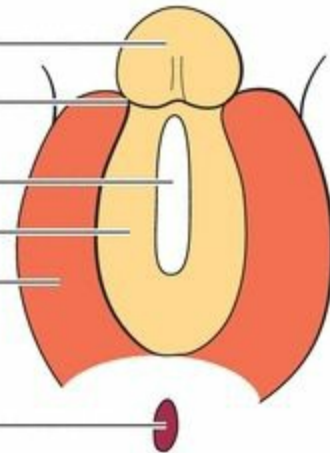

### Bipotential Stage

### Female

### Male

**FIGURE 8.7**

In the female, and in males with defects in androgen synthesis or action, the external genital primordia do not masculinize. **The genital tubercle remains small and becomes the clitoris, the margins of the urogenital sinus remain separate and form the labia minora, the labioscrotal folds form the labia majora, and the urogenital sinus develops into the lower vagina and urethra.**

In females, abnormal androgen exposure between 9 and 14 weeks of gestation results in varying degrees of masculinization, such as clitoral hypertrophy and labial fusion. In males, the external genitalia will not masculinize completely if androgen action is deficient during the same critical time interval, yielding a small phallus, hypospadias, or scrotal defects. **In both sexes, because the external genitalia share a common origin, genital ambiguity results from abnormalities in androgen action—in females from too much and in males from too little.**

# Sexual Differentiation of the Central Nervous System

Experimental evidence from studies in rodents and nonhuman primates suggests strongly that the fetal hormonal environment directs sexual differentiation of not only the genitalia but also the CNS. Treatment with testosterone during early development increases reproductive and other behaviors more common in males and decreases behaviors more common in females. These observations suggest that testosterone and its metabolites play a role in brain development and neuronal organization.<sup>104,105</sup>

Most of our knowledge about the early influence of testosterone on the brain and behavior in humans derives from clinical disorders associated with abnormal hormone production in early life, such as CAH. In male fetuses with classical CAH, sexual development progresses normally, but in female fetuses, testosterone is markedly elevated and causes masculinization of the external genitalia (clitoral enlargement and labial fusion). **Studies in girls with classical CAH indicate that increased prenatal androgen exposure also affects their brains and behavior.** Compared to unrelated age- and sex-matched controls or to unaffected female relatives of similar age, their toy preferences (vehicles, weapons) and play behaviors (rough, active play) are more typical of boys than of girls, to an extent that correlates with the severity of their disorder.<sup>4,106,107</sup> Girls with classical CAH also display more physical aggression and greater spatial abilities.<sup>108,109,110</sup> Although less well studied, there also is evidence to suggest that antenatal androgen exposure may influence sexual orientation. Whereas most females with classical CAH are heterosexual, as a group they are more likely to exhibit a bisexual or homosexual orientation; the effect is more pronounced in women with the severe salt-wasting form of CAH than in those with the milder, simple virilizing CAH.<sup>111</sup> Other studies observing a significant linear relationship between childhood behaviors and maternal serum or amniotic fluid testosterone concentrations during pregnancy suggest that even normal variations in prenatal androgen exposure may influence behavior, in both males and females.<sup>112,113</sup>

Presumably, the behavioral consequences of variations in prenatal androgen exposure reflect changes in neuronal development and organization. In rodents, an area of the anterior hypothalamic/preoptic region, called the sexually dimorphic nucleus of the preoptic area, is substantially larger in males than in females and treatment with androgens increases its size in females.<sup>104</sup> Whereas no comparable, specific, sexually dimorphic region has been identified in the human brain, there is some evidence from studies in females with classical CAH using functional MRI to suggest that prenatal androgen exposure may “masculinize” certain regions of the brain such as the amygdala, which is involved with regulation of emotion and aggression.<sup>114</sup> Variations in fetal

hormonal programming may contribute, therefore, to the spectrum of psychosexual behavior observed in humans. In addition, gender role is influenced heavily by the sex of rearing and by social interactions based upon genital appearance and secondary sexual characteristics.

# DISORDERS OF SEXUAL DEVELOPMENT

---

Disorders of sexual development (DSD) are congenital conditions characterized by atypical development of chromosomal, gonadal, or phenotypic sex. Traditionally, they have been classified according to gonadal sex. A **true hermaphrodite** has both ovarian and testicular tissue. A **male pseudohermaphrodite** has testes, but a female genital phenotype, and a **female pseudohermaphrodite** has ovaries, but masculine genital characteristics. However, recent advances in molecular genetic diagnosis and increasing awareness of ethical issues and patient advocacy concerns suggested the need to reexamine the traditional classification scheme and to retire gender-based terms that many now consider pejorative.

Ideally, a classification system must be flexible, to allow incorporation of new information, logical, to maintain a consistent structure, reflect genetic cause when that is known, and accommodate the spectrum of phenotypic variation. The classification and nomenclature used here, organized by chromosomal composition and causation, conform with recommendations arising from a 2006 consensus conference involving experts in pediatric endocrinology and other specialties involved in the management of patients with DSD ([Table 8.1](#)).<sup>115</sup>

## 46,XX Disorders of Sexual Development

DSD in chromosomal females can result from abnormalities in gonadal development, but most are caused by androgen excess, which may be of fetal, fetoplacental, or maternal origin. Excess fetal androgen production results from steroidogenic enzyme deficiencies causing CAH. Androgen excess of fetoplacental origin results from enzyme deficiencies involving both the fetal adrenal and the placenta. Maternal androgen excess can result from the ingestion of drugs having androgenic properties and from disorders causing gestational hyperandrogenism.

### Disorders of Gonadal (Ovarian) Development

Rarely, 46,XX DSD can result from abnormalities of gonadal development, which include ovotesticular DSD (true hermaphroditism), testicular DSD (46,XX sex reversal), and gonadal dysgenesis.

#### Ovotesticular Disorder of Sexual Development (True Hermaphroditism)

Ovotesticular DSD previously was called true hermaphroditism.<sup>115</sup> Hermaphroditus, the Greek god with bisexual attributes, was the child of Hermes—the god of athletics, secrets, and occult philosophy—and Aphrodite, the goddess of love. The bisexual theme was immortalized in Greek and Roman sculptures depicting a woman with male external genitalia. Pliny (23–79 A.D.) was the first to apply the term hermaphrodite to humans, offering a description in his massive work, *Historia Naturalis*.

Ovotesticular DSD is a rare condition characterized by mixed ovarian and testicular tissue, which may include bilateral ovotestes or an ovotestis and a contralateral ovary or testis. The disorder is described here because the majority of patients have a 46,XX karyotype. However, because 7% of patients with ovotesticular DSD have a 46,XY karyotype and 10–40% exhibit chromosomal mosaicism,<sup>116</sup> the disorder also must be listed among the causes of 46,XY and sex chromosome disorders of sexual development.

Whereas gonads containing testicular tissue are observed most frequently on the right, normal ovaries are observed most often on the left.<sup>116</sup> Usually, both müllerian and wolffian internal genital structures are present, and as could be predicted, internal genital structures correspond with the adjacent gonad. Whereas most have a vagina, the uterus can be normal and functional, hypoplastic, vestigial, or altogether absent.<sup>116,117</sup> External genital development reflects the level of androgen production and exposure, and the phenotype can range widely, from ambiguous genitalia to isolated hypospadias.

Most are virilized sufficiently to allow male sex assignment, but three-fourths develop gynecomastia and half menstruate after puberty.

The genetics and pathophysiology of ovotesticular DSD are not well established. Mechanisms that might explain the testicular development include the translocation of testis-determining genes from the Y to the X chromosome or an autosome and autosomal dominant mutations that promote testis development in the absence of a Y chromosome.<sup>118</sup> In one individual, the condition has been associated with an inactivating mutation in the RSPO1 gene,<sup>119</sup> which is located on chromosome 1p34.2–3.

## **Testicular Disorder of Sexual Development (46,XX Sex Reversal)**

Testicular DSD is a rare “sex reversal” syndrome in which the chromosomal sex (46,XX) is not consistent with the gonadal sex (testes). The disorder was first described by de la Chapelle in 1964<sup>120</sup> and can be divided into two types, SRY positive and SRY negative. **Approximately 90% of cases result from abnormal recombination between the distal portions of the short arms of the X and Y chromosomes and transfer of SRY from the Y to the X chromosome during male meiosis; in 10% of cases, SRY cannot be detected.**<sup>121</sup> In most SRY-negative patients, the mechanism causing testis development cannot be determined.<sup>121,122,123,124</sup>

Although some patients with SRY-positive testicular DSD have ambiguous genitalia, which may result from preferential inactivation of the SRY-bearing X chromosome,<sup>125</sup> the large majority are sterile males with normal genital development, a normal male hair pattern, and short stature. Consequently, unless they have cryptorchid testes, most are not recognized until after puberty, when they may present with hypogonadism, gynecomastia, and/or infertility.<sup>121</sup> In contrast, SRY-negative XX males usually have ambiguous genitalia and often develop gynecomastia or fail to masculinize fully after puberty.<sup>121,122,123,124</sup> Rarely, they may exhibit occult gonadal mosaicism for SRY.<sup>126</sup> In some, the phenotype has been linked to a duplication of sequences on chromosome 17q, including the SOX9 gene, which acts downstream of SRY in the testis-determining pathway.<sup>32,127</sup> However, in most patients with SRY-negative testicular DSD, the cause remains unclear. In theory, XX male sex reversal might result from an inactivating mutation or deletion in genes encoding factors that inhibit testis development, but there is no direct evidence that they are a cause of testicular DSD.<sup>122</sup>

## **Gonadal Dysgenesis**

Some individuals with primary amenorrhea, hypergonadotropic hypogonadism, and gonadal dysgenesis (streak gonads) have a normal 46,XX karyotype, providing indirect evidence that autosomal genes also play a critical role in ovarian differentiation.

Affected women are normal in stature and, in most cases, have no apparent somatic anomalies. A wide variety of candidate genes have been identified, primarily via experiments involving murine knockout models, including several that encode DNA- and RNA-binding proteins and transcription factors expressed during oogenesis.<sup>128</sup>

## **Androgen Excess—Fetal Origin (Congenital Adrenal Hyperplasia)**

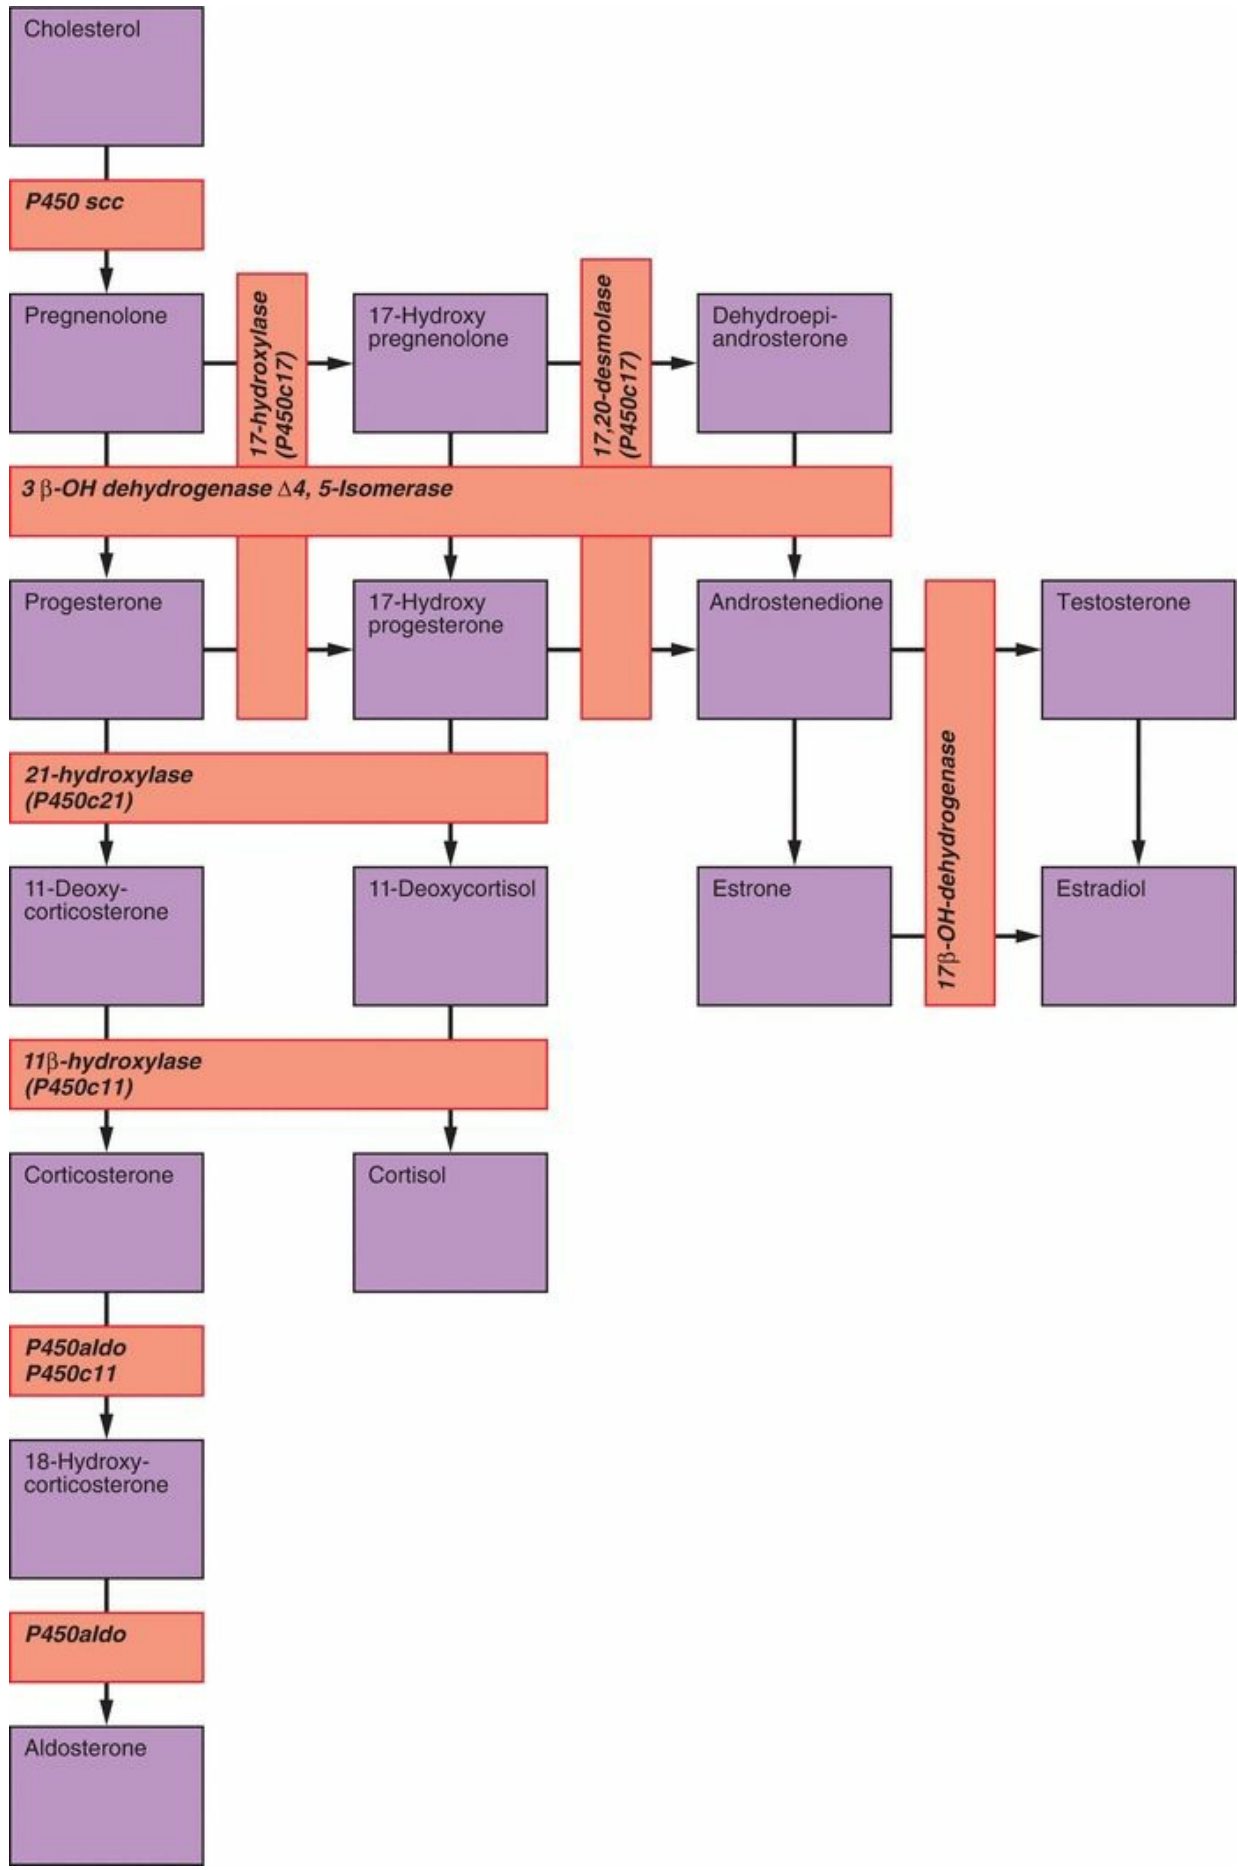

Virilizing CAH is a genetic disorder caused by enzyme defects in adrenal cortisol biosynthesis. More than 90% of cases result from a deficiency in the enzyme 21-hydroxylase.<sup>129,130,131</sup> Deficiencies of 11 $\beta$ -hydroxylase and 3 $\beta$ -HSD are less common causes of CAH. **In all, the pathophysiology relates primarily to decreased cortisol production, which stimulates a compensatory increase in pituitary adrenocorticotrophic hormone (ACTH) secretion, causing adrenal hyperplasia; increased levels of steroid hormones proximal to the enzyme block seek an alternative metabolic pathway, resulting in increased production of androgens.**

In females, the classic forms of CAH (with and without salt wasting) are characterized by genital ambiguity. **Depending on the time, duration, and level of exposure, abnormally high androgen concentrations in utero result in varying degrees of clitoral enlargement and labial fusion and abnormalities of the urethra and vagina; generally, the urethra and vagina share a urogenital sinus that opens at the base of the clitoris.** The fetal adrenal cortex does not achieve a significant level of function before 10 weeks of gestation, and by that time, the vagina and urethra normally have become separated. However, between 10 and 12 weeks, rising androgen levels can promote progressive clitoral enlargement, labial fusion, and even partial closure of the urethra. At birth, the genital anatomy is similar to that in males with hypospadias and bilateral cryptorchidism and can result in incorrect sex assignment. The effects of elevated adrenal androgen levels arising after 12–14 weeks of gestation are more limited. **Female external genital development normally is not completed until approximately 20 weeks of gestation, and the size of the clitoris depends more on the level than on the timing of excess androgen exposure.** Development of the internal genitalia is normal in females with classical CAH because the excess androgen derives from the adrenals and the normal ovaries produce neither AMH nor significant amounts of androgen. **Absent AMH and the high local androgen concentrations required to promote wolffian duct development, the fallopian tubes, uterus, and upper vagina develop normally.**

### **21-Hydroxylase (P450c21) Deficiency**

The enzyme 21-hydroxylase (also designated P450c21 and CYP21A2) mediates the conversion of 17 $\alpha$ -hydroxyprogesterone (17-OHP) to 11-deoxycortisol (the immediate precursor of cortisol) and of progesterone to 11-deoxycorticosterone (an intermediate steroid in aldosterone synthesis). **CAH due to 21-hydroxylase deficiency is the most frequent cause of sexual ambiguity and the most common endocrine cause of neonatal death.** The more serious “salt-wasting” variety of classical 21-hydroxylase deficiency is characterized by severe deficiencies of both cortisol and aldosterone, resulting in salt wasting and dehydration, in addition to virilization. In the less severe “simple virilizing” form of the disorder, elevated levels of ACTH are able to drive sufficient glucocorticoid and mineralocorticoid production to prevent circulatory collapse, but excess androgen production in utero results in masculinization of the external genitalia. The third and least severe “nonclassical” form of 21-hydroxylase deficiency generally does not become apparent until adolescence or early adulthood, when abnormally high androgen levels cause hirsutism and menstrual irregularities.

Data derived from neonatal screening programs for detection of classical CAH indicate that prevalence varies widely with ethnicity. Whereas the overall prevalence is approximately 1 in 15,000 live births,<sup>132</sup> prevalence ranges from 1 in 28,000 Chinese<sup>133</sup> and between 1 in 5,000 and 1 in 23,000 Caucasians,<sup>134,135</sup> to as high as 1 in 280 Yupik Eskimos.<sup>136</sup> In the United States, the prevalence of classical CAH is lower in African Americans (1 in 42,000) than in Caucasians (1 in 15,500).<sup>137</sup> Approximately two-thirds exhibit salt wasting, and one-third has the simple virilizing form of the disorder (**Figure 8.8**).

## FIGURE 8.8

Nonclassical 21-hydroxylase deficiency is one of the most common autosomal recessive diseases, and as in the classical form of the disorder, prevalence varies with ethnicity. Nonclassical 21-hydroxylase deficiency affects between 1 in 100 and 1 in 1,000 Caucasians<sup>136,137,138</sup> and may be even more common among those of Mediterranean, Hispanic, Slavic, and Eastern European Jewish descent.<sup>139</sup> Most affected individuals are not identified in neonatal screening programs because their serum levels of 17-OHP are not sufficiently elevated.<sup>140</sup> Estimates of the carrier frequency (heterozygotes) for nonclassical 21-hydroxylase deficiency generally have ranged between 1 in 60 and 1 in 80 individuals<sup>133,136</sup> but have been as high as 1 in 10 in a European population.<sup>141</sup>

All forms of CAH, including 21-hydroxylase deficiency, are transmitted as autosomal recessive disorders. Humans have two CYP21A genes; one is a nonfunctional pseudogene (CYP21A1, also designated CYP21P, encoding an inactive form of the enzyme), and the other is the active gene (CYP21A2). The two genes have greater than 90% homology and reside in the same region within the HLA histocompatibility complex on the short arm of chromosome 6 (6p21.3), which provides ample opportunity for recombination during meiosis.<sup>142,143,144,145</sup> Most CYP21A2 mutations (approximately 75%) result from nonreciprocal gene conversions in which a segment of the CYP21A1 pseudogene is inserted into the active CYP21A2 gene, altering its sequence and resulting in point mutations that yield a defective enzyme.<sup>144,145,146,147,148</sup> Approximately 20% of CYP21A2 mutations result from unequal crossover exchanges between the two genes, yielding a larger fusion gene that produces an enzyme having reduced or no activity.<sup>134,139,148,149</sup> About 20 gene conversion mutations account for almost all of the affected alleles observed among various ethnic groups.<sup>147,150,151,152,153,154,155,156,157</sup> The remaining 5% of patients with CYP21A2 mutations have 1 or 2 of the more than 60 different point mutations that have been identified.<sup>147,150,151,152</sup>

**Women who carry a classic mutation are at risk for having a child with the severe form of the disorder.** They may be asymptomatic, having one classic mutation and one normal allele, or exhibit the nonclassical form of CAH, having one classic mutation and a variant allele associated with mild enzyme deficiency (compound heterozygote). Compound heterozygotes having two variant alleles can exhibit the features of nonclassical CAH but are not at risk for having a child with classical CAH.

Although phenotype does not reliably predict genotype, the effect of a given mutation generally can be predicted by site-directed mutagenesis and expression and by

analysis of enzyme activity in vitro.<sup>138,147,153,154,155,156,158,159,160,161,162,163,164,165</sup>

- The salt-wasting form of classical 21-hydroxylase deficiency usually is associated with large gene deletions or a mutation that affects splicing and results in no enzyme activity.
- Patients with the simple virilizing form of classical 21-hydroxylase deficiency most often have point mutations that result in low but detectable enzyme activity (e.g., 1–2% of normal) that supports adequate aldosterone and cortisol production.
- Those with the nonclassical form of 21-hydroxylase deficiency usually are compound heterozygotes, having one classic mutation and one variant allele or two variant alleles; the phenotype of compound heterozygotes usually correlates with the less severe of the two mutations.<sup>150</sup>
- Heterozygotes may exhibit biochemical abnormalities but typically have no clinically significant endocrinopathy.<sup>166,167</sup>

**Females with classical 21-hydroxylase deficiency (both salt-wasting and simple virilizing forms) present at birth with ambiguous genitalia (adrenogenital syndrome).**<sup>168,169,170</sup> Boys with salt-wasting CAH typically present as neonates or during early infancy with symptoms of adrenal insufficiency (failure to thrive, dehydration, hyponatremia, hyperkalemia), and those with simple virilizing CAH not identified by neonatal screening generally present as young children with early virilization. **Females with the nonclassical “late-onset” form of 21-hydroxylase deficiency have normal external genitalia and present later, during childhood or early adolescence with precocious puberty, or as young adults with other signs of hyperandrogenism such as hirsutism.**

As discussed earlier in this chapter in reference to the sexual differentiation of the CNS, females with classical CAH tend to exhibit greater interest in male-typical toys and play and more cross-gender and aggressive behavior than do unaffected healthy women.<sup>4,106,107,108,109,110,111</sup> Studies of cognitive function in women with classical CAH have yielded inconsistent results. Whereas some have suggested that such women exhibit lower<sup>171,172</sup> or higher intelligence<sup>173</sup> and differences in verbal learning and memory,<sup>174,175</sup> compared to unaffected women, others have found no evidence to indicate that prenatal androgen exposure has a consistent or predictable effect on cognition in women with CAH.<sup>176</sup>

**Fertility in women with classical CAH is lower than that in normal women,<sup>3,111</sup> primarily due to chronic anovulation relating to excess production of adrenal androgens and progestogens (progesterone, 17-OHP) and disordered patterns of gonadotropin secretion<sup>151</sup>; abnormalities of genital anatomy and psychological**

**factors, such as delayed psychosexual development and decreased sexual activity, also contribute.**<sup>177</sup> In one study of quality of life in women with classical CAH, half reported that their disease adversely affected their sexual life and most were less than satisfied with their genital anatomy and function, regardless whether they had received reconstructive surgery; vaginal stenosis or narrowing were commonly observed.<sup>178</sup> Women with classical CAH also had a later sexual debut and fewer pregnancies and children. Fertility rates correlate with the severity of the disorder and are significantly lower in women with salt wasting than in those with the simple virilizing form of classical CAH.<sup>179</sup> However, outcomes of pregnancies among women with classical CAH who conceive are normal except for an increased incidence of gestational diabetes.<sup>177</sup> Children born to mothers with classical CAH have normal birth weight, have no increased incidence of malformations, and exhibit normal intellectual and social development.<sup>177,180</sup> **Although maternal serum androgen concentrations can increase significantly during pregnancy and should be monitored, the high capacity of placental aromatase activity effectively protects the female fetus from the masculinizing effects of maternal hyperandrogenism.**<sup>180</sup>

Diagnosis of 21-hydroxylase deficiency is based on a high serum concentration of 17-OHP, the primary substrate for the enzyme. **In neonates with either salt-wasting or simple virilizing CAH, 17-OHP levels typically are greater than 3,500 ng/dL**<sup>129,181</sup>; **levels in normal newborns generally are below 100 ng/dL.**<sup>147</sup> To distinguish 21-hydroxylase deficiency from other causes of CAH (11 $\beta$ -hydroxylase and 3 $\beta$ -HSD deficiencies), serum concentrations of 11-deoxycortisol and 17 $\alpha$ -hydroxypregnenolone also should be measured. When the diagnosis is suspected but uncertain, it can be confirmed by performing an ACTH stimulation test, obtaining blood samples before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 1 mg/m<sup>2</sup> or 0.25 mg)<sup>182</sup>; in affected infants, stimulated 17-OHP levels typically exceed 10,000 ng/dL.<sup>168</sup> Diagnosis also can be confirmed by genotyping, which can detect approximately 95% of mutations.<sup>183</sup>

In couples known to be at risk for having an affected child (affected sibling, both partners carriers for a classic mutation), prenatal diagnosis is possible by genotyping amniocytes or, preferably, cells obtained by chorionic villus sampling (CVS).<sup>139,152</sup> Early prenatal diagnosis offers the option for intervention, before the most critical period of fetal genital differentiation, in efforts to avoid severe masculinization of the external genitalia in affected female fetuses.

Neonatal screening programs measure 17-OHP in blood samples dried on filter paper, comparing results to established reference values that vary with weight and gestational age.<sup>184,185</sup> Antenatal corticosteroid treatment can decrease 17-OHP levels

and increase the risk for a false-negative result, particularly when administered repeatedly<sup>186</sup>; screening can be repeated at 1–2 weeks of age, with careful monitoring in the interim, or genotyping can be performed on the dried blood sample.<sup>187</sup>

In the late-onset nonclassical form of 21-hydroxylase deficiency, serum 17-OHP concentrations often are only slightly elevated, especially late in the day, and the serum dehydroepiandrosterone sulfate (DHEA-S) concentration usually is normal. In children, morning values greater than 82 ng/dL suggest the diagnosis, which can be confirmed by performing an ACTH stimulation test. **In adult women, morning values less than 200 ng/dL (obtained during the early follicular phase of the cycle) exclude the diagnosis, levels over 800 ng/dL are virtually diagnostic, and intermediate results require additional evaluation with an ACTH stimulation test; in most patients with nonclassical 21-hydroxylase deficiency, the stimulated 17-OHP level will exceed 1,500 ng/dL.**<sup>139,181,188</sup> A 21-hydroxylase deficiency can be distinguished from 11 $\beta$ -hydroxylase and 3 $\beta$ -HSD deficiencies by also measuring 11-deoxycortisol and 17 $\alpha$ -hydroxypregnenolone, but the distinction in patients with late-onset CAH has little or no clinical relevance and generally is unnecessary.

## 11 $\beta$ -Hydroxylase (P450c11) Deficiency

The enzyme 11 $\beta$ -hydroxylase (also designated P450c11 and CYP11B1) mediates the conversion of 11-deoxycortisol to cortisol and of 11-deoxycorticosterone to corticosterone (an intermediate steroid in aldosterone synthesis). The clinical features of 11 $\beta$ -hydroxylase deficiency result from the excess production of adrenal androgens and the mineralocorticoid action of 11-deoxycorticosterone; 11-deoxycortisol has no significant biologic activity.

Although 11 $\beta$ -hydroxylase deficiency is the second most common cause of CAH, it accounts for only about 5–8% of adrenal steroid enzyme defects.<sup>168,169,189</sup> Like 21-hydroxylase deficiency, 11 $\beta$ -hydroxylase deficiency has severe salt-wasting and simple virilizing forms and a milder late-onset form. In females, 11 $\beta$ -hydroxylase deficiency can result in virilization of the external genitalia, but also may present later, in children with sexual precocity or in adolescent or young women with hirsutism and menstrual irregularity.<sup>190,191,192</sup> In most affected individuals, the disorder has unique clinical features that help to distinguish it from 21-hydroxylase deficiency. **Whereas both 21-hydroxylase deficiency and 11 $\beta$ -hydroxylase deficiency may result in salt wasting, approximately two-thirds of patients with 11 $\beta$ -hydroxylase deficiency exhibit hypertension due to an increased production of mineralocorticoids.**<sup>189,193,194,195</sup> Hypokalemia also may be observed and plasma rennin activity often is low. These effects generally have been attributed to excess production of 11-deoxycorticosterone, which has significant mineralocorticoid activity, although blood pressure and serum 11-

deoxycorticosterone concentrations do not correlate closely.<sup>190,196</sup> The explanation for the wide variation in the clinical manifestations of 11 $\beta$ -hydroxylase deficiency is not clear.

The overall incidence of 11 $\beta$ -hydroxylase deficiency is approximately 1 in 100,000 live births, but like 21-hydroxylase deficiency, incidence varies with ethnicity. In Israel, the incidence of 11 $\beta$ -hydroxylase deficiency is as high as 1 in 5,000 births among Jews of Moroccan ancestry.<sup>197</sup> The enzyme deficiency is an autosomal recessive disorder caused by mutations in the CYP11B1 gene, which is located on the long arm of chromosome 8 (8q21–q22). The known mutations include missense mutations that result in production of an inactive enzyme,<sup>165,198,199,200</sup> frameshift and nonsense mutations that prevent enzyme synthesis,<sup>201,202,203</sup> and others resulting from unequal recombination between the CYP11B1 and CYP11B2 genes.<sup>204,205</sup> The CYP11B2 gene is located in the same region on chromosome 8 and encodes an enzyme having both 11 $\beta$ -hydroxylase and 18-hydroxylase (also designated P450c18 or P450aldo) activity, mediating the conversion of corticosterone to 18-hydroxycorticosterone and, subsequently, aldosterone. There are no specific correlations between genotype and phenotype in patients with 11 $\beta$ -hydroxylase deficiency.<sup>206</sup> Although the late-onset form of 11 $\beta$ -hydroxylase deficiency may be caused by mutations yielding an enzyme with reduced but still significant activity, none has yet been identified.

**Diagnosis of 11 $\beta$ -hydroxylase deficiency is based on demonstrating high serum concentrations of 11-deoxycortisol and 11-deoxycorticosterone, as well as testosterone; both basal and ACTH-stimulated levels generally are elevated in affected neonates.<sup>189,207,208</sup> In adolescents and young adults, basal 11-deoxycortisol and 11-deoxycorticosterone levels may be normal and ACTH stimulation often is required to make the diagnosis; results must be compared to established age and sex-specific normal values.**

### **3 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency**

The enzyme 3 $\beta$ -hydroxysteroid dehydrogenase/D<sup>5</sup>-D<sup>4</sup> isomerase (3 $\beta$ -HSD) catalyzes the oxidation and isomerization of D<sup>5</sup>-3 $\beta$ -hydroxysteroid precursors into D<sup>4</sup>-ketosteroids, an essential step in the formation of all classes of steroid hormones (glucocorticoids, mineralocorticoids, progestogens, androgens, and estrogens). There are two 3 $\beta$ -HSD isoenzymes, designated type I and type II. The type I 3 $\beta$ -HSD gene (HSD3B1) mediates 3 $\beta$ -HSD activity in the placenta and peripheral tissues (skin, breasts, prostate) and the type II 3 $\beta$ -HSD gene (HSD3B2) is active in the adrenal, ovary, and testis. Deficiency of type II 3 $\beta$ -HSD causes an uncommon form of CAH, accounting for less than 5% of cases.<sup>209</sup> The type I isoenzyme is normal in patients with 3 $\beta$ -HSD deficiency.

Consequently, serum concentrations of D<sup>4</sup> steroids, such as 17-OHP and androstenedione, can be normal or even sometimes modestly elevated in affected patients. Serum levels of the substrates for the type I enzyme (pregnenolone, 17 $\alpha$ -hydroxypregnenolone, DHEA) are increased due to the defect in the type II enzyme in the adrenals and gonads.

The clinical presentation of patients with 3 $\beta$ -HSD deficiency varies significantly, but can be divided into salt-wasting and non-salt-wasting forms. The salt-wasting form has been associated with nonsense mutations introducing stop codons,<sup>210</sup> frameshift mutations,<sup>210,211,212</sup> and a variety of point mutations in the HSD3B2 gene.<sup>213,214,215,216,217</sup> Those with the non-salt-wasting form have had missense mutations causing single amino acid substitutions that dramatically decrease the enzyme's affinity for substrates or cofactors.<sup>217,218,219,220</sup>

**The external genitalia of females with 3 $\beta$ -HSD deficiency can be mildly virilized, presumably because DHEA levels are high and some is converted to androstenedione and, subsequently, to testosterone in the periphery.** Whereas the salt-wasting form of classical 3 $\beta$ -HSD deficiency (analogous to those of 21-hydroxylase and 11 $\beta$ -hydroxylase deficiencies) usually is diagnosed during the first few months of life, the non-salt-wasting form of the disorder generally presents later. In females, because the external genitalia often are normal at birth, diagnosis of the non-salt-wasting form of 3 $\beta$ -HSD deficiency typically is delayed, presenting in childhood with premature pubarche or in young women with signs of hyperandrogenism.<sup>209</sup>

Although basal levels of D<sup>5</sup>-3 $\beta$ -hydroxy steroids (pregnenolone, 17 $\alpha$ -hydroxypregnenolone, DHEA, and DHEA-S) generally are elevated in affected individuals, an increased ratio of D<sup>5</sup>/D<sup>4</sup> steroids is a better indication of a possible 3 $\beta$ -HSD deficiency. **The most reliable diagnostic criterion is the serum 17 $\alpha$ -hydroxypregnenolone concentration after ACTH stimulation.** Proposed threshold values are based on observations in patients with documented mutations (neonates,  $\geq 12,600$  ng/dL; Tanner stage I children  $\geq 5,490$  ng/dL, children with premature pubarche,  $\geq 9,790$  ng/dL; adults  $\geq 9,620$  ng/dL). Some have argued that many women with a clinical diagnosis of polycystic ovary syndrome actually may have a late-onset form of 3 $\beta$ -HSD deficiency that may be as or more common than the late-onset form of 21-hydroxylase deficiency.<sup>221</sup> An exaggerated 17 $\alpha$ -hydroxypregnenolone response to ACTH stimulation is relatively common in women with hyperandrogenism, but levels rarely approach those observed in women with proven mutations, suggesting that the response likely reflects only adrenal hyperactivity and not an enzyme deficiency.<sup>222</sup> Furthermore, molecular studies have only rarely identified any mutations in HSD3B2 in patients suspected of having a mild form of 3 $\beta$ -HSD deficiency.<sup>223,224,225</sup>

## Treatment of Congenital Adrenal Hyperplasia

Treatment for classical forms of CAH is aimed at providing sufficient amounts of the deficient hormone, cortisol, to reduce excessive ACTH secretion and to prevent the consequences of excessive androgen production. In mothers at risk for having an affected child, treatment can reduce or prevent masculinization of a female fetus. In neonates with classical CAH, treatment can be lifesaving and prevents further virilization. In children, treatment permits normal growth and sexual maturation. In adults with classical or nonclassical CAH, treatment helps in the management of hirsutism, menstrual abnormalities, and infertility.

## Preimplantation Genetic Diagnosis in Couples at Risk for Having an Affected Child

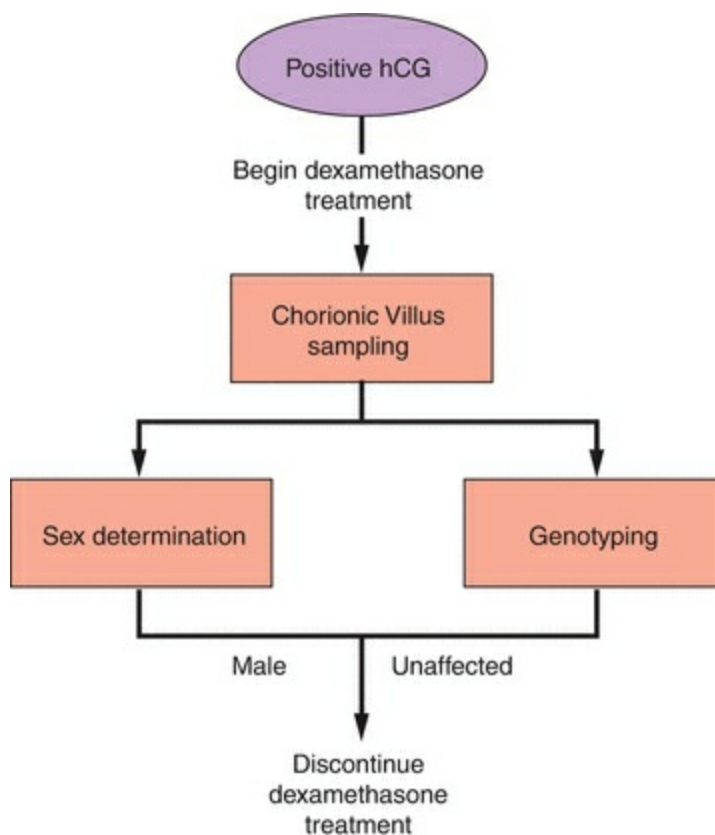

Polymerase chain reaction (PCR)-based genotyping has greatly improved genetic counseling of families with CAH. In couples at risk for conceiving an affected child, the technology also can be applied in preimplantation genetic testing for monogenic disorders (PGT-M, previously called preimplantation genetic diagnosis [PGD]) to detect affected embryos resulting from in vitro fertilization (IVF).<sup>226,227</sup> Previously, this technique was performed by removing a single cell from each embryo reaching the 6–8 cell stage on the 3rd day after oocyte retrieval and fertilization by intracytoplasmic sperm injection (ICSI), with transfer of an unaffected embryo(s) 2 days later at the blastocyst stage. However, following developments in blastocyst culture, day 5 trophoblast biopsy has become the preferred technique.<sup>228</sup> Although PGT-M requires IVF that otherwise would be unnecessary in fertile couples, some may prefer this option over others based on early prenatal diagnosis, as described below.

## Prenatal Treatment of Mothers at Risk for Having an Affected Child

Prenatal maternal treatment with dexamethasone (up to 1.5 mg daily in divided doses) can greatly decrease or prevent fetal female genital virilization.<sup>229</sup> Dexamethasone is not metabolized by the placenta and crosses effectively into the fetal circulation. **For maximum effectiveness, treatment should begin at 4–5 weeks of gestation and not later than 9 weeks.**<sup>148,229,230,231,232</sup> Prenatal maternal treatment poses some potential risks for the fetus, such as postnatal failure to thrive and psychomotor developmental delay, and also can have significant maternal side effects, including severe abdominal striae, hyperglycemia, hypertension, gastrointestinal symptoms, and emotional lability.<sup>232,233</sup>

**Given that only one in eight fetuses will benefit from maternal treatment (one in four affected, half of which will be males), the best approach involves early**

**prenatal diagnosis by CVS with rapid sex determination and genotyping, continuing or beginning treatment only in those mothers having an affected female fetus.** However, because even short-term prenatal treatment with dexamethasone may adversely affect postnatal physical, cognitive, and emotional development, careful pretreatment counseling, monitoring, and long-term follow-up are required and best provided in a research setting<sup>234,235</sup> (**Figure 8.9**).

**FIGURE 8.9**

## Neonatal Treatment

Newborn infants with classical CAH may be identified by prenatal diagnosis or neonatal screening or because they have genital ambiguity (females) or an adrenal crisis (males). Infants who exhibit signs of adrenal crisis (hypotension, hyponatremia, hyperkalemia, hypoglycemia, vomiting and diarrhea, weight loss, anorexia) require urgent medical treatment, focusing first on administration of fluids (10–20 mL/kg 0.9% saline) and correction of any significant hypoglycemia (2–4 mg/kg 10% dextrose); hyperkalemia should be corrected by administering glucose and insulin, if necessary. After a blood sample is obtained for measurement of steroid hormones (17-OHP primarily), a stress dose of hydrocortisone should be administered (50–100 mg/m<sup>2</sup>

intravenously, typically 25 mg), followed by 50–100 mg/m<sup>2</sup> daily in divided doses (every 4 hours). Additional stress doses of hydrocortisone are administered until the infant is stable and feeding normally. Immediate mineralocorticoid replacement is not necessary but will be required if a diagnosis of salt-wasting CAH is confirmed. Initially, doses of fludrocortisone up to 0.3 mg daily and sodium chloride supplementation (1–3 g daily; 17–51 mEq daily) are required.

In infants having a positive neonatal screening test for CAH, the diagnosis should be confirmed with a second blood sample for measurement of 17-OHP and electrolytes. While awaiting the results, electrolytes should be monitored closely if the infant is not treated empirically with glucocorticoids and mineralocorticoids. **Again, the urgent need is to identify infants with salt-wasting CAH before they develop adrenal crisis, which can occur anytime within the first few days or weeks after birth without treatment.**<sup>147,229</sup>

## Treatment in Children

Ideally, the medical, surgical, and psychological management of children with CAH should be guided by a multidisciplinary team, including pediatric endocrinologists, surgeons, urologists, geneticists, and psychologists.<sup>229</sup>

Children with classical or symptomatic nonclassical 21-hydroxylase deficiency require treatment with glucocorticoids.<sup>147,229,236</sup> **The goal of treatment is to promote normal growth and development by providing sufficient hormone to minimize adrenal sex steroid production while avoiding the consequences of glucocorticoid excess. Usually, that can be achieved by treatment with hydrocortisone (cortisol) in a dose of 12–18 mg/m<sup>2</sup> daily,**<sup>139,229,236</sup> which still exceeds normal daily cortisol secretion in children and adolescents (6–9 mg/m<sup>2</sup>/day).<sup>237,238,239</sup> Whereas long-acting glucocorticoids (e.g., prednisone, dexamethasone) also can be used, their longer duration of action and greater potency also increase the risk of overtreatment, which can adversely affect growth before closure of the epiphyses.<sup>148,240,241</sup> Normal growth has been observed in some studies of children treated with prednisone (approximately 1 mg/m<sup>2</sup>/day)<sup>242</sup> or dexamethasone (approximately 0.27 mg/m<sup>2</sup>/day),<sup>243</sup> but hydrocortisone remains the treatment of choice during childhood.<sup>229,236</sup>

**Mineralocorticoid treatment with fludrocortisone is required for children having classical 21-hydroxylase deficiency,** regardless whether they have the salt-wasting or simple virilizing form of the disorder. The goal of treatment is to maintain normal serum sodium and potassium concentrations while avoiding the consequences of overtreatment or undertreatment. Excessive mineralocorticoid treatment can cause hypertension and hypokalemia and may impair growth.<sup>244</sup> Inadequate treatment can

result in poor growth because it increases the glucocorticoid requirement<sup>244,245</sup> and may increase adrenal androgen production, because chronic volume depletion causes increased production of renin and angiotensin II, which can stimulate steroidogenesis.<sup>246</sup> In children, fludrocortisone is administered in a dose ranging between 0.05 and 0.2 mg daily.<sup>229</sup> Salt supplementation can be discontinued as the child begins to eat table food, but may be needed during hot weather or strenuous exercise.

The effectiveness of treatment generally should be monitored approximately every 3 months in infants and every 4–12 months in children,<sup>229</sup> by measuring the serum concentrations of 17-OHP, androstenedione, plasma rennin activity, growth velocity, and skeletal maturation, comparing results to normative data for age and sexual maturation.<sup>139</sup> Ideally, serum hormone measurements should be obtained in the morning when results will reflect peak concentrations.<sup>147,229,236</sup> **Serum 17-OHP levels generally should be maintained in a range between 400 and 1,200 ng/dL, but care must be taken to avoid undertreatment of hyperandrogenism and the consequences of iatrogenic hypercortisolism.**<sup>247</sup> Plasma rennin activity should be kept within the normal range for age by adjusting treatment with fludrocortisone and salt supplementation, before adjusting the level of glucocorticoid treatment. When necessary, a brief 7–10-day course of treatment with dexamethasone can effectively suppress high androstenedione levels that may result from poor compliance. Bone age and growth rate should be monitored every 6 months, with the goal of avoiding a decrease in growth and advanced bone age.<sup>248,249</sup> Patients with classical CAH have an increased risk for developing central precocious puberty due to poor control of adrenal androgen production; in those who do, treatment with a long-acting GnRH agonist may be needed.<sup>250</sup>

**Illness can precipitate adrenal crisis in children with classical CAH unless they receive adequate glucocorticoid treatment.** Signs and symptoms suggesting the possibility include hypotension, electrolyte imbalance (hyponatremia, hyperkalemia, hypoglycemia), and vomiting and diarrhea that sometimes can be accompanied by abdominal pain, fever, loss of appetite, and weight loss. In children with mild illness, the maintenance dose of glucocorticoid generally should be increased by two- to threefold. When illness is associated with diarrhea or vomiting and reduced oral intake, intravenous glucocorticoids, saline, and glucose may be required. In children with severe illness or who require major surgery, intravenous hydrocortisone should be administered in a dose appropriate for age; for those 12 years of age or older, a one-time dose of 100 mg should be administered, followed by 100 mg/day. During recovery, stress doses of hydrocortisone can be gradually decreased, by approximately 50% per day.<sup>229</sup>

**Children with classical CAH are at increased risk for early puberty and short stature because high levels of sex steroids promote premature epiphyseal closure.** In treated patients with classical CAH, adult height usually is lower than in reference populations, by an average of approximately 10 cm, independent of the level of control of adrenal androgen concentrations, which suggests that treatment with exogenous glucocorticoids also suppresses growth.<sup>251,252</sup> The effectiveness of treatment during the first 2 years of life and during puberty appears to have the most important influence on final height.<sup>253,254,255</sup> Treatment with growth hormone and a long-acting GnRH agonist can help to maximize growth and adult height.<sup>256,257</sup> Obesity is a common complication of glucocorticoid treatment in children with classical CAH; body mass index correlates with the dose of prescribed medication.<sup>258</sup> In obese children, the incidence of hypertension also is increased.<sup>259</sup>

The surgical management of the genital abnormalities in virilized female children with classical CAH is quite complicated. Traditionally, surgery has been performed in the first few years of life, when the child is still too young to remember the procedure, to avoid any psychological problems associated with having abnormal external genitalia. **However, the wisdom and outcomes achieved with early surgery recently have been challenged, and many now advocate delaying unnecessary surgery until the child is older and can participate in the decision.**<sup>115</sup> The controversy is discussed in a later section of this chapter devoted to the management of ambiguous genitalia. If clitoroplasty is performed, the clitoral recession procedure, conserving the glans and its innervation, should be employed. It is important to know that women who undergo clitoroplasty and even total clitoral amputation generally do not have an impaired erotic response or decreased capacity for orgasm. When necessary, vaginal reconstruction is best postponed until after puberty when mature compliance is possible. In patients with severe classical CAH, bilateral adrenalectomy offers the potential advantage of preventing adrenal hyperandrogenism, but also increases the risk for developing adrenal crisis.<sup>260,261,262</sup>

## Treatment in Adults

For older adolescent and adult women with classical CAH, the goal of treatment is to lower and maintain serum concentrations of adrenal precursors (17-OHP) and androgens to the upper limits for normal women. **After epiphyseal closure is complete, treatment with long-acting glucocorticoids (e.g., dexamethasone, prednisone) generally is preferred.** When administered at bedtime in a dose ranging between 0.25 and 0.75 mg, ACTH is effectively suppressed for most or all of the following day. Bedtime treatment effectively inhibits the peak of ACTH secretion, which occurs between 2:00 A.M. and 10:00 A.M.<sup>240</sup> **To avoid the risks of osteoporosis and**

**developing Cushing syndrome, dosage must be adjusted to the needs of the individual patient.** Alternative treatment regimens include prednisone (median dose 7 mg/day; range 4–10 mg/day) or single or divided doses of hydrocortisone (median 30 mg/day; range 15–40 mg/day).<sup>263</sup> Supplemental doses of glucocorticoid, generally involving a two- to threefold increase in the usual daily dose, are indicated during times of stress such as febrile illness, surgery, and trauma; normal exercise does not require stress doses of glucocorticoids.<sup>236</sup>

**As in children with classical CAH, mineralocorticoid treatment in adults is provided with fludrocortisone,** in the dose required to maintain normal serum sodium and potassium concentrations and plasma renin activity, usually ranging between 0.1 and 0.2 mg/day. When mineralocorticoid treatment is optimized, the dose of glucocorticoids can be minimized.<sup>244,245</sup> Inadequate treatment can result in chronic volume depletion that promotes excess production of renin and angiotensin II, which, in turn, can stimulate increased adrenal androgen synthesis.<sup>246</sup> Patients with the simple virilizing form of classical CAH who exhibit increased plasma renin activity and aldosterone concentrations can benefit from mineralocorticoid treatment, which helps in controlling 17-OHP levels.<sup>264,265</sup>

**Treatment should be monitored by periodic measurements of bone density, and serum 17-OHP, DHEA-S, androstenedione, and testosterone concentrations, remaining alert to the development of signs or symptoms of Cushing syndrome. In those who require mineralocorticoid treatment, plasma renin activity should be monitored and maintained near the upper limit of normal.**

Many women with classical CAH who underwent reconstructive surgery during childhood later require further reconstructive surgery during late adolescence or early adulthood, generally involving clitoroplasty and vaginoplasty. Approximately half of procedures performed during infancy will require later revision.<sup>139,266</sup>

Psychological counseling, ideally beginning soon after the diagnosis is established, is an important part of the treatment of classical CAH. Although data are limited and conflicting, the incidence of adult psychiatric disorders may be increased in women with classical CAH.<sup>267,268</sup> Sexual relationships may develop somewhat later than usual and sexual function may not be completely normal, even in those having had reconstructive surgery.<sup>5</sup>

## **Treatment During Pregnancy**

Although normal reproduction is possible with effective treatment, fertility generally is decreased in women with classical CAH, particularly in those with the salt-wasting variety of the disorder, due to chronic anovulation and, in some cases, due to poor

surgical results.<sup>3</sup> **In those who do conceive, serum concentrations of androstenedione, testosterone, and 17-OHP should be carefully monitored and the dosage of glucocorticoids increased as needed to maintain normal levels for gestational age. Treatment with long-acting glucocorticoids should be discontinued in favor of treatment with hydrocortisone, which is metabolized by the placenta and thereby avoids the risk of suppressing the fetal hypothalamic-pituitary-adrenal axis.** In general, term pregnancies, delivery of healthy female infants with normal external genitalia, and normal growth and development in both girls and boys can be achieved.<sup>180,269</sup> Even when maternal androgen levels cannot be suppressed to normal, the high capacity of placental aromatase activity effectively protects the fetal female genitalia.<sup>180</sup>

The incidence of cesarean delivery is increased, primarily because of concerns that vaginal delivery may disrupt a previous surgical reconstruction of perineal anatomy. An android pelvis is no more common than usual, because the form and size of the adult pelvis are determined during the pubertal growth spurt. However, a small pelvis might result if bone age is advanced to age 13–14 before treatment started. **The need for stress doses of glucocorticoids during labor and delivery is obvious and does not increase the risk for infection or poor wound healing.**

## **Androgen Excess—Fetoplacental Origin**

Two rare enzyme deficiencies associated with androgen excess—aromatase deficiency and P450 oxidoreductase deficiency—are distinct from those causing classical forms of CAH because they involve both the fetal adrenal and the placenta.

### **Aromatase (P450arom) Deficiency**

The enzyme aromatase (also designated P450arom and CYP19A1) catalyzes the conversion of 19-carbon androgens (androstenedione, testosterone, 16 $\alpha$ -hydroxy DHEA) to aromatic 18-carbon estrogens (estrone, estradiol, and estriol, respectively) and is encoded by the CYP19A1 gene, located on chromosome 15 (15p21.1). The enzyme is active in the gonads, the placenta, the brain, and in adipose; tissue-specific regulation is controlled, in part, by alternative tissue-specific promoters. Aromatase deficiency is a rare autosomal recessive disorder caused by mutations in the CYP19A1 gene. As a consequence, fetal androgens are not converted to estrogens in the placenta, resulting in female fetal virilization (due to the accumulation of fetal androgens), low maternal serum estrogen levels, and maternal hirsutism, which typically develops during the second half of pregnancy and regresses after delivery. **Affected females classically present with ambiguous genitalia at birth and, at puberty, exhibit signs of hyperandrogenism, absent breast development, primary amenorrhea associated**

**with hypergonadotropic hypogonadism, and multicystic ovaries.**<sup>270,271,272,273</sup>  
Aromatase mutations also can produce variable or nonclassic phenotypes characterized by varying degrees of breast development.<sup>274</sup>

## **P450 Oxidoreductase Deficiency**

The classical forms of CAH all are caused by mutations in genes encoding steroidogenic enzymes, resulting in reduced or absent enzyme activity, and in clinical signs and symptoms caused by the accumulation of steroid precursors and/or decreased production of the principal steroid end product. Another newly described form of CAH results from a deficiency in the P450 oxidoreductase (POR) enzyme. Although not a steroidogenic enzyme per se, POR nonetheless affects several steroidogenic pathways and now is recognized as a cause of both 46,XX DSD (female virilization) and 46,XY DSD (incomplete male virilization), which is discussed below.<sup>275</sup>

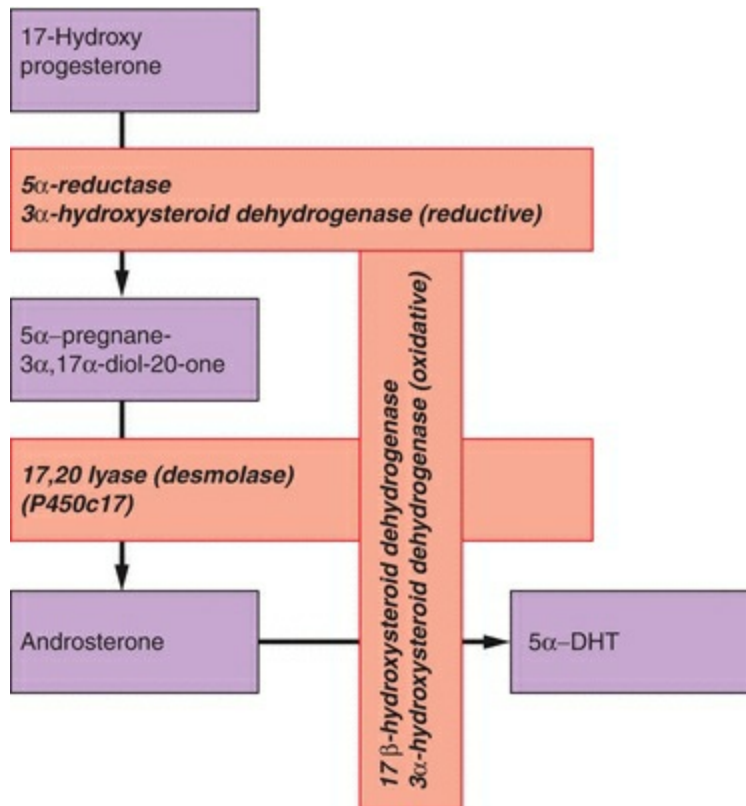

First described in 2004,<sup>276</sup> POR deficiency is perhaps the most complex form of CAH because it affects the activity of all of the P450 enzymes involved in steroidogenesis, to varying degrees, resulting in varying patterns of abnormal steroid hormone production and a spectrum of clinical manifestations, and has other “nonendocrine” effects on skeletal development and drug metabolism. POR is a flavoprotein associated with the endoplasmic reticulum and is encoded by the POR gene, located on chromosome 7 (7q11.2). POR serves as the electron donor in the activation of all microsomal P450 enzymes, including P450c21 (the adrenal 21-hydroxylase, CYP21A2), P450c17 (CYP17A1, which catalyzes both 17 $\alpha$ -hydroxylase and 17,20-lyase activities), and P450arom (aromatase, CYP19A1, which mediates the conversion of androgens to estrogens). POR deficiency is an autosomal recessive disorder and more than 25 different POR mutations already have been identified, most being missense mutations in the central electron transfer domain of the protein.<sup>275,277</sup>

Patients with the same mutation, even siblings, can exhibit phenotypic differences, but the hormonal profile of all patients with POR mutations reflects partial deficiencies of 21-hydroxylase and 17 $\alpha$ -hydroxylase/17,20-lyase. Because 21-hydroxylase and 17,20-lyase activities are impaired to a greater degree than 17 $\alpha$ -hydroxylase activity, basal serum 17-OHP concentrations are elevated and exhibit an exaggerated response to ACTH stimulation (due to impaired 21-hydroxylase activity), and levels of DHEA/DHEA-S and androstenedione are low (due to impaired 17,20-lyase activity). Basal cortisol levels usually are normal or near normal, but do not rise normally with ACTH stimulation, revealing a chronically compensated adrenal insufficiency<sup>275</sup> (Table 8.2).

**TABLE 8.2 Hormone Profile Associated with P450  
Oxidoreductase Deficiency**

Hormone	Basal Level	ACTH-stimulated Response
17-OHP	High	Exaggerated
DHEA/DHEA-S	Low	Low
Androstenedione	Low	Low
Cortisol	Normal	Low

Surprisingly, females with POR deficiency frequently become virilized in utero, something not expected, given that fetal adrenal androgen production should be decreased, not increased. There are two hypotheses concerning the source of androgen excess that might explain the apparent dichotomy, but neither has been established conclusively.<sup>278,279,280</sup> The first envisions that even the modest amount of androgens produced could accumulate due to the deficiency of placental P450arom in patients with POR deficiency. The second invokes an alternative “backdoor pathway” to androgen production in which elevated levels of 17-OHP, which cannot be efficiently metabolized via P450c21 or P450c17 activities, seek alternative metabolism via 5 $\alpha$ -reduction and ultimately are converted to DHT, circumventing the usual pathway via androstenedione and testosterone (“Backdoor pathway” of androgen production is shown in **Figure 8.10**).<sup>279,280,281</sup> Although the backdoor pathway still involves P450c17, the enzyme’s affinity for its substrate in the alternative pathway (5 $\alpha$ -pregnane-3 $\alpha$ , 17 $\alpha$ -diol-20-one) is much higher than for 17-OHP. Therefore, the backdoor pathway likely functions better than the conventional metabolic pathway in patients with POR deficiency.<sup>281</sup>

**FIGURE 8.10**

The phenotype of POR deficiency varies widely. Whereas some exhibit a characteristic spectrum of skeletal abnormalities known as the Antley-Bixler syndrome (craniosynostosis, midface hypoplasia, choanal atresia or stenosis, radiohumeral and/or radioulnar synostosis, femoral bowing and fractures, and joint contractures), indistinguishable from that observed in patients with mutations in the fibroblast growth factor receptor-2 gene (FGFR2), bony abnormalities are subtle or altogether absent in others.<sup>275</sup> The phenotypic spectrum in patients with proven POR deficiency has included asymptomatic patients identified by neonatal screening for 21-hydroxylase deficiency, asymptomatic patients whose mothers virilized during pregnancy, virilized female infants, and an adult female with primary amenorrhea and multicystic ovaries.<sup>276,278,281,282</sup> The widely varying phenotype has led to speculation that POR deficiency may be relatively common and frequently goes unrecognized or is misdiagnosed.

Diagnosis of POR deficiency is not straightforward. The diagnosis should be considered in the evaluation of children with sexual ambiguity and when prenatal screening for trisomy 21 reveals low maternal estriol levels. Mutation analysis is indicated for patients who exhibit compatible steroid hormone profiles.

## **Androgen Excess—Maternal Origin (Gestational Hyperandrogenism)**

Maternal gestational hyperandrogenism is another, albeit very uncommon, cause of fetal virilization and may result from maternal ingestion of androgens or drugs having androgenic actions or from excess maternal androgen production. The possibility should be considered when a pregnant woman exhibits a rapid onset of masculinizing signs, including hirsutism, temporal balding, clitoromegaly, and deepening of the voice. It also should be considered after delivery of a virilized female infant, remembering that luteomas and theca-lutein cysts regress after delivery.

**The possible or probable extent of fetal virilization relates to the time of exposure to maternal androgens. Whereas exposure during early pregnancy can cause labioscrotal fusion and clitoromegaly, exposure after 12 weeks of gestation causes only clitoral hypertrophy.**

### **Drug Ingestion**

Most cases of female fetal virilization resulting from maternal drug ingestion have involved treatment with danazol for endometriosis<sup>283</sup> or with progestins for threatened or recurrent abortion.<sup>284,285</sup> **The risk appears limited to progestins that bind to the androgen receptor.**<sup>286</sup> Given their potential risks, progestational agents other than progesterone or 17-hydroxyprogesterone are no longer administered to pregnant women. **However, virilization of female infants has not been observed in women exposed to oral contraceptives after conception.**<sup>287</sup> Maternal ingestion of androgens also can cause fetal virilization, but often does not, probably because fetal exposure is limited by the high capacity of placental aromatase activity.

### **Excess Androgen Production**

Women who develop gestational hyperandrogenism merit a thorough evaluation.<sup>288</sup> Luteomas and theca-lutein cysts are the most common causes; virilizing ovarian or adrenal tumors are rarely encountered during pregnancy.<sup>289,290,291,292,293,294,295</sup> However, all diagnostic possibilities warrant consideration.

Pelvic ultrasonography is helpful for distinguishing between adrenal and ovarian tumors, solid and cystic ovarian masses, and unilateral from bilateral ovarian disease. Approximately one-half of luteomas and almost all theca-lutein cysts are bilateral<sup>296</sup>; other ovarian tumors usually are unilateral. Malignant tumors are most likely to be solid and unilateral. Serum hormone measurements have limited diagnostic value, given that maternal serum testosterone concentrations normally rise progressively during

pregnancy, primarily due to the marked increase in sex hormone-binding globulin (SHBG) levels. **Surgery is rarely needed for women with luteomas or theca-lutein cysts because both characteristically regress after delivery.** However, when a tumor is highly suspected and cannot be excluded, laparoscopy or laparotomy may be required to establish the correct diagnosis.

## Pregnancy Luteoma

Pregnancy luteomas are hyperplastic masses of luteinized cells and not true tumors. Their true incidence is unknown and most likely go unrecognized because they produce little androgen or have little or no significant androgenic effect. Luteomas may be discovered incidentally at the time of cesarean delivery or other abdominal surgery during pregnancy or the early puerperium or when they are large or cause maternal virilization. Typically, luteomas are solid masses ranging between 6 and 10 cm in size; in approximately half of cases, they are bilateral.<sup>297,298</sup>

In women with luteomas, serum concentrations of androstenedione, testosterone, and DH are increased, sometimes dramatically.<sup>288,297,299</sup> However, only approximately one-third of reported pregnancy luteomas have been associated with maternal hirsutism or virilization,<sup>288,300</sup> probably because any increase in serum free testosterone is limited by the large increase in SHBG levels that occurs during pregnancy. **There is essentially no risk that the female fetus of a woman with a luteoma will become virilized if the mother herself does not.** However, approximately 80% of female infants born to virilized mothers also are virilized, to an extent that correlates with the severity, duration, and, most importantly, the stage of pregnancy at the time of androgen exposure.<sup>301,302</sup>

The typically prompt regression of luteomas after delivery suggests that hCG may play some role in stimulating or perpetuating androgen production in luteomas.<sup>303</sup> However, most luteomas are identified late in gestation, long after the peak in maternal serum hCG concentrations. Moreover, theca-lutein cysts, rather than luteomas, are more commonly associated with excessively high hCG levels, as observed in women with gestational trophoblastic disease. Consequently, it seems likely that some other mechanism is responsible for the growth and androgen production of luteomas in late gestation.

## Theca-Lutein Cysts

Clinically apparent theca-lutein cysts, also known as hyperreactio luteinalis, develop most frequently in women with multiple pregnancies, isoimmunized mothers, those with molar pregnancies or gestational trophoblastic disease, and women with diabetes mellitus, all of which are associated with increased maternal serum hCG

concentrations; the highest incidence (10–20%) is observed in women with trophoblastic disease.<sup>304</sup> However, not all women with such conditions develop theca-lutein cysts, which also may persist long after evacuation of molar pregnancies despite the rapid decrease in serum hCG levels.<sup>304,305,306</sup> Rarely, mothers with pre-existing hirsutism related to polycystic ovary syndrome or ovarian stromal hyperthecosis may develop theca-lutein cysts and gestational hyperandrogenism.<sup>307,308</sup>

Ovaries containing theca-lutein cysts can become quite enlarged, reaching 10–15 cm in diameter. Histologically, the ovarian cortex usually exhibits focal hyalinization. **Approximately 30% of pregnant women with clinically apparent theca-lutein cysts become hirsute or virilize.**<sup>288,309,310,311</sup> In most of those who exhibit virilization, serum concentrations of testosterone and androstenedione are elevated; cord serum testosterone levels also may be elevated in their infants,<sup>309,310,312,313</sup> but no cases of virilized female infants have been reported.

## Other Disorders of Genital Development

There is a last group of 46,XX DSD that cannot yet be classified by cause, because their causes are unknown. The category includes cloacal exstrophy, müllerian agenesis, and the syndrome of müllerian, renal, and cervicothoracic somite dysplasia known as the MURCS association.

### Cloacal Exstrophy

Cloacal exstrophy is a rare and complex anorectal and genitourinary malformation in which the rectum, vagina, and urinary tract share a common everted orifice, accompanied by an omphalocele, and an imperforate anus. Typically, the bladder and genitalia are divided into two halves on either side of an exposed segment of bowel; a number of variants have been described.<sup>314</sup> The disorder is believed to result from the failed migration of the lateral mesodermal folds of the infraumbilical anterior abdominal wall, leading to an enlarged cloacal membrane that ruptures prematurely, before descent of the urorectal septum, sometime prior to 8 weeks of gestation.<sup>314,315</sup>

### Müllerian Agenesis (Mayer-Rokitansky-Küster-Hauser Syndrome)

**Müllerian agenesis is a disorder of genital development characterized by absence of the vagina, an absent or hypoplastic uterus, and normal or hypoplastic fallopian tubes.**<sup>316</sup> The disorder is a relatively common cause of primary amenorrhea and is described in detail in [Chapter 10](#) (Amenorrhea). Typically, the ovaries are entirely normal, although one or both also may be undescended, hypoplastic, or associated with an inguinal hernia. Affected patients often also have urologic anomalies (unilateral renal

agenesis, ectopic or horseshoe kidney, and duplication of the collecting systems) and skeletal malformations (e.g., hemiverterbrae and scoliosis or the Klippel-Feil syndrome, which includes a short neck, low hairline, limited range of motion, and neurologic symptoms, resulting from one or more fused vertebrae).<sup>317,318</sup> The cause is unknown, although some cases are associated with chromosomal translocations or occur in familial aggregates, suggesting a genetic basis. Logically, müllerian agenesis might be attributed to an activating mutation in the gene encoding AMH or its receptor, causing excess AMH activity, but none have been identified.<sup>319</sup>

**Patients with müllerian agenesis typically present in late adolescence or as young adults with primary amenorrhea, exhibiting normal breast and pubic hair development and no visible vagina.** A few may have functional islands of endometrium, resulting in obstructed menses and symptoms of cyclic pain.<sup>317,318</sup> Evaluation should include a karyotype, renal ultrasonography, spinal x-rays, and pelvic ultrasonography or MRI when there is reason to suspect a functional uterine remnant.<sup>320,321</sup> Surgery generally is indicated only for those with symptoms relating to hematometra, endometriosis, or an inguinal hernia. When the time is appropriate, a functional vagina can be created by progressive vaginal dilation,<sup>322,323,324</sup> traditional vaginoplasty,<sup>325</sup> or the modified Vecchiotti operation, which is performed laparoscopically.<sup>326,327</sup> Women with müllerian agenesis are infertile but can expect normal sexual function and have their own genetic offspring via IVF using oocytes retrieved from their own normal ovaries and their partner's sperms, with subsequent transfer of embryos to a gestational surrogate.<sup>328,329</sup> While still experimental, uterine transplantation has become an option for patients with MRKH to carry their own pregnancy since the first report of successful live birth following uterine transplant in 2015.<sup>330</sup> To date, approximately 40 live and deceased donor uterine transplants have been performed with numerous live births using IVF. Additional optimization is ongoing with use of utero-ovarian vein pedicles in live donor procedures and minimizing cold ischemia time in deceased donors. Consequently, uterine transplantation is likely to become a more prevalent and accepted treatment.<sup>331</sup>

## **Müllerian Renal Cervicothoracic Somite Dysplasia (The MURCS Association)**

The MURCS association is a syndrome characterized by müllerian (MU) aplasia or hypoplasia, unilateral renal (R) agenesis or ectopy and cervicothoracic somite (CS) dysplasia, which results in vertebral defects (e.g., Klippel-Feil anomaly, scoliosis), and abnormalities of the ribs, upper limbs, and scapula.<sup>332</sup> Other associated anomalies have included cleft lip and palate, ovarian agenesis, abnormal pulmonary fissures, tetralogy

of Fallot, anorectal malformations, and transmissive deafness.<sup>333,334,335,336</sup> The pathophysiology involved is unclear but logically may involve an event occurring very early in development when the blastemas of the pronephric buds and cervicothoracic buds are closely located. The disorder has similarities to the 22q11 deletion syndrome (aortic arch anomalies, facial deformities, nasal voice, mild learning difficulties, renal agenesis, autoimmune disease, and cervical spine anomalies) and to the Mayer-Rokitansky-Küster-Hauser syndrome, suggesting a similar pathophysiology.<sup>332,337</sup>

# 46,XY Disorders of Sexual Development

DSD occurring in chromosomal males (46,XY) can result from abnormalities in gonadal development, from decreased fetal androgen synthesis relating to deficiencies of steroidogenic enzymes or regulatory proteins, from androgen receptor defects that prevent normal androgen action, from LH receptor defects causing Leydig cell hypoplasia, or from mutations affecting AMH or its receptor.

## Disorders of Gonadal (Testicular) Development

Normal gonadal development requires normal germ cells and normal gonadal somatic cells. Disorders of testicular development include complete gonadal dysgenesis (Swyer syndrome), partial gonadal dysgenesis (a variety of single-gene disorders and chromosomal abnormalities involving key genes), and the loss of otherwise normally developed testes during fetal life (testicular regression syndrome). In addition, a small proportion of patients with ovotesticular DSD (discussed in an earlier section of this chapter) has a 46,XY karyotype.

### Complete Gonadal Dysgenesis (Swyer Syndrome)

Swyer syndrome is an uncommon form of gonadal dysgenesis, characterized by a 46,XY karyotype.<sup>338</sup> **Despite the presence of a Y chromosome, the phenotype is female because the dysgenetic (streak) gonads produce neither AMH nor androgens.** Consequently, the vagina, cervix, uterus, and fallopian tubes develop normally and the internal and external genitalia do not masculinize.<sup>339</sup> **In approximately 10–15% of patients, the disorder results from an inactivating mutation in the SRY gene, but in most, no cause can be identified.**<sup>340</sup> Mutations in other genes involved in the regulation of SRY expression or encoding important downstream elements in the testis-determining pathway have been implicated.<sup>341,342,343</sup>

**Patients with Swyer syndrome generally present after the expected time of puberty with delayed sexual maturation, primary amenorrhea, normal pubic hair, and normal female internal and external genital anatomy.** Evaluation reveals hypergonadotropic hypogonadism, prompting a karyotype that establishes the diagnosis. **Gonadectomy is indicated soon after diagnosis due the significant risk for development of germ cell tumors in occult testicular elements (20–30%).**<sup>344</sup>

**Sex of assignment and rearing and gender identify is unequivocally female, and no specific treatment is required other than estrogen therapy to induce breast development and, subsequently, estrogen and progestin therapy (cyclic or combined) to maintain sexual maturation. Pregnancy can be achieved with IVF**

using donor oocytes and has not been associated with any specific risks or complications.<sup>345</sup>

## **Partial Gonadal Dysgenesis**

Partial gonadal dysgenesis describes a group of disorders resulting from a wide assortment of genetic mutations causing abnormal gonadal development and function. In affected patients, müllerian structures may be present or absent, the external genitalia may be female, ambiguous, or male, and the phenotype can include developmental abnormalities outside of the reproductive tract. The wide variations in phenotype reflect the many different actions of the gene products, which are involved in the regulation of SRY expression, müllerian regression, testis differentiation, and developmental patterning. Examples include single-gene disorders involving WT1, SF1, SRY, SOX9, DHH (an intercellular signaling molecule having an important role in morphogenesis and testis development), ATRX (a transcriptional regulator expressed during development), and ARX (a homeobox-containing gene expressed during development), as well as chromosomal aberrations involving key genes such as a DMRT1 (hemizyosity), DAX1 (duplication), and WNT4 (duplication)<sup>115,346,347</sup> (Table 8.3).

## **TABLE 8.3 Genes Associated with 46,XY Partial Gonadal Dysgenesis**

Gene	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features
<b>Single-gene disorders</b>						
<i>WT1</i>	11p13	Autosomal dominant	Dysgenetic testis	+/-	Female or ambiguous	Wilms tumor, renal anomalies, gonadal tumors
<i>SFI</i>	9q33	Autosomal dominant/recessive	Dysgenetic testis	+/-	Female or ambiguous	Adrenal failure (some)
<i>SRY</i>	Yp11.3	Y	Dysgenetic testis/ovotestis	+/-	Female or ambiguous	
<i>SOX9</i>	17q24-5	Autosomal dominant	Dysgenetic testis/ovotestis	+/-	Female or ambiguous	Campomelic dysplasia
<i>DHH</i>	12q13.1	Autosomal recessive	Dysgenetic testis	+	Female	
<i>ATRX</i>	Xq13.3	X	Dysgenetic testis	-	Female, ambiguous, or male	Alpha thalassemia, mental retardation
<i>ARX</i>	Xp22.13	X	Dysgenetic testis	-	Ambiguous	Lissencephaly, epilepsy, temperature instability
<b>Chromosomal aberrations</b>						
<i>DMRT1</i>	9p24.3	Hemizyosity	Dysgenetic testis	+/-	Female or ambiguous	Mental retardation
<i>DAX1</i>	Xp21.3	Duplication Xp21	Dysgenetic testis or ovary	+/-	Female or ambiguous	
<i>WNT4</i>	1p35	Duplication 1p35	Dysgenetic testis	+	Ambiguous	Mental retardation

## Testicular Regression Syndrome

Testicular regression syndrome is a condition in which a developmentally normal testis existed during fetal life but subsequently regressed or was lost. **The disorder can be unilateral or bilateral and is characterized by partial or complete absence of testicular tissue in the presence of normal male external genitalia.**<sup>348</sup> Typically, the vas and associated vessels end blindly with a varying amount of testicular tissue remaining. The natural history of the disorder is poorly understood. Current concepts presume normal early embryonic development and testicular descent, followed by a catastrophic event such as torsion. If the process occurs relatively late in pregnancy, the internal and external genitalia virilize and the müllerian ducts regress normally, but the testes are absent at birth (anorchia). However, earlier loss of both testes can result in a small phallus or incomplete masculinization.<sup>349</sup>

In histopathologic studies of atretic nodular testicular remnants obtained from

affected neonates or young boys, only 10% of specimens have contained any identifiable seminiferous tubules, which consisted mainly of Sertoli cells enveloped in fibrous strands with no visible germ cells.<sup>348</sup> Hemosiderin-laden macrophages, generally a late cellular response to tissue damage, are present in approximately two-thirds of cases and, occasionally, a vas and epididymis can be observed.<sup>348,350,351</sup>

## Disorders of Androgen Synthesis

A number of steroidogenic enzymes and regulatory proteins are involved in androgen synthesis, and a deficiency in any one of them can result in decreased fetal androgen production and its consequences. All are rare, but each is a recognized cause of 46,XY DSD; together, they account for less than 5% of cases. Disorders of testosterone synthesis usually impair virilization of the external genitalia to a greater extent than the internal genitalia.

### Steroid 5 $\alpha$ -Reductase Deficiency

**Steroid 5 $\alpha$ -reductase (type 2) deficiency is an autosomal recessive disorder characterized by a 46,XY karyotype and severe perineal hypospadias (describing a genital configuration consisting of a phallus midway in size between penis and clitoris, a chordee tethering the phallus to the perineum, a urethral opening usually on the perineum, and an incompletely closed urogenital opening resembling a small and shallow vagina), which results from impaired virilization during embryogenesis due to defective conversion of testosterone to dihydrotestosterone (DHT).**<sup>352,353,354</sup>

In the classical presentation, the external genitalia are predominantly female at birth, exhibiting failed fusion of the labioscrotal folds and a urogenital sinus or separate urethral and vaginal openings, with or without clitoromegaly. The internal genitalia are male; the epididymides, vasa deferentia, seminal vesicles, and ejaculatory ducts form, but empty into a shortened, blind vagina. In some, the wolffian duct derivatives end on the perineum, on either side of the urethra. The testes are located in the inguinal canals, in the labia majora, or in the scrotum and exhibit impaired spermatogenesis. **The distinguishing feature of the disorder is that affected individuals virilize, to varying degrees, at the time of puberty.** Unlike in disorders relating to abnormalities in the androgen receptor, breast development in men with steroid 5 $\alpha$ -reductase is like that in normal males. Although a few individuals with 5 $\alpha$ -reductase deficiency are sufficiently virilized to be assigned a male gender at birth,<sup>355</sup> most have been reared as females and assumed a male gender and behavior at the time of puberty.<sup>356</sup>

The clinical features of steroid 5 $\alpha$ -reductase deficiency again illustrate the mechanisms involved in phenotypic sexual differentiation.<sup>357</sup> The wolffian duct

derivatives (the ejaculatory ducts, epididymides, vasa deferentia, and seminal vesicles) form normally, in response to normal fetal testosterone levels, but the genital structures that derive from the urogenital sinus and genital tubercle (the external genitalia, urethra, and prostate) do not virilize normally, because they are dependent on the intracellular conversion of testosterone to DHT. Affected men develop a normal muscle mass, libido, and deepening of the voice, which result from the actions of testosterone, but have less body hair and less temporal hairline recession, and no problems with acne, all of which result primarily from the actions of DHT. The unique importance of DHT during fetal development is demonstrated by the significant genital virilization that occurs after puberty.<sup>358</sup>

There are two types of steroid 5 $\alpha$ -reductase, designated types 1 and 2,<sup>359</sup> encoded by two separate genes; the gene encoding the type I enzyme (RD5A1) is located on chromosome 5 (5p15) and that encoding the type 2 enzyme (RD5A2) is located on chromosome 2 (2p23). In those with the disorder recognized as steroid 5 $\alpha$ -reductase deficiency, the type 2 enzyme is defective and the type 1 enzyme is normal.<sup>360</sup> **The resulting impaired conversion of testosterone to DHT prevents normal virilization of the male external genitalia during fetal development.** Affected individuals typically have very low but measurable serum DHT concentrations, which could reflect limited activity of the abnormal enzyme but more likely results from the actions of the type 1 enzyme.<sup>355</sup> The virilization that occurs at puberty may be driven by serum DHT or by testosterone itself. Transient gynecomastia may develop at puberty but does not persist, because androgen and estrogen production is like that in normal adult men.

A wide variety of RD5A2 mutations has been described, most being point mutations that yield a low concentration of enzyme, an unstable enzyme having reduced activity, or an enzyme with decreased affinity for testosterone and/or essential cofactors. Approximately 40% of affected individuals are homozygous for the same mutation, the remainder being compound heterozygotes.<sup>360</sup> Nearly half have similarly affected family members, likely reflecting consanguinity and a founder effect.<sup>361</sup> In women, mutations are essentially silent; although body hair may be reduced and menarche delayed, even those with homozygous mutations are phenotypically normal and have normal menstrual function and fertility.<sup>362,363</sup>

**The diagnosis of 5 $\alpha$ -reductase deficiency should be suspected in infants with genital ambiguity and in adolescents or young adults having the characteristic phenotype and serum hormone profile (a normal male serum testosterone concentration and an increased testosterone/DHT ratio), which typically exceeds 10 in infants and often exceeds 20 in older children and adults.**<sup>354,364</sup> In infants and prepubertal children, basal testosterone and DHT levels may not be sufficient for diagnosis and are best evaluated by performing an hCG stimulation test, measuring

testosterone and DHT before (basal, day 1) and after (stimulated, days 3 and 6) administering exogenous hCG (1,500 IU/m<sup>2</sup> on days 1 and 3).<sup>364,365,366</sup> Individuals with 5 $\alpha$ -reductase deficiency can be distinguished from those having defects of testosterone synthesis by their normal or elevated serum testosterone levels and from those with incomplete androgen insensitivity by demonstrating normal ratios of 5 $\beta$ - to 5 $\alpha$ -reduced glucocorticoid metabolites, as indicators of hepatic steroid metabolism.<sup>367</sup> A definitive diagnosis can be established by analyzing DNA extracted from blood or tissue.<sup>360</sup>

The management of patients with steroid 5 $\alpha$ -reductase deficiency is complicated because half or more initially assigned as females undergo a change in gender identity and behavior in later life.<sup>356</sup> The sex of rearing, the age of the subject, and the gender identity influence the choice of management. The decision to raise an individual as female should be made only after thorough psychological evaluation to confirm a female gender identity, but once made, management is relatively straightforward. Gonadectomy should be performed to prevent later virilization and tumor development in cryptorchid testes.<sup>368</sup> Any clitoromegaly can be surgically corrected, taking care to maintain the glans clitoris. If required, a functional vagina can be established by progressive vaginal dilation<sup>323,324,369</sup> or by surgical vaginoplasty.<sup>370</sup> Estrogen treatment to induce and maintain feminine characteristics should be started at the usual time of puberty or immediately after gonadectomy in adults.

The decision to raise an individual as male is no less complex and also will involve surgical and medical treatment. The timing of surgery to correct the hypospadias and cryptorchidism depends on the degree of hypospadias and the size of the phallus. Unfortunately, the extent of virilization at puberty usually is less than desired,<sup>364,371</sup> prompting efforts to improve results by treatment with exogenous testosterone or DHT. Treatment with testosterone before puberty can help to enlarge the phallus.<sup>364</sup> Treatment with DHT can raise serum DHT concentrations, but must be specially prepared as there is no commercially available preparation.<sup>372,373</sup> Although sperm counts are quite low in most patients,<sup>374</sup> fertility can be achieved via intrauterine insemination<sup>375</sup> or IVF and ICSI.<sup>376</sup>

The change from a female to a male gender identity can be extremely traumatic psychologically, but some have managed the transition quite successfully.<sup>356</sup> In one such case, the patient effectively conducted a “double life,” functioning in all public respects as a female while having numerous clandestine heterosexual relationships. Aware of his male sexual identity since puberty, he nonetheless delayed seeking medical assistance for fear that exposure would bring shame and guilt to his religiously devout elderly “old-world” mother. Although he had planned to keep his secret until his mother died, he finally sought diagnostic help at age 65, because his mother, then age 93, continued to

enjoy good health. The transition from a female to a male gender in an individual with steroid 5 $\alpha$ -reductase deficiency was chronicled in the Pulitzer Prize–winning novel, *Middlesex*, authored by Jeffrey Eugenides, which features the heroine Calliope Stephanides who becomes the hero, Cal.<sup>377</sup>

## 17 $\alpha$ -Hydroxylase Deficiency

The CYP17A1 gene encodes an enzyme having both 17 $\alpha$ -hydroxylase and 17,20-lyase activities, which are required for synthesis of cortisol, androgens, and estrogens. Deficiency of 17 $\alpha$ -hydroxylase is a rare cause of CAH, with little more than 100 cases reported.<sup>378,379</sup> Human 17 $\alpha$ -hydroxylase deficiency syndromes involving a loss of only 17 $\alpha$ -hydroxylase or 17,20-lyase have been observed,<sup>380,381</sup> but in most affected patients, both enzymes are deficient.<sup>382</sup>

The compensatory increase in ACTH stimulation that accompanies decreased cortisol synthesis stimulates increased production of 11-deoxysteroids (via 21-hydroxylase), including corticosterone and the mineralocorticoids 11-deoxycorticosterone and 18-hydroxy-deoxycorticosterone.<sup>383,384</sup> In turn, mineralocorticoid excess leads to volume expansion, which inhibits renin release and the synthesis of aldosterone.<sup>385</sup> Production of androgens (dependent on 17,20-lyase activity) and, subsequently, estrogens is decreased in both the adrenals and the gonads. Serum concentrations of progesterone are increased, but those of 17-OHP, cortisol, DHEA, DHEA-S, androstenedione, testosterone, and estradiol are low.

Like other forms of CAH, 17 $\alpha$ -hydroxylase deficiency is an autosomal recessive disorder. The CYP17A1 gene is located on chromosome 10 (10q24.3) and numerous different mutations have been described,<sup>386</sup> including small insertions that disrupt the normal reading frame of the gene (resulting in early termination),<sup>387</sup> deletions of a single or several codons,<sup>388,389</sup> large deletions with insertion of foreign DNA,<sup>390</sup> and nonsense or missense mutations that yield stop codons or an enzyme with decreased activity.<sup>389,391,392,393,394,395,396,397,398</sup> **Females with 17 $\alpha$ -hydroxylase deficiency typically present with delayed puberty, primary amenorrhea, and hypergonadotropic hypogonadism; most are hypertensive (due to hypernatremia and hypervolemia) and some also have hypokalemia.<sup>399,400</sup> Affected males usually have female external genitalia (male pseudohermaphroditism), a blind vagina, and intra-abdominal testes; most have been raised as girls, with the underlying disorder recognized only later during evaluation for delayed puberty.<sup>401</sup>**

The treatment of 17 $\alpha$ -hydroxylase deficiency involves giving sufficient glucocorticoids to suppress excess production of ACTH and mineralocorticoids while avoiding glucocorticoid excess. Because almost all affected patients are raised as

females, estrogen therapy also should be provided, at the time of diagnosis at puberty or the expected time of puberty. In genetic females having a uterus, progestational treatment also must be provided.

### **3 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency**

Defects in the enzyme 3 $\beta$ -hydroxysteroid dehydrogenase/ D<sup>5</sup>-D<sup>4</sup> isomerase (3 $\beta$ -HSD) and its endocrine and developmental consequences in genetic females are discussed in detail in the earlier section of this chapter devoted to causes of female virilization (46,XX DSD). The enzyme defect is considered here again, briefly, because it can cause incomplete masculinization of males as well as virilization in females.

Type II 3 $\beta$ -HSD catalyzes the oxidation and isomerization of D<sup>5</sup>-3 $\beta$ -hydroxysteroid precursors into D<sup>4</sup>-ketosteroids in the adrenals and gonads. A 3 $\beta$ -HSD deficiency results in the accumulation of excessive amounts of D<sup>5</sup>-3 $\beta$ -hydroxysteroids, including pregnenolone, 17 $\alpha$ -hydroxypregnenolone, DHEA, and DHEA-S, and in low levels of D<sup>4</sup>-ketosteroids such as androstenedione and testosterone and, subsequently, DHT. Consequently, affected males exhibit varying degrees of incomplete masculinization, ranging from hypospadias to nearly normal female external genitalia.<sup>219,402,403</sup>

### **17 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency**

The 17 $\beta$ -hydroxysteroid dehydrogenase (17 $\beta$ -HSD) family of enzymes includes the type 3 isoenzyme, which catalyzes the conversion of androstenedione into the biologically active androgen, testosterone, in the Leydig cells of the testis. Mutations in the HSD17B3 gene, located on chromosome 9 (9q22), can result in 17 $\beta$ -HSD deficiency, an autosomal recessive disorder caused by impaired testicular testosterone production.<sup>404,405</sup> Although rare, 17 $\beta$ -HSD deficiency is the most common hereditary defect in testosterone synthesis.

**Males with homozygous or compound heterozygous mutations have testes and normally developed internal genitalia but have severely undervirilized external genitalia, which typically appear female and include a short, blind vagina, much like patients with incomplete androgen insensitivity.**<sup>405,406</sup> Consequently, most are assigned a female gender at birth and are raised as females. **Alternatively, they can exhibit genital ambiguity, with varying degrees of clitoromegaly and labial fusion, or have male genitalia with micropenis or hypospadias.**<sup>404,407</sup> The testes may be located in the abdomen, in the inguinal canals, or in the labia majora. **Virilization occurs at puberty, probably due to extratesticular conversion of androstenedione to testosterone by unaffected 17 $\beta$ -HSD isoenzymes in peripheral tissues (e.g., liver, skin, adipose).**<sup>405,408,409,410</sup> The phallus enlarges, muscle mass increases, a male body

habitus and hair pattern develop, and the voice may deepen. Gender role reversal has been observed in one- to two-thirds of those affected and raised as girls.<sup>411</sup> Ideally, therefore, the diagnosis is best made before puberty and followed with gonadectomy and estrogen therapy in those with female genitalia. In those born with ambiguous genitalia, early diagnosis may allow male sex assignment because androgen treatment can promote development of a nearly normal adult male phenotype.<sup>412,413</sup>

When suspected, an elevated basal serum androstenedione level and low serum testosterone/androstenedione ratio (<0.8–0.9) after exogenous hCG stimulation suggest the diagnosis of 17 $\beta$ -HSD deficiency, but the method lacks specificity, because normal values have not been firmly established in age-matched controls and because similar results can be observed in individuals with other defects in testosterone biosynthesis or Leydig cell hypoplasia. Genotyping permits definitive diagnosis. A variety of different mutations has been described, most yielding an enzyme having little or no significant activity.<sup>405</sup>

## **P450 Oxidoreductase Deficiency**

The genetics and pathophysiology of P450 oxidoreductase (POR) deficiency are discussed in detail in the earlier section of this chapter devoted to causes of 46,XX DSD (female virilization). The disorder is included again here because, like 3 $\beta$ -HSD deficiency, P450 oxidoreductase deficiency also is among the causes of 46,XY DSD (incomplete masculinization in males).

As described earlier, POR is not a steroidogenic enzyme but a flavoprotein that serves as the electron donor in the activation of all microsomal P450 enzymes, including P450c21 (the adrenal 21-hydroxylase, CYP21A2), P450c17 (CYP17A1, which catalyzes both 17,20-lyase and 17 $\alpha$ -hydroxylase activities), and P450arom (aromatase, CYP19A1, which mediates the conversion of androgens to estrogens).<sup>275</sup> The developmental consequences of POR deficiency in males result primarily from partial deficiencies of 21-hydroxylase and 17,20-lyase, and to a lesser extent, 17 $\alpha$ -hydroxylase activity. Serum concentrations of 17-OHP are elevated and androgen levels are low. Not surprisingly, affected boys often are undervirilized, because decreased 17,20-lyase activity prevents generation of 19-carbon androgens, including testosterone.

## **Steroid Acute Regulatory (StAR) Protein Deficiency**

The rarest and most severe form of CAH is known as congenital lipoid adrenal hyperplasia. The disorder is characterized by a deficiency of all adrenal and gonadal steroid hormones, increased ACTH secretion, and marked adrenal hyperplasia associated with progressive accumulation of cholesterol esters.

**Congenital lipoid adrenal hyperplasia is an autosomal recessive disorder that**

**results from mutations in the gene encoding the steroidogenic acute regulatory (StAR) protein.**<sup>414,415</sup> StAR mediates the acute response to steroidogenic stimuli by facilitating transport of cholesterol from the outer to the inner mitochondrial membrane, the rate-limiting step in steroidogenesis,<sup>415,416</sup> and is expressed in the adrenal cortex and gonads, but not in the placenta. A wide variety of mutations in the StAR gene (located at 8p11.2) have been described, most resulting in reduced activity of the protein.<sup>414,417,418,419</sup> The disorder also can result from a heterozygous mutation in the CYP11A1 gene encoding the cholesterol side chain cleavage enzyme, which converts cholesterol to pregnenolone.<sup>420</sup> In either case, all steroidogenic pathways are affected, resulting in a global deficiency of steroid hormones that reflects both the intrinsic defect in steroidogenesis and the progressive cellular damage that results from the accumulation of cholesterol.<sup>417</sup> Serum cortisol and aldosterone concentrations are very low, ACTH and plasma renin activity levels are very high, sex steroid concentrations are low, and serum gonadotropin levels are elevated, even in young children.<sup>420,421</sup>

Patients with congenital lipoid adrenal hyperplasia typically present very soon after birth or in early infancy with symptoms of severe adrenal insufficiency (vomiting, diarrhea, volume depletion, hyponatremia, hyperkalemia).<sup>422</sup> Male infants usually have female external genitalia due to the severe androgen deficiency. Females are normally developed at birth and even may undergo spontaneous puberty,<sup>423</sup> possibly because the prepubertal ovary, unlike the adrenals and testes, is relatively dormant and thus may escape cellular damage from cholesterol accumulation. Although two-thirds of reported patients died in infancy,<sup>421</sup> some treated with glucocorticoids and mineralocorticoids have survived to reach puberty.<sup>424</sup>

## Disorders of Androgen Action

Mutations in the gene that encodes the androgen receptor (AR) can produce a variety of phenotypes in males having normal testes and testosterone production; more than 400 different AR mutations have been identified.<sup>425</sup> Collectively, these 46,XY DSD are known as androgen insensitivity syndromes (AISs). The genetics, pathophysiology and endocrinology of androgen receptor disorders are quite similar. The phenotype depends on whether androgen receptors are absent entirely,<sup>426,427</sup> present but functionally abnormal,<sup>428,429,430</sup> or normal but decreased in quantity<sup>428,431</sup> (**Figure 8.11**).

**FIGURE 8.11**

## Complete Androgen Insensitivity Syndrome

Complete androgen insensitivity was first described in detail by Morris, at Yale, who coined the name “testicular feminization.”<sup>432</sup> However, complete AIS now is the preferred term.<sup>433</sup> Complete AIS can result from a wide variety of inactivating mutations in the AR gene, including major gene deletions, premature stop codons, splicing abnormalities, and missense mutations that result in amino acid substitutions in the androgen receptor. The AR gene is located on the X chromosome (Xq12), and complete AIS therefore follows an X-linked recessive pattern of inheritance. One in three phenotypic sisters of an affected individual will have an XY karyotype. Consequently, careful investigation to identify other affected family members is warranted. Approximately 40% of patients with complete AIS have no family history of the disorder,<sup>434</sup> presumably representing de novo mutations.

The pathophysiology, and the phenotype, of complete AIS are logical and predictable. The receptor defect results in insensitivity to androgen. Consequently, androgen-induced wolffian duct development cannot proceed normally; the presence or absence of wolffian duct derivatives (epididymides, vasa deferentia) varies with the

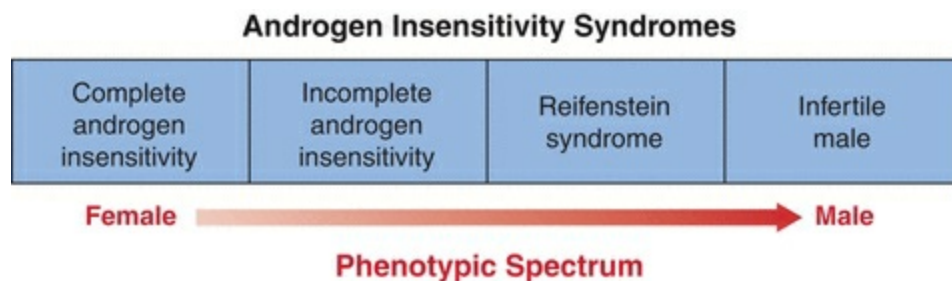

type of mutation. Whereas remnants can be observed (adjacent to the testes) in those having point mutations in the ligand-binding domain of otherwise normally expressed receptors, which may permit a very limited response to high local androgen concentrations in utero, wolffian structures are completely absent in those having mutations that yield premature stop codons or frameshift mutations that prevent androgen receptor expression.<sup>435</sup> The normal testes produce normal amounts of AMH, which effectively suppress müllerian duct development. Therefore, the uterus and fallopian tubes typically are absent, although vestiges also have been observed.<sup>436</sup> The testes may be found in the abdomen but, more commonly, are located in the inguinal canals or in the labia majora, probably because AMH normally mediates their descent; their histology resembles that of undescended testes, with a normal or increased number of Leydig cells and absent spermatogenesis. The external genitalia are clearly female, due to androgen insensitivity, although the labia and clitoris may be slightly underdeveloped. The vagina is either blind and short or altogether absent, reflecting only the developmental contribution of the urogenital sinus. Axillary and pubic hair is scant or absent, again due to androgen insensitivity. Breast development is female and may be enhanced, probably due to the action of estrogen unopposed by the actions of androgens. The overall body habitus also is female, although the average height and weight of women with complete AIS is greater than that of normal women.<sup>437,438</sup> Women with complete AIS also exhibit normal female sexual orientation and maternal instincts.<sup>439,440</sup>

**In women with complete AIS, serum testosterone concentrations are normal or moderately increased, LH levels are increased, and the serum FSH usually is in the normal range.** The increase in LH levels results from resistance to the negative feedback effects of androgens at the hypothalamic-pituitary level; both the frequency and amplitude of pulsatile LH secretion are increased in patients with complete AIS.<sup>441,442</sup> Whereas estrogen production (estrone and estradiol) also is increased by approximately 70% over that in normal men, DHT production is decreased due to the absence of male urogenital tissues, which are the primary site of DHT production.<sup>367</sup>

The diagnosis of complete AIS should be suspected in girls with inguinal hernias or labial masses<sup>443</sup> and in women with primary amenorrhea. In the adolescent or adult, diagnosis usually is not difficult. **Most patients with complete AIS present with primary amenorrhea, normal breast development, absent or scant pubic and axillary hair, a short vagina, and an absent cervix and uterus; a serum testosterone in the normal male range and a 46,XY karyotype establish the diagnosis.** Whereas males with defects in testosterone biosynthesis can have a female phenotype, breast development does not occur. **Patients with complete AIS generally are easily differentiated from those with müllerian agenesis who have normal amounts of pubic and axillary hair, normal female serum testosterone concentrations, and a**

**46,XX karyotype.** The location of the testes usually can be defined by ultrasonography or MRI.<sup>444</sup>

The clinical management of complete AIS includes appropriate hormone therapy, creation of a functional vagina, gonadectomy to prevent tumorigenesis in cryptorchid testes, and psychological support, all discussed in detail in [Chapter 10](#) (Amenorrhea) and summarized here. Estrogen treatment is indicated when gonadectomy is performed after puberty is completed, or at the time of expected puberty if the gonads were removed before puberty. Options for creation of a functional vagina include progressive vaginal dilation and vaginoplasty. The short but distinct vagina observed in most patients with complete AIS facilitates efforts with vaginal dilation,<sup>323,324,369</sup> but surgical treatment also produces good results, when necessary.<sup>370</sup> **In patients with complete AIS, gonadectomy generally is best delayed until after puberty is completed (approximately age 16–18) because pubertal development generally proceeds more smoothly in response to endogenous hormone production and because the overall risk for tumor development is quite low (5–10%), particularly before puberty.**<sup>431,445,446,447</sup> Psychological support should be directed toward reinforcement of their female gender identity and include truthful education for both patient and parents ([Figure 8.12](#)).

**FIGURE 8.12**

### **Incomplete Androgen Insensitivity Syndromes ([Table 8.4](#))**

### **TABLE 8.4 Androgen Insensitivity Syndromes**

	Complete	Incomplete	Reifenstein	Infertile
<b>Inheritance</b>	X-linked recessive	X-linked recessive	X-linked recessive	X-linked recessive
<b>Spermatogenesis</b>	Absent	Absent	Absent	Decreased
<b>Müllerian</b>	Absent	Absent	Absent	Absent
<b>Wolffian</b>	Absent	Underdeveloped	Male	Male
<b>External</b>	Female	Female (clitoromegaly)	Male (hypospadias)	Male
<b>Breasts</b>	Female	Female	Gynecomastia	Male (gynecomastia)

Incomplete AIS describes a variety of disorders that result from defects in androgen action less severe than those associated with complete AIS. **The spectrum of clinical presentations can vary from phenotypic females with mild virilization to undervirilized males who may be fertile or infertile, even within one affected family.**<sup>448,449</sup>

Phenotypic women with mild virilization are at one end of the clinical spectrum of incomplete or partial AIS. They resemble women with complete AIS but have normal body hair, external genitalia exhibiting partial fusion of the labioscrotal folds, with or without clitoromegaly, and they both virilize and feminize at puberty. They have no müllerian structures (due to the actions of AMH), underdeveloped male internal genitalia (epididymides, vasa deferentia, seminal vesicles, ejaculatory ducts), and testes similar to those with complete AIS. Axillary and pubic hair is normal. Breast development, the overall body habitus, and gender identity are distinctly female. The phenotype is approximately one-tenth as common as that of complete AIS.<sup>431</sup>

**Reifenstein syndrome** describes individuals having a predominantly male phenotype who are undervirilized.<sup>450</sup> **The most common clinical presentation is an infertile man with a bifid scrotum and perineoscrotal hypospadias.** However, the appearance of the external genitalia can vary widely, from a microphallus with a normal penile urethra to complete failure of scrotal fusion. The internal genitalia are male but not completely developed; müllerian structures are absent and, usually, so too is the prostate. The testes can be cryptorchid or normally descended and small and exhibit a maturation arrest in spermatogenesis. Men with Reifenstein syndrome have normal axillary and pubic hair but, typically, little or no chest or facial hair. They have a male body habitus but usually develop gynecomastia at the time of puberty. Gender identity corresponds with the sex of rearing, and sexual dysfunction is common in those raised as males.<sup>451,452,453</sup>

**Some men with partial androgen insensitivity are only mildly undermasculinized and infertile.**<sup>454</sup> Their internal and external genitalia are normal and their testes are

normally descended but exhibit either an absent germinal epithelium or spermatogenic arrest. They have normal amounts of body hair and some have gynecomastia. **The prevalence of partial androgen insensitivity in men with azoospermia or severe oligospermia is unknown but may be as high as 10%.**<sup>455,456</sup> Still other men with partial androgen insensitivity are undervirilized but fertile<sup>457,458</sup> (Table 8.4).

Serum hormone levels in phenotypic women with incomplete AIS, in men with Reifenstein syndrome, and in infertile men with partial androgen insensitivity are similar to those in individuals with complete AIS.<sup>450,454,459</sup> In undervirilized fertile men with partial androgen insensitivity, testosterone concentrations are elevated but LH levels are in the normal range.<sup>457</sup>

Whereas major AR gene deletions and premature termination codons have been identified only in patients with complete AIS, point mutations resulting in amino acid substitutions in the androgen receptor can cause the entire spectrum of phenotypes associated with androgen insensitivity. Approximately 80% of amino acid substitutions are located in the hormone-binding domain of the receptor. Most of the remainder is in the DNA-binding domain, permitting normal androgen binding but preventing activation of androgen-responsive genes.<sup>460</sup> How or why different mutations or even the same mutation can result in varying degrees of androgen insensitivity is poorly understood but may relate to differences in the timing of receptor expression, differences in testosterone synthesis or metabolism, differences in transcription factors, or polymorphisms that influence the effect of a given mutation.<sup>460,461,462,463</sup> In some, androgen resistance results not from a mutation in the androgen receptor but from a defective coactivator protein required for normal function of the androgen-androgen receptor complex.<sup>464,465</sup> In others with somatic mosaicism, the androgen receptor is normal in some, but not all, tissues.<sup>466,467</sup>

**Incomplete AIS often presents in newborns, as ambiguous genitalia. In adults, the diagnosis generally is not difficult. Affected individuals present as phenotypic women with mild virilization of the external genitalia (otherwise appearing the same as women with complete AIS) or as phenotypic men with gynecomastia and perineoscrotal hypospadias.** In phenotypic women with incomplete AIS, the family history can be very helpful because others who are affected have a similar appearance, but in undervirilized men, the phenotype of affected family members can vary significantly. At all ages, the differential diagnosis includes steroid 5 $\alpha$ -reductase deficiency, defects in testosterone biosynthesis, and mixed gonadal dysgenesis, which is discussed below. The ratio of testosterone to DHT in serum helps to differentiate incomplete AIS from steroid 5 $\alpha$ -reductase deficiency; the ratio is normal in most with incomplete AIS but increased in patients with steroid 5 $\alpha$ -reductase deficiency. In most cases, androgen receptor defects can be differentiated from defects of testosterone

biosynthesis by the serum testosterone concentration, which typically is normal or high in the former and decreased in the latter. Individuals with mixed gonadal dysgenesis (characterized by a unilateral testis, a contralateral streak gonad, and a 46,XY or 45X/46,XY karyotype) often have a single descended gonad or exhibit some of the phenotypic features of Turner syndrome. Androgen insensitivity also should be suspected in undervirilized men with azoospermia or severe oligospermia. Testosterone or LH concentrations may be elevated but are normal in most<sup>455</sup>; some have high serum FSH levels and resemble men with microdeletions in the AZF (azoospermia factor) region of the Y chromosome.<sup>468</sup> Although only a few families with the undervirilized fertile male syndrome have been reported, the disorder might be suspected in undervirilized men with a normally formed male urethra and gynecomastia, particularly in those having other family members who are similarly affected.

Androgen receptor binding can be evaluated in vitro, using cultured fibroblasts derived from genital skin. However, the method is labor intensive and costly and cannot exclude abnormalities of androgen receptor function unrelated to binding. Techniques involving the insertion of an androgen-responsive reporter gene in fibroblasts that can demonstrate impaired androgen receptor function have been described, but their usefulness for diagnosis of mild androgen insensitivities is unclear.<sup>469</sup> **The most reliable method for diagnosis of androgen insensitivity is to sequence the AR gene using DNA derived from blood or tissue, with reference to a database that lists all of the mutations that have been identified in patients with androgen insensitivity.** Once characterized, the defect can be identified in fetuses at risk using DNA obtained via CVS or amniocentesis or in embryos using preimplantation genetic testing for monogenic disorders (PGT-M, previously called PGD).<sup>470,471,472</sup>

The clinical management of incomplete AIS syndromes is directed toward appropriate gender assignment in infants with ambiguous genitalia, hormone therapy, psychological support, gonadectomy to prevent tumorigenesis in cryptorchid testes, reconstructive surgery where it is needed, and the treatment of gynecomastia in men.

**In determining gender assignment, the size of the phallus and the feasibility of constructing a penile urethra are the most important considerations.** For phenotypic females and those who are raised as females, estrogen treatment is indicated when gonadectomy is performed after puberty or at the expected time of puberty if gonadectomy was performed earlier. **Whereas adult women can receive normal doses of estrogen therapy immediately, the age and the dose of treatment in children must consider the growth percentile, growth velocity, bone age, target height, and predicted adult height.** In boys with Reifenstein syndrome, treatment with high doses of testosterone or DHT can achieve greater phallic growth<sup>473,474,475</sup>; in adult men, high-dose testosterone treatment can,<sup>371,476</sup> but does not always,<sup>442</sup> improve masculinization.

As in women with complete AIS, psychological support should be aimed at truthful education after consultation with the family and the development of a support network; early disclosure may help to limit emotional trauma.<sup>477</sup> Gonadectomy is performed to eliminate the risk of tumors developing in cryptorchid testes (1–2% of undescended testes, more often in abdominal than in inguinal testes), some of which are malignant.<sup>478</sup> **Whereas gonadectomy generally is best postponed until after puberty is completed in women with complete AIS, earlier surgery is indicated to prevent the virilization at puberty in those with incomplete AIS.** In boys with Reifenstein syndrome, early surgery to correct cryptorchidism both decreases the risk of tumor and helps to maximize testicular function. The gynecomastia observed in men with Reifenstein syndrome and in undervirilized fertile males, which results from both increased estrogen production and androgen resistance, can be treated by mastectomy when it is disfiguring or otherwise disturbing to the individual. The incidence of breast cancer may be increased in men with Reifenstein syndrome.<sup>479</sup>

## LH Receptor Defects

**Leydig cell hypoplasia, describing the absence of mature Leydig cells in the testes, is a rare autosomal recessive 46,XY disorder of sexual development caused by inactivating mutations in the LH/hCG receptor.**<sup>480,481</sup> Testicular Leydig cell testosterone production is stimulated by hCG during fetal life and by LH after birth. In the fetus, the number and differentiation of Leydig cells and levels of androgen production parallel the changes in serum hCG concentrations during pregnancy. Consequently, a decrease in the number or function of Leydig cells results in decreased fetal testosterone production and in the failure of normal male sexual differentiation. Large deletions or nonsense mutations in the LH/hCG receptor gene (LHCGR) yield defective receptors that prevent normal hormone binding; more subtle mutations allow binding but prevent normal signal transduction or cause misfolding of the receptor that interferes with its normal transport to the cell surface.<sup>481,482,483</sup>

In affected individuals, müllerian duct derivatives are absent (reflecting the normal action of AMH), wolffian duct development is impaired (reflecting the decreased level of testosterone production), and the testes fail to descend, because normal descent requires the actions of testosterone and insulin-like factor 3, both deriving from Leydig cells.<sup>484,485</sup> **The phenotype of patients with Leydig cell hypoplasia otherwise generally correlates with the level of residual LH/hCG receptor activity, ranging from completely female external genital development to nearly normal male genitalia.** Those having no significant testosterone production appear female at birth and present at puberty with primary amenorrhea and sexual infantilism, lacking both pubic hair development (due to the lack of testosterone) and breast development (due to

the absence of aromatizable substrate); the serum LH concentration is elevated and testosterone levels are abnormally low. Others in whom LH receptor function is only partially impaired and testosterone production is decreased but still significant can present with ambiguous genitalia, hypospadias, or micropenis.<sup>481,483</sup>

## **Disorders of Antimüllerian Hormone and Its Receptor**

The **hernia uterine inguinale syndrome** is a rare autosomal recessive disorder that results from a failure of müllerian duct regression, due to mutations in the genes encoding AMH or its receptor.<sup>486,487</sup> Affected patients appear as normal males having an inguinal hernia containing relatively well-differentiated müllerian duct structures, usually including a uterus and fallopian tubes. They have normal male internal and external genitalia and, usually, cryptorchid testes. In affected families, genetic studies have identified mutations in the AMH gene in 45% and in the AMHR2 receptor gene in another 39%; in the remaining 15%, no mutation was detected, implicating genes coding for other factors in the AMH transduction cascade.<sup>488</sup>

# Sex Chromosome Disorders of Sexual Development

Sex chromosome DSD describes a group of disorders associated with an abnormal karyotype, including 45,X (Turner syndrome and variants), 47,XXY (Klinefelter syndrome and variants), 45,X/46,XY mosaicism (mixed gonadal dysgenesis), and 46,XX/46,XY mosaicism (chimerism). Ovotesticular DSD (true hermaphroditism), discussed in the earlier section of this chapter devoted to 46,XX DSD, also can be associated with a mosaic 45,X/46,XY or 46,XX/46,XY karyotype.

## 45,X (Turner Syndrome and Variants)

Turner syndrome was first described in 1938<sup>489</sup> and now is recognized as important cause of short stature in girls and primary amenorrhea in young women. The disorder also is discussed in [Chapter 10](#), as a cause of amenorrhea. Turner syndrome results from loss of all or part of an X chromosome and is very common; approximately 15% of all spontaneous abortions have a 45,X karyotype.<sup>490,491</sup> The incidence of Turner syndrome among newborn girls ranges around 1 in 2,000–5,000 live-born phenotypic females.<sup>492,493,494</sup>

Although Turner syndrome classically is associated with a 45,X karyotype, more than half of patients are mosaics (e.g., 45,X/46,XX). The prevalence of mosaicism varies directly with the method used for detection, ranging from 34% with conventional cytogenetics, to 60% with fluorescence in situ hybridization, to nearly 75% when a reverse transcriptase PCR assay is used.<sup>495</sup> Some patients with Turner syndrome lack only part of one X chromosome or exhibit one of a variety of structural abnormalities of the X, including ring chromosomes, isochromosomes, and terminal deletions.

## Clinical Features

**The sine qua non of Turner syndrome is short stature.** It is the only abnormality present in virtually all patients and can be attributed to deletion of the short stature homeobox-containing gene (SHOX), which is located in the pseudoautosomal region at the distal end of the short arm of the X chromosome (Xp22.33).<sup>496,497</sup> **The classical phenotype of Turner syndrome also includes the absence of sexual development, a webbed neck, low set ears and posterior hairline, widely spaced nipples (“shield chest”), short fourth metacarpals, and an increased carrying angle at the elbow (“cubitus valgus”).** The phenotype of patients with Turner syndrome relates, in part, to the parental origin of their X chromosome; most with a 45,X karyotype retain the maternal X.<sup>498</sup>

Most women with Turner syndrome have no pubertal development and primary amenorrhea. However, some develop normally and later present with secondary amenorrhea. Approximately 15% of patients with Turner syndrome begin but do not complete pubertal development and approximately 5% complete puberty and begin menstruation.<sup>499</sup> The streak gonads in women with Turner syndrome characteristically are composed of connective tissue with no follicles or only a few atretic follicles. About one-third have ovaries that can be imaged with pelvic ultrasonography, and those who do more commonly exhibit spontaneous breast development at puberty.<sup>500</sup> Although a few women with Turner syndrome conceive naturally, pregnancies are rare and associated with a relatively high risk for sex chromosome aneuploidy and spontaneous abortion.

Approximately 30–50% of patients with Turner syndrome have renal anomalies; horseshoe kidney is the most common and predisposes to hydronephrosis due to obstruction.<sup>501,502</sup> Cardiac malformations also are common. Approximately 20–30% of patients have aortic valve disease (bicuspid aortic valve, aortic root dilation) and 3–10% have coarctation<sup>503,504,505,506</sup>; The prevalence of cardiac anomalies may be higher in those with a 45,X karyotype than in mosaics.<sup>504</sup> Other cardiovascular anomalies include elongation of the transverse aortic arch (49%), persistent left superior vena cava (13%), anomalous pulmonary venous return (13%), and an aberrant right subclavian artery (8%); their prevalence is higher in patients with abnormal neck and chest development.<sup>507</sup> A prolonged QT interval can be observed, even in young children with Turner syndrome.<sup>508,509</sup> Idiopathic hypertension also is common, even in the absence of any apparent renal or cardiac malformations.<sup>510,511</sup>

Patients with Turner syndrome are predisposed to developing osteoporosis, primarily due to ovarian failure but possibly also relating to haploinsufficiency for genes affecting bone located on the X chromosome.<sup>512,513</sup> Many also have ocular abnormalities, including amblyopia, strabismus, ptosis, hypertelorism, epicanthus, farsightedness, and red-green color blindness.<sup>514,515,516</sup> The prevalence of endocrine diseases such as hypothyroidism and diabetes is increased and, for hypothyroidism, correlates with the karyotype (X isochromosome, 38%; 45,X, 14%; other, 6%).<sup>517</sup> Celiac disease, hearing loss, and liver function abnormalities also are more common in patients with Turner syndrome.<sup>518,519,520,521</sup>

Patients with Turner syndrome typically have normal intelligence.<sup>522</sup> The rare patient having a small X-ring chromosome may have severe mental retardation, because the ring chromosome does not undergo X-inactivation.<sup>523,524</sup> Nonetheless, formal evaluation of intellectual, learning, and motor skills generally is recommended before enrollment in school.<sup>525</sup> Attention deficit/hyperactivity disorder (ADHD)<sup>526</sup> and

problems with visual-spatial organization<sup>527</sup> are more common in girls with Turner syndrome.

Overall mortality is increased approximately threefold, relating primarily to circulatory disease, diabetes, and liver and renal disease.<sup>528</sup> Although overall cancer risk in women with Turner syndrome is similar to that in the general population, the incidence of CNS tumors, bladder cancer, and endometrial cancer may be increased, and the risk of breast cancer is decreased<sup>529</sup> (Figure 8.13).

**FIGURE 8.13**

## Diagnosis

The diagnosis of Turner syndrome sometimes is incidental, discovered when prenatal CVS or amniocentesis is performed for advanced maternal age or prenatal testing raises suspicion for chromosomal anomalies.<sup>530</sup> Diagnosis can be made at birth but often is delayed until childhood or adolescence. Neonates frequently exhibit lymphedema of the hands and feet, a webbed neck, nail dysplasia, a high palate, or short fourth metacarpals; short stature and delayed puberty are the later diagnostic keys.<sup>531</sup> **Therefore, karyotyping is recommended for all girls with unexplained short stature, delayed puberty, a webbed neck, lymphedema, or aortic coarctation and should be considered for those with two or more phenotypic features suggesting the diagnosis.**

Karyotype should include an examination of at least 30 cells, to detect significant mosaicism (e.g., 45,X/46,XX; 45,X/46,XY). For those with a suspicious phenotype but having a normal lymphocyte karyotype, a second tissue (e.g., skin fibroblasts) should be

examined to exclude tissue-specific mosaicism.<sup>532</sup> **Patients with Turner syndrome having a chromosomal fragment of uncertain origin and those exhibiting any evidence of virilization also should be evaluated specifically using FISH and Y chromosome-specific probes, because those having all or part of a Y (approximately 5%) are at increased risk for developing gonadoblastoma.**<sup>533,534,535,536,537</sup>

## Clinical Management

The spectrum of medical problems in patients with Turner syndrome and their health implications require specific evaluation and periodic monitoring, as described in detail in [Chapter 10](#).<sup>534</sup> In brief summary, evaluation should include periodic echocardiography (or MRI if required), renal ultrasonography, thyroid function studies, a complete blood count, fasting glucose, lipid profile, and renal and liver function tests, antiendomysial antibodies (to detect celiac disease), and audiometry. Those with coarctation of the aorta should undergo surgery for its correction, and those with other anomalies must be monitored carefully. Hypertension, hypothyroidism, and hearing and visual problems also require specific treatment.

Growth hormone therapy should begin as soon as height falls below the 5th percentile for age, usually between 2 and 5 years of age.<sup>538</sup> Early diagnosis and treatment with growth hormone can increase lean body mass<sup>539</sup> and help patients to achieve a normal adult height.<sup>540,541,542</sup> Combined treatment with growth hormone and low doses of oxandrolone (an anabolic steroid) can help to maximize growth for older girls between 9 and 12 years of age when diagnosis is delayed.<sup>543,544</sup> Estrogen therapy decreases height velocity and gain in height and therefore generally is not recommended before age 13 or 14 years.<sup>543,545,546</sup> **Estrogen treatment should begin at a low dose (0.25–0.5 mg micronized estradiol or its equivalent) and increase gradually at 3–6-month intervals until reaching the final dose (2.0 mg micronized estradiol or its equivalent); the goal is to complete sexual maturation over a period of 2–3 years. Transdermal options may offer a superior metabolic profile benefit.** Once treatment with estrogen begins, linear growth will continue for no longer than another 18–36 months. Treatment with a cyclic progestin (e.g., medroxyprogesterone acetate, 5 mg daily for 12–14 days of each month) should begin after the first episode of menstrual bleeding or after 12–24 months of treatment.<sup>534</sup> Treatment with oral contraceptives offers a convenient alternative for longer-term management. Recent reconsideration regarding oral estrogens due to the first-pass effect from the liver has made transdermal estrogens a potentially more preferred option. A meta-analysis showed improved whole-body bone mineral density, fasting glucose, and total cholesterol with transdermal estrogen. The lowest commercially available patches deliver 14–25

µg/day. These can be cut into smaller pieces to deliver 3–7 µg daily, which is recommended at the start of puberty or 11–12 years of age. The dose is then escalated in 6-month intervals up to a 100-µg daily dose following 2–3 years of therapy.<sup>547</sup>

**Oocyte donation offers the possibility of pregnancy to patients with Turner syndrome, but the cardiovascular demands of pregnancy pose unique and potentially serious risks that must be carefully considered. The risk of death during pregnancy is increased as much as 100-fold, primarily due to complications of aortic dissection or rupture.** Risk is greatest for those with preexisting abnormalities such as a bicuspid aortic valve or a dilated aortic root, but even those without such findings remain at risk. Consequently, Turner syndrome generally should be regarded as a relative contraindication to pregnancy. Those expressing serious interest in oocyte donation must receive thorough evaluation and counseling, and those having any significant cardiac abnormality should be strongly discouraged.<sup>548</sup>

## **47,XXY (Klinefelter Syndrome and Variants)**

Klinefelter syndrome is the most common congenital cause of hypogonadism in males, affecting approximately 1 in 1,000 male births.<sup>549,550</sup> The most common karyotype associated with the disorder is 47,XXY, but additional X chromosomes (e.g., 48,XXXY) and mosaics (e.g., 46,XY/47,XXY) also have been described.<sup>551</sup> Klinefelter syndrome results from nondisjunction of the sex chromosomes of either parent during meiosis; mosaics likely result from mitotic nondisjunction.

The phenotype of men with Klinefelter syndrome varies with the number of extra X chromosomes.<sup>551</sup> The gonads are almost always small and firm and sperm production usually is severely decreased. Serum testosterone concentrations generally are low, causing decreased virilization, and gonadotropin levels are elevated.<sup>552</sup> The body habitus exhibits long arms and legs, due both to a long bone abnormality and the influence of testosterone deficiency, and a short trunk. Affected patients also commonly exhibit a variety of psychosocial problems unrelated to hypogonadism.<sup>553,554,555</sup> The prevalence of pulmonary disease, breast<sup>556</sup> and mediastinal cancers,<sup>557</sup> varicose veins, and diabetes is increased in patients with Klinefelter syndrome.<sup>558</sup> Their mortality from breast cancer is higher than in the general population, and that from prostate cancer is lower.<sup>559</sup>

**Diagnosis of Klinefelter syndrome is made by karyotype.** Hypogonadism can be treated effectively with testosterone. Fertility is possible via ICSI, even when there are no sperms in the ejaculate. In a substantial number of azoospermic men with Klinefelter syndrome, sperms can be obtained via testicular sperm extraction (TESE). However, the prevalence of sex chromosome hyperploidy and autosomal aneuploidies is increased

in sperms obtained from men with Klinefelter syndrome, compared to normal men, and those chromosomal errors might in some cases be transmitted to their offspring unless preimplantation or prenatal testing is performed.<sup>560</sup>

## **45,X/46,XY (Mixed Gonadal Dysgenesis)**

Mixed gonadal dysgenesis is a term used to describe asymmetrical gonadal dysgenesis, where one gonad can be identified as a testis and the other is a streak or absent altogether. The most common karyotype associated with the condition is 45,X/46,XY. The dysgenetic testis typically contains immature seminiferous tubules lined by immature Sertoli cells and primitive germ cells. Rarely, the gonad contains primitive sex cord-like structures, with or without germ cells, within an ovary-like stroma.<sup>561</sup>

The phenotype in mixed gonadal dysgenesis can vary widely, probably reflecting the relative proportions of 45,X and 46,XY cells in the gonadal ridge. **Typically, the genitalia are ambiguous, but also can be female or male.** Müllerian and wolffian duct development correspond with the character of the ipsilateral gonad.<sup>562,563</sup> In prepubertal children, basal serum testosterone and gonadotropin concentrations are normal and the testosterone response to exogenous hCG stimulation is highly variable. After puberty, patients exhibit varying degrees of virilization, depending on the level of testosterone production, and serum gonadotropin concentrations are elevated.<sup>563</sup> As might be expected, the incidence of gonadal tumors is relatively high (25%).

## **45,XX/46,XY (Chimerism)**

Chimerism is the term used to describe one body derived from the fusion of cells from both twins of a dizygotic pair. **All chimeras are, by definition, mosaics but are derived from two distinct zygotes rather than from a single zygote.**<sup>564</sup> Chimeras are not visibly different unless a developmental anomaly in one of the cell lines or sex discordance between the cell lines causes a visibly abnormal phenotype. Most known chimeras are discovered in one of two ways. One is random chance, when people with normal phenotypes are genotyped (e.g., as prospective transplant donors or recipients) and found to carry three or four alleles at multiple loci, instead of one or two.<sup>565,566,567,568</sup> Most of the other known chimeras are recognized because of a sex difference between their cell lines, resulting in anomalies of sexual anatomy, maturation, or function that spur the search for an explanation, leading to discovery of mixed cell lines.<sup>569,570</sup> Consequently, a predominance of abnormal sexual development can be expected in chimeras, due to ascertainment bias. The disturbance in sexual development presumably results from conflicting directions generated by sexually distinct gonadal cells during embryogenesis.

# DIAGNOSIS AND MANAGEMENT OF AMBIGUOUS GENITALIA

---

A newborn infant with ambiguous external genitalia presents a major diagnostic challenge and a social and medical emergency. The physicians involved must make an important decision regarding the sex of rearing. The evaluation must be organized and efficient to ensure that the appropriate gender is assigned, that potential life-threatening conditions are recognized, and that the necessary medical, surgical, and psychological interventions begin promptly. A multidisciplinary approach is essential, drawing on the expertise of specialists in neonatology, endocrinology, urology, genetics, psychology, and, if available, medical ethics.<sup>571</sup> Diagnostic procedures may delay the decision, but a period of delay is far better than a later reversal of sex assignment. Naming the child should be delayed until a gender is firmly assigned. Open communication with the parents and family is key, emphasizing initially that the team will work with them to make the best possible decisions and that the child can become a well-adjusted, functional member of society. Ideally, one member of the team should be designated to conduct discussions with the family.<sup>572</sup> Parental education, guidance, support, and ongoing communication with the family's primary care physician are essential.<sup>573,574</sup>

# Diagnostic Evaluation

The initial evaluation of an infant with ambiguous genitalia should include a thorough history, complete physical examination, abdominal/pelvic ultrasonography, a karyotype and FISH for SRY, and endocrine studies of adrenal and gonadal steroid secretion.

## History and Physical Examination

The history should focus on identifying any prenatal exposure to androgens or medications that might act as endocrine disruptors, maternal virilization during pregnancy, and any previously affected relatives, unexplained infant death, or consanguinity.

A careful physical examination cannot establish a diagnosis but can provide useful clues. The presence or absence of dysmorphic features or other anomalies should be noted because the finding usually excludes most forms of CAH and suggests a broader pattern of malformations characteristic of a trisomy (trisomy 21, 18, or 13) or a specific syndrome. Hyperpigmentation suggests high levels of ACTH as in CAH. A systematic examination of the genitalia should answer each of the following questions:

- **Are gonads palpable?** Palpation of the genital and inguinal regions is perhaps the most important part of the physical examination. Gonads in the inguinal regions or in scrotal folds are almost certainly testes.<sup>575</sup> Asymmetry of the gonads or genitalia suggests gonadal dysgenesis or the presence of both testis and ovary (ovotesticular DSD). **Gonads that are not palpable may be in the abdomen and can be ovaries or testes, but virilizing CAH must be excluded specifically.**
- **What is the length and diameter of the phallus?** Careful examination of the phallus may help differentiate between a penis and a clitoris. Whereas the penis has a midline ventral frenulum, the clitoris has two folds extending from its lateral aspects to the labia minora. The phallus should be measured from the pubic ramus (compressing any suprapubic fat) to the tip of the glans (excluding any excess foreskin) after stretching to the point of resistance; diameter should be measured at the midpoint. Measurements should be compared to established norms, which are adjusted for gestational age. In a term infant, normal penile length is 2.5 cm or greater and normal diameter is 0.9 cm or greater.<sup>576</sup> In normal neonates, clitoral length ranges between 2 and 6 mm and measurements greater than 9 mm are unusual.<sup>577,578</sup> Micropenis that is not accompanied by hypospadias can be caused by decreased testosterone production in utero or by growth hormone or gonadotropin deficiency. Clitoromegaly resulting from androgen exposure can be caused by maternal androgen exposure, CAH, or ovotesticular DSD.

- **What is the position of the urethral meatus?** The urethral meatus may be found anywhere along the ventral surface of the phallus or on the perineum. Hypospadias is almost always accompanied by chordee, which is a ventral curvature of the phallus resulting from a shortened urethra. A single opening at the base of the phallus can represent either an incompletely fused penile urethra (hypospadias) or a virilized urogenital sinus. In either case, the findings must be confirmed radiologically or by cystoscopy/vaginocopy.
- **Are the labioscrotal folds fused?** The findings can range widely from the unfused labia majora of a normal female, to varying degrees of posterior fusion, to a bifid scrotum, to a fully fused normal-appearing male scrotum. The anogenital ratio is defined by the distance from the anus to the posterior fourchette of the vagina, divided by the distance from the anus to the base of the clitoris.<sup>579</sup> A ratio greater than 0.5 suggests virilization and some degree of labioscrotal fusion. Once the karyotype is known, the extent of virilization can be further defined by comparison to established gender-specific standards<sup>139,580</sup> to more objectively document the genital phenotype.

## Imaging

Imaging with abdominal and pelvic ultrasonography can help to determine the location of the gonads and the presence or absence of a uterus. However, an infantile uterus can be difficult to image, even with MRI. Imaging is informative when it reveals a uterus but inconclusive when it does not. Although a retrograde urethrogram can be used, cystoscopy/vaginocopy generally is the best method for defining the urethral and vaginal anatomy.<sup>581</sup> Rarely, laparoscopy may be needed to confidently define the reproductive anatomy and to biopsy the gonads.

## Initial Laboratory Evaluation

The initial laboratory evaluation should include the following:

- Karyotype, to determine the chromosomal sex
- FISH, to determine the presence or absence of SRY
- Measures of adrenal and gonadal steroid secretion, including:
  - 17-OHP—rapidly excludes CAH due to 21-hydroxylase deficiency, a common cause of ambiguous genitalia that can be life-threatening.
  - Electrolytes—should be measured immediately and monitored at least daily until salt wasting can be excluded.
  - ACTH, cortisol, DHEA, 17 $\alpha$ -hydroxypregnenolone, and 11-desoxycortisol—identify less common causes of CAH caused by enzyme deficiencies other

than 21-hydroxylase deficiency.

# Differential Diagnosis

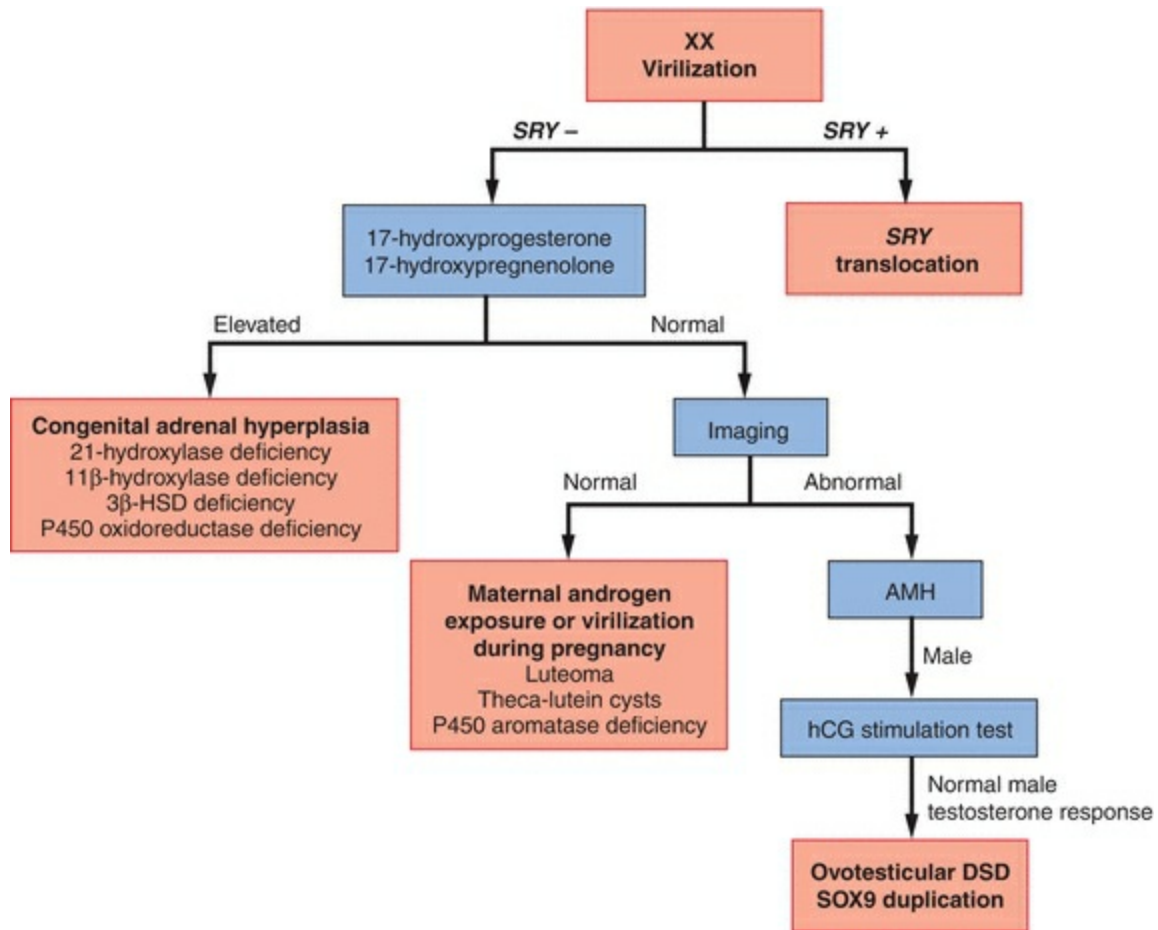

Based on the karyotype, the infant can be placed in one of three diagnostic categories: (1) XX virilization, (2) XY undervirilization, or (3) mixed sex chromosome pattern.<sup>115</sup>

## XX Virilization

The differential diagnosis of XX virilization includes disorders of gonadal (ovarian) development and androgen excess of fetal, fetoplacental, or maternal origin. FISH detection of SRY indicates an SRY translocation. In the absence of SRY, CAH is the most common diagnosis in XX virilized infants. An elevated serum 17-OHP or 17 $\alpha$ -hydroxypregnenolone concentration clearly suggests CAH. The most common cause, 21-hydroxylase deficiency, can be differentiated from other less common causes of CAH (11 $\beta$ -hydroxylase, 3 $\beta$ -HSD, and P450 oxidoreductase deficiencies) by the serum levels of ACTH, cortisol, DHEA, and 11-desoxycortisol, because each has a characteristic serum steroid hormone pattern (described in earlier sections of this chapter).

When CAH has been excluded, imaging revealing a uterus or a history of maternal androgen exposure or virilization during pregnancy points clearly toward maternal gestational hyperandrogenism (pregnancy luteoma, theca-lutein cysts) or P450 aromatase deficiency. Some of the remaining uncommon causes of XX virilization due to testicular DSD can be differentiated by measuring AMH (or inhibin B) and performing an hCG stimulation test (described below); male levels of AMH and a normal testosterone response to hCG indicate the presence of functional testicular tissue, suggesting the diagnosis of ovotesticular DSD or a SOX9 duplication<sup>127,582</sup> (**Figure 8.14**).

**FIGURE 8.14**

## XY Undervirilization

The differential diagnosis of XY undervirilization includes disorders of gonadal (testicular) development, disorders of androgen synthesis or action, LH receptor defects, and disorders of AMH and its receptor. The diagnostic evaluation for SRY-positive infants is challenging due to the large number of possible causes. In addition to the initial laboratory evaluation described above, XY undervirilized infants require further evaluation by measuring the serum LH, FSH, AMH, testosterone, androstenedione, and DHT concentrations. Gonadotropin and sex steroid levels should be measured when they normally are detectable, either in the first 24 hours after birth or between 2 and 6 months of age.<sup>583,584</sup> Provocative tests (ACTH stimulation test, hCG stimulation test) and other specialized tests also may be required to establish a diagnosis.

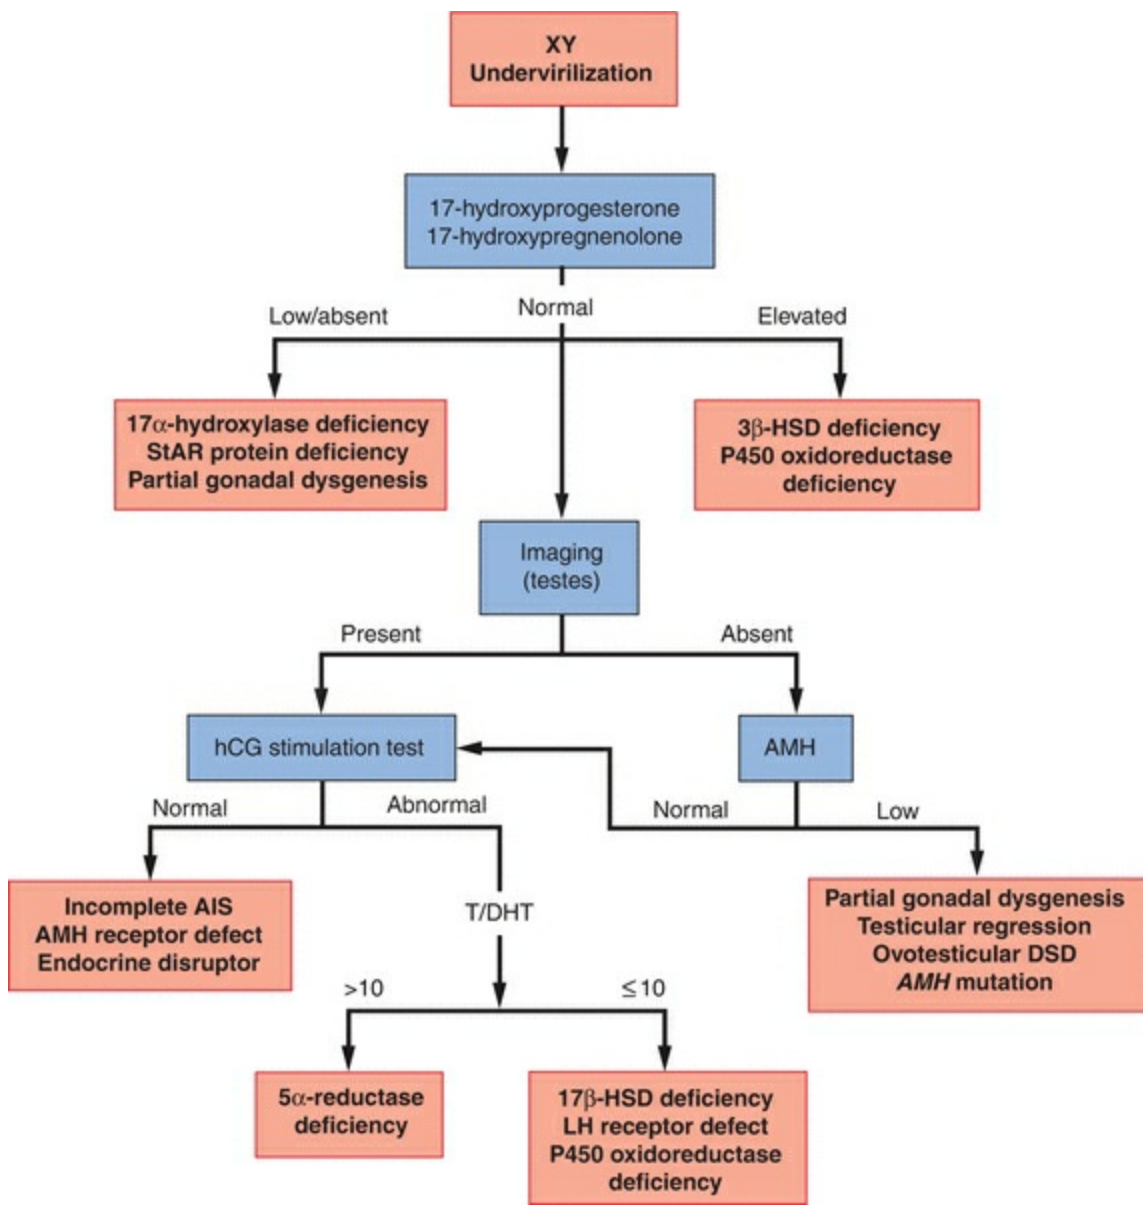

The serum concentrations of 17-OHP and 17 $\alpha$ -hydroxypregnenolone help to narrow the spectrum of diagnostic possibilities. Low or absent levels indicate a 17 $\alpha$ -hydroxylase or StAR protein deficiency or partial gonadal dysgenesis (SF1 mutation,

DAX1 duplication), and elevated levels point to a 3 $\beta$ -HSD or P450 oxidoreductase deficiency; an ACTH stimulation test can better demonstrate the different adrenal enzyme deficiencies<sup>585</sup> and also excludes adrenal insufficiency. The test involves measurements of serum ACTH, cortisol, progesterone, pregnenolone, 17-OHP, 17 $\alpha$ -hydroxypregnenolone, DHEA, and androstenedione before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 1 mg/m<sup>2</sup> or 0.25 mg)<sup>182</sup>; hormone values must be compared to age-adjusted normal ranges. The absence of any significant steroidogenic response suggests partial gonadal dysgenesis due to a StAR deficiency, an SF1 mutation, or a DAX1 duplication. Normal 17-OHP and 17 $\alpha$ -hydroxypregnenolone concentrations require additional evaluation.

AMH (or inhibin B) is a marker of Sertoli cell mass and identifies patients having functional testicular tissue, even when the testes cannot be imaged.<sup>586</sup> A low serum AMH level suggests a form of partial gonadal dysgenesis, testicular regression syndrome, ovotesticular DSD, or an AMH mutation. Those with AMH mutations typically have normal male external genitalia, variable testicular descent, and persistent müllerian ducts. When the serum AMH level is normal or imaging reveals testes, disorders of androgen synthesis (steroid 5 $\alpha$ -reductase, 17 $\beta$ -HSD, and P450 oxidoreductase deficiencies), LH receptor defects, incomplete androgen insensitivity, and AMH receptor defects must be considered. In patients with steroid 5 $\alpha$ -reductase deficiency, the testosterone/DHT ratio typically is greater than 10. In those with 17 $\beta$ -HSD deficiency, the serum testosterone concentration often is in the lower normal range, but the serum androstenedione level is elevated severalfold and the testosterone/androstenedione ratio usually is less than 0.8.<sup>587</sup> In patients with LH receptor defects, LH levels are high, testosterone concentrations are low, and androstenedione levels are not elevated. An hCG stimulation test helps to better define and distinguish suspected enzyme deficiencies from incomplete androgen insensitivity and LH receptor defects. The test involves measurements of serum hCG, LH, FSH, testosterone, androstenedione, and DHT on days 1 (basal), 3, and 6, with exogenous hCG (1,500 IU/m<sup>2</sup>) administered on days 1 and 3. A normal response is a twofold increase in the testosterone level on day 3 and a fourfold rise on day 6, a testosterone/DHT ratio less than 10,<sup>366</sup> and a testosterone/androstenedione ratio greater than 0.8.<sup>587</sup> However, because endocrine evaluation may not distinguish clearly between patients with 17 $\beta$ -HSD deficiency and those with LH receptor defects, genotyping may be required to establish the correct diagnosis.

In patients exhibiting normal basal and stimulated androgen levels, the remaining possibilities include incomplete androgen insensitivity, an AMH receptor defect, and prenatal exposure to an endocrine disruptor. Sequencing of the AR gene will identify some, but not all, patients with incomplete AIS; a demonstrable mutation will be found

in fewer than half of those in which the diagnosis is suspected,<sup>464</sup> and other possibilities (e.g., SF1 mutation) must then be considered. Those having an AMH receptor mutation typically have normal male external genitalia and cryptorchid testes. Occasionally, ambiguous genitalia may result from prenatal exposure to phenytoin, phenobarbital, or an environmental exposure<sup>588</sup> (Figure 8.15).

**FIGURE 8.15**

### Mixed Sex Chromosome Pattern

The differential diagnosis of a mixed sex chromosome pattern includes only a few disorders associated with genital ambiguity, such as mixed gonadal dysgenesis,

ovotesticular DSD, and chimerism. Patients with mixed gonadal dysgenesis typically exhibit external genital asymmetry, and those with ovotesticular DSD generally can be expected to have a low serum AMH level.

# Clinical Management of Children with Ambiguous Genitalia

The management of children born with ambiguous genitalia focuses initially on stabilization, averting the possibility of adrenal crisis in infants with salt-wasting forms of CAH being the most urgent medical issue. Thereafter, management decisions regarding the sex of rearing must consider a great many interacting and sometimes conflicting factors. Recent years have witnessed a growing appreciation for the complexities of psychosexual development, which reflects the influence of genes, societal and cultural norms, and family dynamics, and the effects of prenatal androgen exposure on sexual differentiation of the brain. Consequently, the wisdom of traditional management paradigms, in which sex assignment has been based primarily on the potential for reproduction and traditional sexual function, has come into question.<sup>589,590,591</sup>

## Stabilization

**CAH is the most common cause of 46,XX disorders of sexual development, one of the causes of 46,XY disorders of sexual development, and can be life-threatening. Consequently, infants with ambiguous genitalia and no palpable gonads should be assumed to have CAH and treated empirically until the diagnosis is confirmed or excluded.** If CAH is not promptly and effectively treated, hypoglycemia and symptoms of salt wasting (vomiting, diarrhea, hypovolemia, hyperkalemia, and cardiovascular collapse) can occur anytime within the first few days and weeks of life. The treatment of infants with classical forms of CAH is described in detail in an earlier section of this chapter and is only summarized here. Initial treatment includes fluid administration (5% dextrose in 0.9% saline), correction of any electrolyte abnormalities, and administration of stress doses of steroids. Patients with a confirmed diagnosis of CAH will require careful monitoring of electrolytes (hyperkalemia usually is the first indication of impending adrenal crisis), prompt treatment with adequate doses of hydrocortisone (which has some mineralocorticoid activity), and treatment with mineralocorticoids once stable and feeding normally.

## Family Counseling

Initial discussions should focus on helping the parents to gain a basic understanding of the causes of ambiguous genitalia, first explaining that the genitalia are not fully formed or are overdeveloped, and providing additional, more detailed information in accordance with the family's intellectual and emotional capacity and considering their cultural and religious background. Until the diagnosis and sex of rearing have been

established, birth announcements describing gender should be postponed, requiring careful and sensitive counseling. If the family inquires, matters relating to long-term reproductive function and sexuality should be discussed openly and frankly.

## Gender Decisions

In some cases, the decision is relatively straightforward, such as in mildly virilized girls with CAH. However, in many, the influence of sex assignment and rearing on ultimate gender identity cannot be predicted confidently, primarily because there are few data regarding long-term outcomes to guide the decision.<sup>592,593,594</sup>

**Traditional approaches have focused on early gender assignment and reconstructive surgery, but many now advocate postponing surgery until the patient can participate in the decision, when possible.**<sup>595</sup> The traditional approach was based on the assumptions that gender identity reflects gender assignment and the sex of rearing and can be imposed; that preservation of fertility (if possible), sexual function, and appearance should be the primary goals; and that a good anatomical result will translate to a healthy adaptation and patient satisfaction. Consequently, virilized female infants were assigned a female sex and underwent staged genital reconstruction during infancy, and undervirilized boys often were managed similarly, based on judgments regarding the feasibility of constructing a penile urethra.<sup>596</sup> These traditional principles were promulgated by the American Academy of Pediatrics as recently as 2000,<sup>597</sup> but an international (American and European) consensus conference conducted in 2006 has questioned their wisdom,<sup>115</sup> citing the lack of evidence that early genital surgery effectively reinforces gender assignment or influences gender identity or that genital appearance directs gender role decisions in adults. Vocal advocates have argued passionately that reconstructive surgery should be delayed until the patient can participate in the decision, but whether most affected adults agree is unknown.

Available data from long-term studies reflecting the traditional approach to gender assignment must be interpreted cautiously, because many of the most discontented affected adults may have declined to participate. Studies involving patients who had early feminizing surgery indicate that many had a poor cosmetic result and most required further surgery<sup>598</sup> and that sexual dysfunction is common among women who underwent clitoral surgery as infants or children.<sup>599</sup> Surgical techniques have improved,<sup>600,601</sup> but long-term outcomes remain uncertain. Two studies of long-term psychosocial outcomes in patients with 46,XY DSD found that half were living as men and half as women and that the two groups did not differ in satisfaction with their appearance, function, or sex of rearing.<sup>451,602</sup> Most patients assigned a female gender were satisfied with their sex of rearing, but only half had exclusively heterosexual

interests. Overall, half felt they did not have adequate information about their medical histories.<sup>451,602</sup> Whereas these data suggest that early gender assignment based on appearance usually results in a healthy psychosocial adjustment and outcome, the studies focused primarily on patients having limited potential for virilization. In contrast, patients having significant potential for virilization, such as those with steroid 5 $\alpha$ -reductase or 17 $\beta$ -hydroxysteroid dehydrogenase deficiencies, do not readily accept female gender assignment.<sup>603</sup>

Currently, there are no universally accepted guidelines for gender assignment. The Consensus Statement on the Management of Intersex Disorders offered numerous specific conclusions and recommendations.<sup>115</sup> Guidelines published by another group separate decisions regarding gender assignment from those regarding genital surgery.<sup>604</sup> The Intersex Society of North America, a peer support, education, and advocacy group founded and operated by and for intersexuals also has published recommendations, emphasizing the importance of avoiding harmful or unnecessary surgery, qualified professional mental health care for the child and family, and empowering patients by helping them to understand their condition and to choose or decline medical interventions.

Although expert opinions and recommendations vary, the guiding principles can be summarized as follows:

- Gender assignment and sex of rearing should be based on the most probable adult gender identity and the potential for adult function.
- Decisions should respect the family's own values and preferences.
- Children should be raised in the predicted and selected gender role but should also participate actively in longer-term gender decisions.

There is general agreement on some issues. Almost all virilized 46,XX children with CAH should be raised as females, primarily because more than 90% identify as females as adults, and 46,XX infants having essentially normal male external genitalia probably should be raised as males. When female gender is assigned, clitoral surgery probably is best delayed until the child expresses gender identity and can participate in the decision. When male gender is assigned, phallic reconstruction can be performed at a time acceptable to the family and to the surgeon while still permitting a later change in gender decision by the adult patient. Finally, purely cosmetic surgery should be postponed until the patient can participate in the decision.

## **Long-Term Care**

Patients with DSD and their families should receive ongoing support to help in their

psychosexual development. Support groups offer many affected patients useful information and insights and include the Intersex Society of North America ([www.isna.org](http://www.isna.org)), the Androgen Insensitivity Syndrome Support Group ([www.aissg.org](http://www.aissg.org)), Bodies Like Ours ([www.bodieslikeours.org](http://www.bodieslikeours.org)), and The Magic Foundation ([www.magicfoundation.org](http://www.magicfoundation.org)).

Patients having all or part of a Y chromosome whose gonads are located in the abdomen are at significant risk for developing a gonadal tumor. Consequently, they should be removed or, when possible and appropriate, moved to the scrotum, soon after diagnosis, except in those with complete AIS, in whom surgery generally is best postponed until after puberty.

Long-term care also must consider the potential effects of sex steroid exposure, the possibility and effects of a changing hormone environment at puberty, and the need for timely and effective sex steroid therapy.

# Normal and Abnormal Growth and Pubertal Development

In many societies throughout history, puberty has been a time of celebration. The changes that accompany puberty announce the transition from childhood to adulthood and the development of fertility. Puberty is the process of cognitive, psychosocial, and biologic maturation. Whereas growth and the development of secondary sexual characteristics are the most visible manifestations of the onset of puberty, changes in body composition and cognitive development are no less significant.<sup>1</sup> Puberty can be a difficult transition for many adolescents, even when it progresses normally, and presents substantially greater challenges when its onset is premature or delayed. The recent trend toward an earlier pubertal maturation and some of its consequences, notably earlier sexuality and the problem of teen pregnancy, make it all the more important to understand the physiology of normal puberty.

This chapter focuses first on the endocrinology and physiology of normal puberty, to provide the foundation for subsequent discussion of the pathophysiology, diagnosis, and management of abnormalities of growth and pubertal development.

# THE ENDOCRINOLOGY OF NORMAL PUBERTY

---

The hypothalamus, anterior pituitary gland, and gonads of the fetus, neonate, infant, and prepubertal child are all capable of secreting hormones in adult concentrations. The key to understanding the endocrinology of puberty lies in first understanding the mechanisms that govern the hypothalamic-pituitary-gonadal axis.

# The Ontogeny of the Hypothalamic-Pituitary-Gonadal Axis

The “hypothalamic pulse generator,” the term chosen by Ernst Knobil to describe the rhythmic, pulsatile nature of gonadotropin-releasing hormone (GnRH) secretion,<sup>2</sup> consists of approximately 1,500–2,000 specialized neurosecretory cells in the arcuate nucleus, located in the medial basal hypothalamus. The resident GnRH neurons exhibit spontaneous “autorhythmicity” and function as an oscillator in the pulsatile secretion of GnRH.<sup>3,4</sup> In response to the pulsatile GnRH signal, pituitary gonadotropes, which contain plasma membrane GnRH receptors, secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH), also in a pulsatile manner. In turn, the episodic gonadotropin signal stimulates maturation of the germinal elements of the gonads and is transmitted into the pulsatile secretion of sex steroids. Ultimately, the patterns of gonadotropin and gonadal steroid secretion during fetal life, infancy, childhood, adolescence, and adulthood primarily reflect changes in the activity of the hypothalamic pulse generator.

## Fetal Life and Infancy

The hypothalamic-pituitary-gonadal axis becomes functional even before birth. Neurons that synthesize GnRH originate in the olfactory placode and migrate to the hypothalamus between 6 and 9 weeks of gestation.<sup>5</sup> By 10 weeks, the hypothalamus contains significant amounts of GnRH.<sup>6</sup> Development of the hypothalamic-pituitary portal venous system begins between 9 and 10 weeks of gestation and is completed by 19–20 weeks.<sup>7</sup> Consequently, FSH and LH concentrations in fetal pituitary glands increase dramatically soon thereafter. The pituitary begins to secrete FSH and LH into the fetal circulation by week 12.<sup>8</sup> Fetal serum gonadotropin levels rise progressively, reaching a peak between 20 and 24 weeks<sup>9</sup> and then decrease steadily over the last 10 weeks of pregnancy, probably due to a developed sensitivity to the negative feedback effects of high circulating estrogen and progesterone concentrations derived from the placenta.<sup>10,11</sup>

After birth, steroid levels fall precipitously due to the loss of maternal and placental hormones, allowing the newborn’s hypothalamic-pituitary-gonadal axis to escape their suppressive effects. The characteristic pulsatile pattern of hypothalamic GnRH secretion emerges,<sup>12,13</sup> and serum gonadotropin concentrations rise again promptly, with a striking sex difference; FSH rises to a greater extent in females and LH to a greater extent in males.<sup>11</sup> In female infants, FSH concentrations occasionally reach levels even greater than those observed in the normal adult menstrual cycle.<sup>14,15</sup> Consequently, waves of ovarian follicular development begin, and estradiol levels during the first few

months of life are comparable to those observed during the midfollicular phase of the menstrual cycle.<sup>16</sup> In male infants, elevated LH levels stimulate increased testosterone secretion from the testes. Gonadotropin and gonadal steroid levels peak at about 3–6 months in boys and 12–18 months in girls and steadily decline thereafter, presumably because normal negative feedback mechanisms become fully functional. By approximately 9–12 months of age in boys and 24–36 months in girls, gonadotropin concentrations fall to typical prepubertal levels, remaining at very low concentrations until the onset of puberty.<sup>11</sup> Suppression of hypothalamic pulse generator activity is less intense and shorter in duration in females than in males, probably reflecting the influence of testosterone on hypothalamic programming.<sup>17</sup>

## Childhood and Early Adolescence

During the interval between infancy and puberty, known as the “juvenile pause” in nonhuman primates, the hypothalamic-pituitary-gonadal axis lies dormant. Normal ovulatory menstrual cycles can be induced in prepubertal female monkeys by administering a higher-amplitude pulsatile infusion of exogenous GnRH, indicating that neither the anterior pituitary nor the gonads are the limiting factor.<sup>18</sup> Although the GnRH pulse generator is active, the frequency and amplitude of pulsatile GnRH secretion generally are irregular and very low.<sup>19,20,21,22</sup> Low-amplitude pulses of gonadotropin secretion can be detected in prepubertal children as young as 5 years of age, primarily during sleep.<sup>22,23,24</sup> FSH levels rise more than LH, but there is no detectable increase in steroid hormone concentrations.

For a long time, the prevailing theory to explain the juvenile pause that precedes puberty envisioned a hypothalamic “gonadostat” controlling the level of sensitivity to the central negative feedback actions of gonadal steroids. In that context, the changing patterns of gonadotropin secretion were attributed to changes in the “gonadostat” setting. Decreasing gonadotropin levels in late infancy and sustained low concentrations during childhood reflected a rising and ultimately high sensitivity to even very low levels of sex steroid feedback, and increasing gonadotropin concentrations at the onset of puberty reflected a decrease in feedback sensitivity.<sup>25,26</sup> The “gonadostat” theory prevailed until cross-sectional and longitudinal studies in children with gonadal dysgenesis revealed a similar, but exaggerated, “diphasic” pattern of gonadotropin secretion. Serum gonadotropin levels in girls with Turner syndrome are markedly elevated in infancy, decline to very low levels during childhood, and rise again to grossly high concentrations at pubertal age, all in the absence of any possible change in the level of negative feedback from gonadal steroids.<sup>27</sup> These and similar observations in castrate nonhuman primates demonstrated that steroid hormone feedback affects the amount, but not the pattern, of gonadotropin secretion, contradicting the traditional

“gonadostat” theory and establishing a new paradigm. The typical “diphasic” pattern of gonadotropin secretion from infancy to puberty results primarily from changing levels of central inhibition of pulsatile GnRH secretion and, to a lesser extent, from a high sensitivity to low levels of gonadal steroid feedback (Figure 9.1).

**FIGURE 9.1**

## Puberty

About 1 year before breast budding in prepubertal girls, the character of nocturnal pulses of gonadotropin secretion changes with LH levels exceeding those of FSH. Breast budding occurs when the nocturnal pulses of gonadotropin secretion become great enough to generate detectable coincident increases in serum estradiol concentrations. At that time, LH peak amplitude increases about 10-fold, whereas FSH pulse amplitude only doubles, resulting in a marked decrease in the serum FSH/LH ratio.<sup>22,24</sup> The change reflects an increase in pituitary responsiveness to GnRH, which has a priming effect on pituitary LH secretion and increases the number of GnRH receptors on gonadotropes (up-regulation). Gonadotropes first increase their capacity for response to GnRH by synthesis and later by secretion of gonadotropins. Pulse frequency also increases, but to a much lesser extent. Gonadotropin pulses become diurnal and the duration of increases in estradiol levels becomes more prolonged. As puberty progresses, the amplitude of pulsatile LH secretion increases further, to levels 20–40 times greater than those detected during prepubertal years, probably reflecting the influence of rising estradiol levels at both the hypothalamic and pituitary levels. Although nocturnal pulse amplitudes are still greatest, significant pulses occur during daytime, and basal LH levels become detectable.<sup>22</sup> LH bioactivity also increases, due to changes in glycosylation.<sup>28</sup>

In response to increasing gonadotropin secretion, basal estradiol levels increase progressively.<sup>20</sup> Inhibin B levels, which are low or undetectable in prepubertal girls, increase sharply in midpuberty and then decline in its later stages, first reflecting increasing ovarian stimulation and then the onset of the menstrual cycle and the appearance of a luteal phase, when levels are low.<sup>29</sup> Inhibin A concentrations, undetectable or very low through early puberty, increase gradually thereafter but reach adult levels only after menarche, consistent with the corpus luteum being the primary source.<sup>29</sup> Menarche occurs in late puberty, after a yearlong rise in daily estrogen production,<sup>30</sup> probably when estradiol and inhibin B levels become sufficient to exert significant negative feedback on gonadotropin secretion, resulting in cyclic estrogen production. Cycle length and menstrual characteristics vary until the positive feedback relationship between estradiol and gonadotropin secretion matures and ovulation becomes established, often a year or more after menarche.

## Central Control Mechanisms

Some of the factors governing the “neuroendocrine switch” for the GnRH pulse generator that is “on” in early infancy, turns “off” during childhood, and switches back “on” again at puberty have now been identified. Most of the important work on the neuroendocrinology of puberty has been performed in nonhuman primate models. The list of factors that modulate the activity of the hypothalamic-pituitary-gonadal axis includes both inhibitory and excitatory neurotransmitters and peptides.

## Gamma-Aminobutyric Acid

Gamma-aminobutyric acid (GABA) is an inhibitory neurotransmitter produced by specialized neurons in the hypothalamus and has an important role in regulating the activity of the GnRH pulse generator. Elegant hypothalamic perfusion studies have revealed that the release of GABA into the median eminence decreases as pulsatile GnRH secretion increases at the onset of puberty.<sup>31</sup> Conversely, central perfusion with a GABA<sub>A</sub> receptor antagonist (bicuculline) or the antisense oligodeoxynucleotide for the mRNA coding the GABA<sub>A</sub>-synthesizing enzyme (glutamate acid decarboxylase) stimulates GnRH release.<sup>31,32</sup> Chronic administration of bicuculline into the third ventricle induces precocious puberty and menarche in prepubertal female monkeys.<sup>33</sup> Evidence suggests that changes in the subunit composition of GABA<sub>A</sub> receptors may contribute to the disinhibition of pulsatile GnRH secretion at the onset of puberty.<sup>34</sup> These observations suggest that central GABA signaling is one of the factors that restrains GnRH neuronal activity during childhood.

## Neuropeptide Y

Neuropeptide NPY (NPY) is a hypothalamic peptide involved in the control of food intake behavior and reproductive function in adults. In castrate adult female monkeys, intracerebroventricular administration of NPY inhibits pulsatile GnRH release.<sup>35</sup> In males, the postnatal pattern of GnRH pulse generator activity is inversely related to NPY gene and protein expression in the medial basal hypothalamus, and central administration of an NPY receptor antagonist stimulates GnRH release in juveniles.<sup>36</sup> These observations suggest that NPY, like GABA, is an important component of the “neurobiologic brake” that restrains the GnRH pulse generator in prepubertal primates. However, others have observed that NPY levels increase in the median eminence at the onset of puberty,<sup>37</sup> that infusion of NPY into the median eminence increases GnRH release,<sup>38</sup> and that infusion of NPY antiserum into the median eminence did not stimulate GnRH secretion in prepubertal monkeys.<sup>37</sup> The varying effects of NPY appear to relate to the site of infusion within the brain and not on the steroid milieu.<sup>35</sup> Additional work will be required to clarify the role of NPY in the regulation of the hypothalamic pulse generator and the onset of puberty.

## Glutamate

Glutamate is an excitatory neurotransmitter in the hypothalamus and stimulates GnRH release via N-methyl-D-aspartate (NMDA) receptors both in vivo and in vitro.<sup>39</sup> An intravenous bolus of NMDA stimulates hypothalamic GnRH release,<sup>40</sup> and treatment with a specific glutamate receptor antagonist blocks the effect in nonhuman primates. Moreover, prolonged (16–30 weeks) intermittent NMDA stimulation (1 minute every 3 hours) activates the hypothalamic-pituitary-gonadal axis and stimulates precocious puberty and the initiation of spermatogenesis in juvenile males.<sup>41</sup> These observations suggest that glutamate signaling may play a role in the resurgence of pulsatile GnRH secretion at the onset of puberty.

## Kisspeptins

In just the past few years, kisspeptins have emerged as a critical component of the system that controls the level of GnRH neuronal activity between infancy and puberty. Kisspeptins are neuropeptides (encoded by the *KISS1* gene) that signal via the G-protein-coupled receptor, GPR54 (encoded by the *KISS1R* gene).<sup>42</sup> Interestingly, the first evidence of their importance in the regulation of the hypothalamic-pituitary-gonadal axis came from observations in humans. Several members of a large consanguineous family with hypogonadotropic hypogonadism and delayed puberty were found to harbor homozygous inactivating mutations for GPR54.<sup>43,44</sup> One affected compound heterozygote

exhibited an exaggerated pituitary response to exogenous pulsatile GnRH administration, suggesting a hypothalamic locus for the disorder.<sup>44</sup> More importantly, the observation also suggested that kisspeptin signaling via GPR54 might play a major role in the resurgence of pulsatile GnRH secretion at puberty in primates. The results of subsequent studies in nonhuman primates and humans strongly support that interpretation.

Neurons expressing KISS1 are located exclusively in the arcuate nucleus,<sup>45,46</sup> where GnRH neurons also express GPR54.<sup>42</sup> Kisspeptin release appears to be regulated by neurokinin B and dynorphin, which are coproduced by the same neurons in this region of the brain.<sup>47</sup> In castrate male and intact female monkeys, the pubertal resurgence of pulsatile GnRH secretion is associated with a nearly fivefold increase in KISS1 expression and, in females, also with an increase in KISS1R expression.<sup>48</sup> Hypothalamic kisspeptin secretion is distinctly pulsatile and highly correlated with that of GnRH.<sup>49</sup> An intermittent kisspeptin infusion can sustain pulsatile LH secretion in castrate juvenile animals after discontinuation of a priming pulsatile infusion of exogenous GnRH, but not in the presence of a GnRH receptor antagonist, indicating that the effect of kisspeptin is mediated via pulsatile GnRH secretion.<sup>48</sup> The observation that patients with inactivating mutations of GPR54 exhibit pulsatile LH secretion with low amplitude and normal frequency suggested that kisspeptin might only amplify and not stimulate GnRH pulse generator activity directly.<sup>44,50</sup> However, a continuous kisspeptin infusion, which down-regulates GPR54, suppresses both LH pulse amplitude and frequency, implying that kisspeptin has similar effects on pulsatile GnRH secretion.<sup>51,52</sup> Finally, an activating KISS1R mutation resulting in prolonged activation of the KISS1R signal transduction pathway has been described in a young girl with GnRH-dependent (central) precocious puberty.<sup>53</sup> **Taken together, these observations indicate that hypothalamic kisspeptin-GPR54 signaling is a key component of the neurobiologic mechanism that triggers the onset of puberty. They further suggest that kisspeptin neurons may provide the fuel for the hypothalamic GnRH pulse generator.** The report of undetectable serum gonadotropins in an infant boy bearing a loss-of-function mutation in the KISS1R gene suggests that kisspeptin input to the GnRH neuronal network also is necessary for the increased pulsatile GnRH secretion normally observed during early infancy.<sup>54</sup>

There is increasing evidence from studies in nonhuman primates that kisspeptin neurons also are involved in mediating the feedback actions of both testicular and ovarian hormones. In males, testosterone negative feedback, which regulates LH secretion by slowing the pace of pulsatile GnRH secretion,<sup>55</sup> is associated with a decrease in hypothalamic KISS1 mRNA levels.<sup>56</sup> The observation suggests that

kisspeptin neurons play an important role in the negative feedback loop that regulates LH secretion in the male, which also involves opioid and GABA neuronal input.<sup>57</sup> Gonadal steroids also suppress hypothalamic KISS1 expression in females. In postmenopausal women and ovariectomized monkeys, the density of neurons expressing KISS1 mRNA is significantly higher than in premenopausal women and in intact female monkeys, and treatment with estrogen and progesterone markedly decreases KISS1 expression,<sup>46</sup> suggesting that kisspeptin neurons also participate in mediating the hypothalamic negative feedback actions of ovarian steroid hormones. **The collective body of evidence thus indicates that kisspeptin neurons are a critical component of the neurobiologic mechanism that regulates the activity of the hypothalamic pulse generator.**

In some way, the system that controls the ontogeny of pulsatile GnRH secretion integrates kisspeptin signaling with that of other neurotransmitters (glutamate, GABA) and neuropeptides (NPY). Whether kisspeptin neurons in the arcuate nucleus function by tracking growth as a “pubertal clock” or simply relay information from such centers to the GnRH neuronal network is unknown.<sup>58</sup> Regardless, kisspeptin neurons have emerged as one of the primary transducers of the internal and external environmental cues that regulate the neuroendocrine reproductive axis.

## Peripheral Signaling

The age at onset of puberty has been declining steadily as the prevalence of obesity has been increasing, suggesting that a critical body weight<sup>59</sup> or body composition<sup>60</sup> may be an important factor in determining the timing and progression of puberty.<sup>61</sup> Conversely, the suppressive effects of fasting<sup>62,63</sup> and chronic malnutrition<sup>64</sup> on the neuroendocrine control of reproduction are well known and consistent with the hypothesis. The manner in which such metabolic signals might be communicated and integrated with the reproductive axis in primates is unknown, but studies in ungulates suggest an effect on pulsatile hypothalamic GnRH secretion.<sup>65</sup>

## Leptin

Leptin is produced by adipocytes and serum concentrations are strongly associated with body fat and changes in body fat content. Not surprisingly, leptin has been implicated as one way in which metabolic signals might be communicated to the higher centers controlling the activity of the hypothalamic pulse generator at the onset of puberty.

Leptin-deficient mice and rats fail to enter puberty, and treatment with leptin induces the onset of puberty.<sup>66</sup> Studies in transgenic mice in which the leptin receptor (LEPR) has been knocked out of GABAergic and glutamatergic neurons via Cre/Lox

recombination showed decreased fecundity in mice with changes in GABAergic neurons, but not in glutamatergic neurons. Furthermore, this influence on GABA signaling affects the onset of puberty, as well as the regulation of fertility throughout adult life.<sup>67,68</sup>

In humans, serum leptin concentrations in boys and girls diverge at puberty. In males, leptin levels first increase and then decrease again to prepubertal concentrations, whereas in females leptin concentrations rise throughout puberty.<sup>69,70</sup> One study found that serum leptin levels were directly related to the amount of subcutaneous fat and inversely related to androgen levels.<sup>71</sup> Another in girls observed that an increase in the mean serum leptin concentration to 12.2 ng/mL, corresponding to 29.7% body fat and a body mass index (BMI) of 22.3, was associated with a decrease in age at menarche and that a 1 ng/mL increase in serum leptin lowered the age at menarche by 1 month.<sup>72</sup>

Evidence from studies in children with congenital leptin deficiency has provided insights into the potential importance of leptin as a somatic stimulus for the onset of puberty. In affected pubertal age children, treatment with recombinant leptin has been associated with endocrine changes consistent with the onset of puberty, whereas all adults with congenital leptin or LEPR deficiency described have had severe hypogonadotropic hypogonadism.<sup>73</sup> However, similar treatment in younger children has not induced premature puberty.<sup>74</sup> These clinical observations suggest that leptin plays an important, but only permissive, role in the onset of puberty. Nonetheless, they are consistent with the idea that a circulating somatic hormone might have the ability to influence or modulate the activity of the hypothalamic GnRH pulse generator.<sup>17</sup>

## **Other Candidate Metabolic Signals**

Numerous other metabolic signals have been suggested as playing a role in the nutritional regulation of reproduction, such as insulin, ghrelin (the endogenous ligand of the growth hormone [GH] secretagogue with a putative role in energy balance),<sup>75</sup> galanin-like peptide (a potential neuronal target of leptin),<sup>76</sup> and free fatty acids.<sup>77</sup> Recent work has suggested that ghrelin suppresses kisspeptin secretion in the arcuate nucleus and anteroventral periventricular area. Neuropeptide Y and pro-opiomelanocortin (POMC) may also have a role in kisspeptin secretion (the role of these hormones in feeding behavior is discussed in [Chapter 19](#)).<sup>78</sup> However, the manner in which these signals might interact with inhibitory and excitatory hypothalamic neurotransmitters and peptides and any role they may have in the onset of puberty remain to be established.

# THE PHYSIOLOGY OF NORMAL PUBERTY

---

Although the timing, sequence, and pace of pubertal maturation vary among individuals, the sentinel events of puberty generally follow a predictable pattern. **Adrenarche** describes the activation of adrenal androgen secretion that begins before puberty and ultimately stimulates **pubarche**, the appearance of pubic hair. **Gonadarche** describes the activation of the hypothalamic-pituitary-gonadal axis, which facilitates the pubertal growth spurt and stimulates **thelarche**, the appearance of breast tissue, and finally **menarche**, the onset of menses.

# Adrenarche

Adrenarche is the term used to describe the increase in adrenal androgen production that begins at approximately 6 years of age in both boys and girls.<sup>79,80</sup> **Although adrenarche is independent of the maturation of the hypothalamic-pituitary-gonadal axis, the two often are temporally related.**<sup>81</sup> The increase in adrenal androgen production results from a change in the adrenal response to adrenocorticotrophic hormone (ACTH) stimulation, characterized by a shift toward increased production of  $\Delta^5$ -3 $\beta$ -hydroxysteroid intermediates (17-hydroxypregnenolone; dehydroepiandrosterone, DHEA) and decreased production of  $\Delta^4$ -ketosteroids (17 $\alpha$ -hydroxyprogesterone, 17-OHP; androstenedione), with no change in cortisol secretion.<sup>82</sup> Consequently, an increase in serum DHEA sulfate (DHEA-S) levels heralds the onset of adrenarche. **Generally, the best indicator of adrenarche is a serum DHEA-S concentration greater than 40  $\mu\text{g}/\text{dL}$ , which is higher than that normally seen in children 1–5 years of age (5–35  $\mu\text{g}/\text{dL}$ ).**

Adrenal androgens derive from the zona reticularis, the innermost layer of the adrenal cortex,<sup>83</sup> which begins to form at approximately 3 years of age and becomes well defined coincident with the increase in DHEA-S production at adrenarche. The molecular mechanisms that govern adrenal cortical differentiation involve a variety of different genes, but little is known about their transcriptional regulation.<sup>84</sup> The zona reticularis exhibits a unique enzymatic profile. The activity of 3-hydroxysteroid dehydrogenase/  $\Delta^5$ - $\Delta^4$  isomerase (3 $\beta$ -HSD), which catalyzes the oxidation and isomerization of  $\Delta^5$ -3 $\beta$ -hydroxysteroid precursors into  $\Delta^4$ -ketosteroids, is low.<sup>85</sup> In contrast, the activities of P450c17, including both 17 $\alpha$ -hydroxylase (catalyzing the conversion of pregnenolone to 17-hydroxypregnenolone) and 17,20 lyase (catalyzing the conversion of 17-hydroxypregnenolone to DHEA), are high, as is steroid sulfotransferase activity.<sup>86</sup> Cytochrome b5, which facilitates 17,20 lyase activity, also is preferentially expressed.<sup>87</sup> Taken together, the enzyme profile of the zona reticularis favors the formation of DHEA and DHEA-S.

**The primary stimulus for adrenarche is unknown.** Although ACTH is an obvious candidate, circulating levels of adrenal androgens change without any corresponding changes in ACTH or cortisol during fetal life, puberty, and with aging. In other conditions such as chronic disease, surgical stress, recovery from secondary adrenal insufficiency, and anorexia nervosa, changes in ACTH-induced cortisol secretion are not accompanied by any change in serum adrenal androgen concentrations.<sup>88</sup> Although derivatives of POMC (produced by pituitary corticotropes)<sup>89</sup> and other pituitary-dependent factors have been implicated,<sup>90</sup> conclusive evidence for an adrenal androgen-

stimulating hormone is lacking.<sup>91,92</sup> Whatever the stimulus might be, it might act to spur the growth and differentiation of the zona reticularis, which may derive from cells originally contained within the “fetal zone” of the adrenal cortex having a unique enzymatic profile (described above). Alternatively, it might act by suppressing 3 $\beta$ -HSD<sup>85</sup> or by stimulating the 17,20 lyase activity of P450c17.<sup>86</sup> Interleukin-6 has been implicated as a mediator because it is highly expressed in the zona reticularis and can stimulate DHEA secretion.<sup>93</sup> Leptin also has been implicated, because adrenarche coincides with the preadolescent increase in body fat<sup>94</sup> and leptin levels<sup>95</sup> and leptin stimulates 17,20 lyase activity.<sup>96</sup> However, the temporal linkage between adrenarche and increasing body fat also might result from a compensatory hyperinsulinemia or from activation of the GH/insulin-like growth factor 1 (IGF-1) axis.<sup>97</sup>

The steady increase in adrenal androgen secretion after adrenarche ultimately stimulates **pubarche**, the appearance of pubic hair, and also the development and activity of the pilosebaceous unit, consisting of a hair follicle and sebaceous gland.<sup>98</sup> Adrenal androgen levels correlate with changes in bone density, suggesting they also may contribute to growth in cortical bone.<sup>99</sup> If adrenarche has any more fundamental role in the onset of puberty, the mechanism is unknown. **Adrenarche generally precedes activation of the hypothalamic-pituitary-gonadal axis, or gonadarche, by approximately 2–3 years.** The temporal relationship suggests that adrenal androgen secretion might stimulate the pubertal transition, but several lines of evidence indicate otherwise. First, premature adrenarche generally is not associated with an earlier onset of thelarche or menarche. Second, adrenarche occurs in those with congenital hypergonadotropic hypogonadism (e.g., gonadal dysgenesis) or hypogonadotropic hypogonadism (e.g., Kallmann syndrome). Third, gonadarche occurs in children with Addison disease (hypoadrenalism) treated with glucocorticoids. Finally, in children under age 6 with true precocious puberty, gonadarche precedes adrenarche.

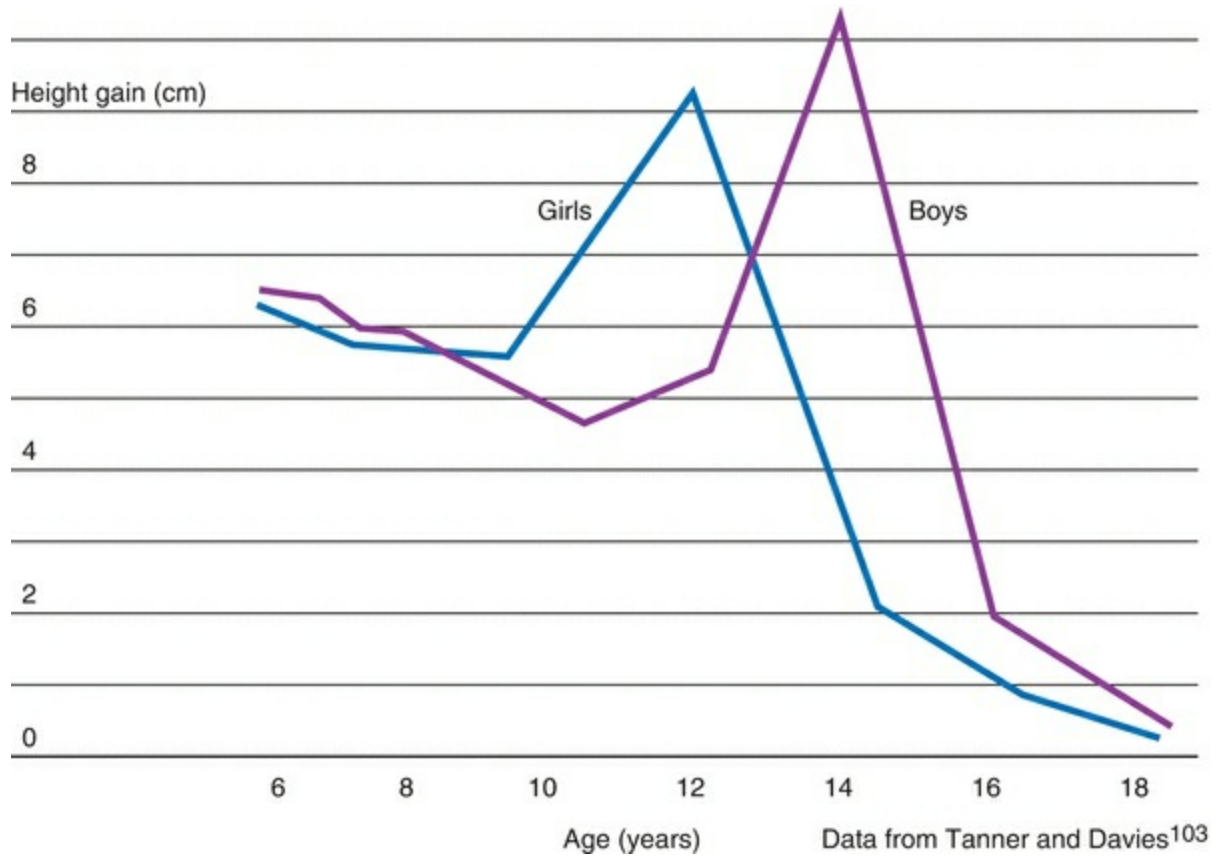

# Growth

**A substantial proportion of adult height, about 17–18%, is gained during puberty.<sup>100</sup>** Growth of the limbs precedes that of the trunk, beginning in the distal portions and later also involving the proximal part of the limbs; growth of the trunk occurs primarily during later puberty.<sup>101</sup> **The pubertal growth spurt occurs approximately 2 years earlier in girls than in boys, and, in general, peak height velocity is reached approximately 6 months before menarche.<sup>102</sup>**

The difference in adult height of men and women relates to the onset and time of the growth spurt in boys and girls. Boys are approximately 2 cm taller than girls when girls reach their peak height velocity, grow 3–4 cm/year for another 1–2 years before entering puberty, and reach a greater peak height velocity (9.3 cm/year) than girls (9.0 cm/year).<sup>103</sup>

**Bone mass accumulation during puberty is critical to the development of peak bone mass, which is a major determinant of the risk for developing osteoporosis in later life.** Although genetics may be the most important determinant of peak bone mass, other factors such as nutrition and hormone exposure during puberty also contribute. About one-half of total body calcium is accrued during puberty in females and one-half to two-thirds in males.<sup>104,105</sup> **In girls, the peak velocity in bone mineral accretion occurs at menarche, approximately 9–12 months after peak height velocity is attained.<sup>106,107</sup>** The pubertal increase in bone density is greater in black females than in white females.<sup>108</sup> Taken together, these data suggest that the window of opportunity to maximize peak bone mass is relatively narrow.<sup>105</sup>

Weight changes during pubertal maturation reflect changes in body composition and the relative proportions of lean body mass and fat. Skinfold thickness decreases in early puberty and increases after peak height velocity, particularly in girls. Adolescent girls have more body fat than boys, most being deposited in the upper arms, thighs, and back; the gender difference increases throughout puberty. The increase in BMI before 16 years of age relates primarily to changes in fat-free mass and thereafter to an increase in fat mass.<sup>109</sup> If desired, BMI can be tracked from adolescence to adulthood using published tables for comparison by age and ethnicity<sup>110</sup> (**Figure 9.2**).

**FIGURE 9.2**

# Growth Hormone

GH, produced by somatotropes, is the pituitary hormone produced in greatest abundance. The GH gene family includes five distinct genes, all of which are located on chromosome 17 (17q22).<sup>111</sup> The pituitary GH gene (GH1) encodes two alternatively spliced mRNAs, yielding a predominant 22-kDa GH molecule and another 20-kDa molecule that accounts for approximately 10% of circulating GH. Placental syncytiotrophoblasts express a GH variant in addition to three other genes encoding human chorionic somatotropin, also known as human placental lactogen (discussed in [Chapter 7](#)). The regulation of pituitary GH secretion is highly complex. GH secretion is controlled primarily by hypothalamic GH-releasing hormone (GHRH) and by peripheral factors acting on somatotropes that stimulate (e.g., ghrelin)<sup>112</sup> or inhibit (e.g., somatostatin)<sup>113</sup> GH release.<sup>114,115,116</sup> Most of the peripheral actions of GH are mediated by insulin-like growth factor I (IGF-I), which inhibits GH release. Nutritional factors also play a role in the regulation of GH secretion; whereas fasting<sup>117</sup> and high-protein meals<sup>118</sup> stimulate GH release, hyperglycemia and leptin inhibit GH secretion.<sup>119</sup> Estrogens stimulate, and excess glucocorticoids inhibit GH release. **GH secretion peaks during puberty and declines with age, by approximately 50% every 7 years.**<sup>117</sup>

Like the gonadotropins, GH is secreted in a pulsatile fashion, and at the onset of puberty, GH pulse amplitude increases, especially during sleep.<sup>120</sup> Consequently, GH concentrations rise progressively. **The rate of the increase in circulating GH levels is the most important determinant of the pubertal growth rate; slower-growing children exhibit fewer and lower-amplitude GH pulses and a more gradual increase in serum GH concentrations.**<sup>121</sup>

GH acts via binding to a specific receptor to stimulate hepatic synthesis and secretion of IGF-I, which promotes both growth and differentiation.<sup>111</sup> GH receptor mutations result in GH insensitivity and growth failure (Laron dwarfism);<sup>122</sup> in affected individuals, serum GH concentrations are elevated and levels of IGF-I are low. GH stimulates growth via direct and indirect (via IGF-I) actions on the epiphyseal plates of long bones. GH also has a number of metabolic actions, which include increased lipolysis, stimulation of protein synthesis, insulin antagonism, and water and sodium retention.

## Insulin-Like Growth Factor I

IGF-I is synthesized and secreted by the liver in response to GH stimulation and circulates in serum bound to high-affinity IGF-binding proteins (IGFBPs). The genes

encoding IGF-I, IGF-II, and insulin all belong to the same family. The IGF1 gene has several components and yields several different mRNAs, including the 6 kb form that is regulated by GH. IGF-I acts via its own receptor, which is widely distributed in a variety of tissues and organs.<sup>123</sup> IGF-I receptor concentrations are controlled by GH, thyroxine, and other growth factors such as fibroblast growth factor and platelet-derived growth factor. IGF-I acts via a complex signaling cascade to stimulate cell growth and to inhibit apoptosis.

The family of IGFBPs includes six proteins having greater affinities for IGF-I than the IGF-I receptor. IGFBPs are present in all extracellular fluids and serve both to transport IGF-I and to control the amount of IGF-I available to bind to the IGF-I receptor. IGFBP-3 is the most abundant in serum and has the highest affinity for IGF-I, but generally is saturated. Although present in lower concentrations, IGFBP-1 is unsaturated and therefore has greater impact on the levels of free IGF-I. The serum IGFBP-1 concentration is regulated by insulin, increasing during fasting when insulin levels are low and decreasing after feeding or administration of insulin.<sup>124</sup> IGF-I levels are decreased in diseases associated with malnutrition such as inflammatory bowel disease and in hypothyroidism. IGF-I augments the effects of FSH and LH in the ovary, the effect of ACTH on adrenal steroidogenesis, and the thyroid response to thyroid-stimulating hormone (TSH). **IGF-I levels rise sevenfold from very low concentrations at birth to peak values at puberty, fall rapidly by approximately 50% by age 20, and then decline slowly with advancing age.**<sup>125</sup>

## Gonadal Steroids

The pubertal growth spurt is stimulated primarily by rising levels of GH and IGF-I, but a substantial body of evidence indicates that sex steroids also play an important role. In children with central (gonadotropin-dependent) precocious puberty treated with a long-acting GnRH agonist, mean height velocity and nocturnal serum GH and IGF-I levels, initially above the means for chronologic age, decrease significantly after 6–12 months and remain suppressed for the duration of treatment.<sup>126,127</sup> A study in children with central precocious puberty and GH deficiency (due to an intracranial lesion) observed that bone age was advanced in GH-deficient subjects, but not as much as in control subjects with precocious puberty and normal GH secretion; IGF-I levels were lower in GH-deficient subjects, but greater than in age-matched prepubertal GH-deficient children.<sup>128</sup> In a subset of GH-deficient subjects, treatment with a GnRH analog suppressed gonadal sex steroid levels and decreased height velocity, with no appreciable change in GH or IGF-I levels. In girls with Turner syndrome, treatment with exogenous estrogen increases growth velocity and bone age, compared to those observed in placebo-treated controls.<sup>129,130</sup> **Taken together, these observations**

**indicate that the pubertal growth spurt is mediated, at least in part, by a sex steroid-induced increase in GH secretion. Moreover, they demonstrate that precocious puberty can induce a substantial growth spurt, even in the absence of a normal pubertal increase in circulating GH or IGF-I. However, normal pubertal growth requires the combined actions of sex steroids and GH. Ultimately, sex steroids limit adult height by stimulating epiphyseal fusion.**

# The Timing of Puberty

What triggers the onset of puberty remains one of the most compelling unanswered questions in reproductive endocrinology. The age at onset of puberty and menarche is influenced by genetics, overall health, social environment, and environmental exposures.

An analysis of two genome-wide association studies including more than 17,000 women from the Nurses' Health Study and the Women's Genome Health Study identified 10 common variants or single nucleotide polymorphisms (SNPs) clustered in the regions of chromosomes 6q21 and 9q31.2 that were associated with age at menarche.<sup>131,132</sup> Genetic variation in or near the locus (6q21) of the LIN28B gene (encoding a developmentally regulated RNA binding protein)<sup>133</sup> has been associated with age at menarche in a number of human populations.<sup>132,134,135</sup> Some genetic variants associated with adult height also have been associated with age at menarche, suggesting the association between height and age at menarche has a genetic basis.<sup>132,134</sup> Other genes associated with age at menarche include FTO (fat mass and obesity-associated gene) and NEGR1 (neuronal growth regulator 1), both of which also are associated with childhood obesity.<sup>134</sup> Children with a family history of early puberty are more likely to experience an early puberty themselves; age at menarche correlates relatively well between mothers and daughters and between sisters.<sup>136</sup>

Children who live closer to the equator, at lower altitudes, and in urban areas and mildly obese children generally begin puberty earlier than those who live in northern latitudes, at higher elevations, and in rural areas and those of normal weight. Accumulating evidence suggests that certain environmental toxicants acting as “endocrine disruptors” also may influence the timing of sexual development.<sup>137</sup>

The age at onset of puberty has been declining gradually in the general population of the United States over the past century. Although the rate of decrease has slowed considerably more recently, the trend has continued. Overall, the average age at menarche for American girls decreased from approximately 12.75 years in the 1960s to approximately 12.5 years in the early 1990s.<sup>138,139</sup> A 1997 study conducted by the Pediatric Research in Office Settings (PROS) network examined the timing of pubertal development in more than 17,000 American girls (90% white, 10% black) and found that the earliest signs of puberty were occurring at ages significantly younger than in the past, with striking racial differences, as follows<sup>140</sup> (Table 9.1).

**TABLE 9.1 Age-based Pubertal Milestone Data from the 1997 PROS Network Study. Note the Differences between**

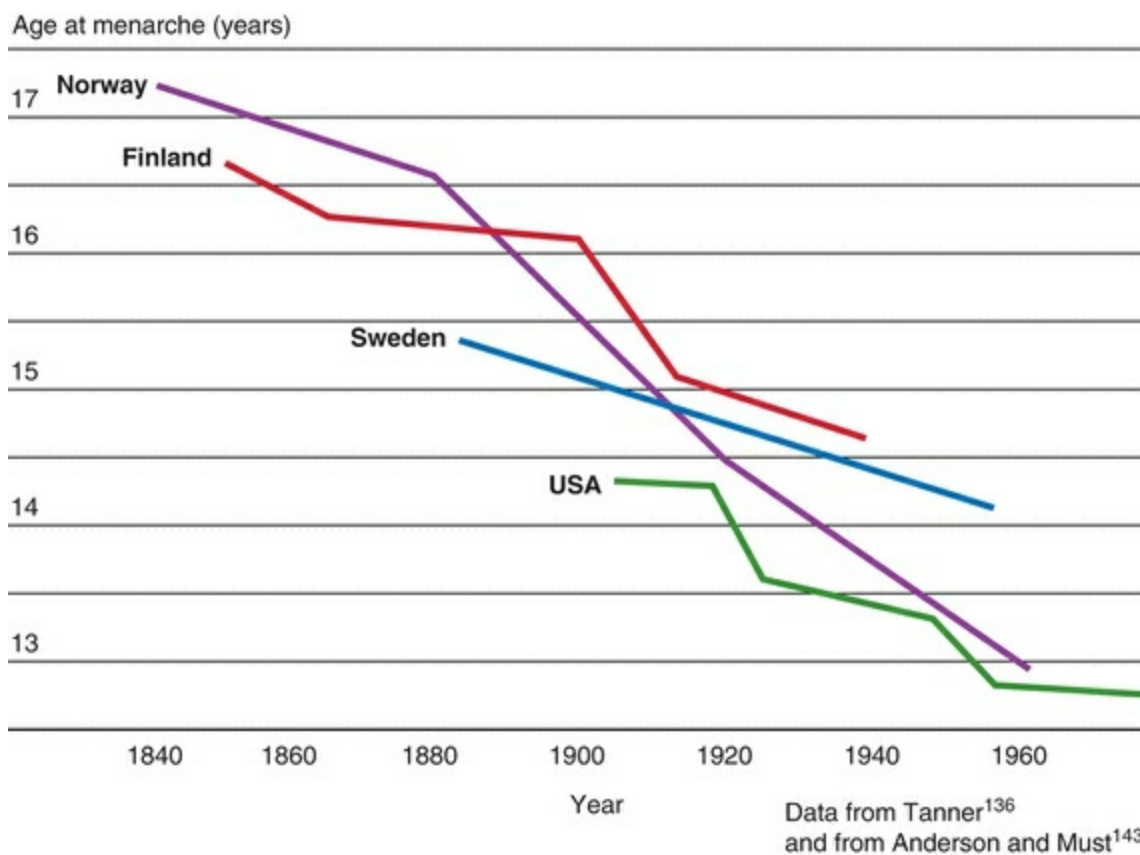

# **Caucasian and Black girls with the Latter Achieving Thelarche, Pubarche, Adrenarche**

<b>Pubertal Milestone</b>	<b>Black American Girls</b>	<b>White American Girls</b>
<b>Thelarche</b>		
Mean age	8.9 y	9.0 y
Age 6	6.4%	2.9%
Age 7	15.4%	5.0%
Age 8	37.8%	9.5%
Age 9	62.6%	32.1%
Age 10	80.2%	61.5%
Age 11	96.0%	85.4%
Age 12	98.9%	96.0%
<b>Pubarche</b>		
Mean age	8.8 y	9.5 y
Age 6	9.5%	1.4%
Age 7	17.7%	2.8%
Age 8	34.3%	7.7%
Age 9	62.6%	20.0%
Age 10	85.6%	46.4%
Age 11	95.2%	74.3%
Age 12	98.9%	92.2%
<b>Thelarche and/or pubarche</b>		
Age 6	14.3%	3.7%
Age 7	27.2%	6.7%
Age 8	48.3%	14.7%
Age 9	77.4%	38.2%
Age 10	94.6%	67.9%
Age 11	98.4%	88.0%
Age 12	100.0%	96.6%
<b>Menarche</b>		
Mean age	12.2 y	12.9 y
Age 9	2.7%	0.2%
Age 10	6.3%	1.8%
Age 11	27.9%	13.4%
Age 12	62.1%	35.2%

These data indicate that a substantial proportion of American girls begin pubertal development 6–12 months earlier than previously observed. **On average, black American girls begin puberty between ages 8 and 9 and white American girls by age 9. However, thelarche and/or pubarche can occur normally in black girls as early as age 6 and in white girls as early as age 7.**

Subsequent studies analyzing data from the National Health and Nutrition Examination Survey (NHANES) have observed a 2.3-month decrease in the average age of menarche between surveys for the years 1988–1994 (12.53 years) and 1999–2002 (12.34 years) and an overall 4.9-month decrease since 1960.<sup>138,141,142,143</sup> The decrease in age of menarche has been observed in all ethnic groups, declining from 12.57 to 12.52 years in non-Hispanic White girls, from 12.09 to 12.06 years for non-Hispanic Black girls, and from 12.24 to 12.09 for Hispanic American girls.<sup>143</sup> Changes in the population distribution of race and ethnicity over time explain the larger change in overall average age compared to those within groups (**Figure 9.3**).

**FIGURE 9.3**

Historically, the trend to an earlier onset of sexual development has been attributed to improved nutrition and less stressful living conditions.<sup>144</sup> The age at menarche has declined as the prevalence of obesity has increased, suggesting that a critical body weight<sup>59</sup> or body composition<sup>60</sup> is an important factor in determining the onset and progression of puberty.<sup>61</sup> **Indeed, higher weight and body fat mass are associated with an increased likelihood of early menarche.**<sup>61,138,145,146,147</sup> Data from the U.S. NHANES survey indicated that a girl with a BMI at the 85th percentile is more than twice as likely to have reached menarche as a girl of the same age and race/ethnicity having a BMI at the 50th percentile.<sup>143</sup> However, girls reach menarche over a wide range of weight and BMI, and age at menarche cannot be predicted reliably for individuals on that basis.<sup>148</sup> **Importantly, early pubertal development is associated with slightly decreased adult height and an increased risk for obesity, compared to a late menarche**<sup>149,150,151</sup> (Table 9.2).

From Ma HM, Du ML, Luo XP, Chen SK, Liu L, Chen RM, Zhu C, Xiong F, Li T, Wang W, Liu GL, Onset of breast and pubic hair development and menses in urban Chinese girls, *Pediatrics* 124:e269, 2009.

# Stages of Pubertal Development

Puberty includes a series of predictable events that vary in timing, sequence, and pace. **In general, the first sign of puberty in most adolescent girls is an acceleration of growth, followed by breast budding (thelarche), the appearance of pubic hair (pubarche), and, finally, the onset of menses (menarche).**

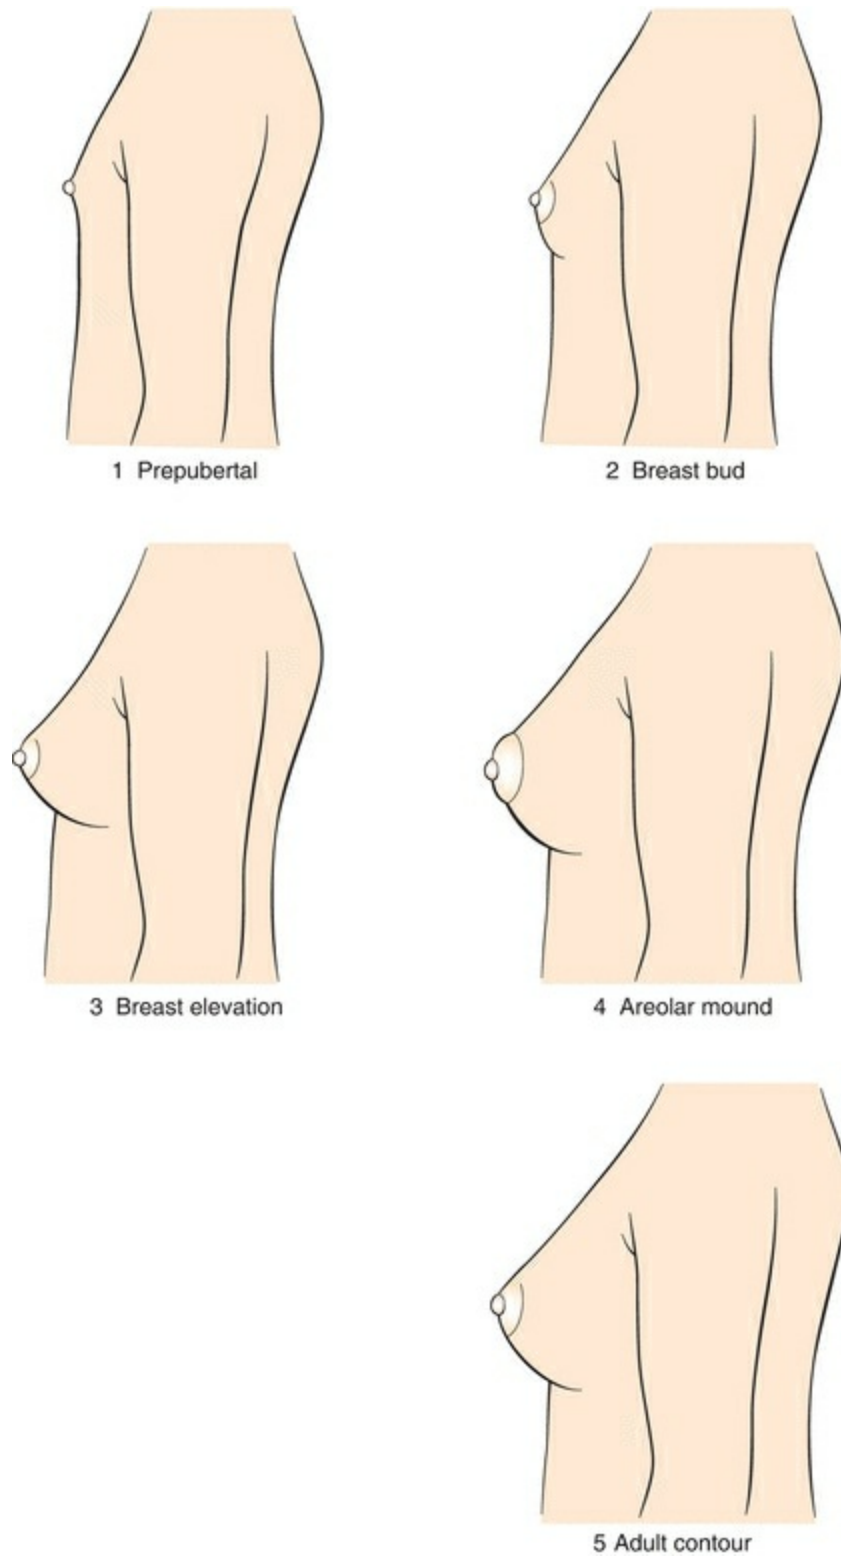

The staging systems used most frequently to describe the physical changes of puberty were first described by Marshall and Tanner in 1969 (girls)<sup>152</sup> and 1970 (boys).<sup>153</sup> The Tanner stages describe secondary sexual characteristics, including breast development in girls, pubic hair growth in both sexes, and genital development in boys. As shown in the diagrams, there are five Tanner stages of breast and pubic hair development in girls, with stage 1 representing the prepubertal state and stage 5 representing adult development.

Breast development follows a recognized sequence of events. Breast budding (Tanner stage 2) is distinguished by enlargement and by widening of the areolae. The breast then enlarges, becoming elevated beyond the areolae (Tanner stage 3). The breast enlarges further and the areolae and nipple form secondary mounds (Tanner stage 4), just before the breast achieves an adult contour (Tanner stage 5).

In the majority of adolescents, pubarche closely follows thelarche, but in a substantial minority, the sequence is reversed and pubarche precedes thelarche. In either case, the two are closely linked and progress in parallel. Pubarche (Tanner stage 2) is distinguished by the emergence of a small amount of long, relatively straight hair on the labia majora. The hair then becomes curly and coarser and extends outward (Tanner stage 3). The hair extends further to cover the labia (Tanner stage 4) before assuming an adult pattern with extension onto the medial thigh (Tanner stage 5).

**Menarche occurs an average of 2.6 years after the onset of puberty and after the peak of growth has passed.**<sup>102, 106, 152</sup> **On average, the pubertal sequence of accelerated growth, thelarche, pubarche, and menarche requires a period of 4.5 years (range, 1–6 years).** The relationship between menarche and the growth spurt is relatively fixed. After menarche, growth slows and generally does not increase more than about 6 cm (2.4 inches). The menses immediately following menarche usually are anovulatory, irregular, and occasionally heavy. Anovulatory cycles frequently persist for as much as 12–18 months and are not (**Figures 9.4 and 9.5**) uncommon even up to 4 years after menarche.<sup>154, 155</sup> However, the frequency of menses generally increases rapidly over the first year after menarche; 65% of adolescent girls report having 10 or more periods per year at the end of the first postmenarcheal year and 90% after 3 years.<sup>30</sup> The hallmark of the maturation of the hypothalamic-pituitary-ovarian axis and of the completion of puberty is the development of estrogen positive feedback, which

stimulates the midcycle LH surge and ovulation. In general, ovulatory cycles become progressively more frequent. The time required to establish ovulatory cycles relates to the age at menarche; when menarche occurs after the age of 13, only one-half have ovulatory cycles within 4.5 years<sup>156</sup> (Figure 9.6).

# Summary of Pubertal Events

The onset of puberty is an evolving sequence of maturational steps. The hypothalamic-pituitary-gonadal axis differentiates and develops during fetal life and becomes fully functional before birth. Beginning in late infancy and continuing through childhood, the axis is inactive because pulsatile secretion of hypothalamic GnRH is suppressed to very low levels of activity by central inhibitory mechanisms and, to a lesser extent, by a high sensitivity to low levels of gonadal steroid feedback.

In late childhood, adrenal androgen production increases (adrenarche), in response to an unknown stimulus, rises steadily thereafter, and ultimately stimulates the growth of pubic and axillary hair (pubarche). After a decade of quiescence, pulsatile GnRH secretion increases and the hypothalamic-pituitary-gonadal axis is reactivated (gonadarche), probably in response to metabolic signals from the periphery. FSH and LH levels rise moderately before age 10, followed by a gradual increase in estradiol concentrations, which stimulates breast development (thelarche). The increase in pulsatile gonadotropin secretion occurs first at night, during sleep, but gradually extends throughout the day.

The rapid increase in skeletal growth (the pubertal growth spurt) that precedes thelarche and pubarche is mediated primarily by a sex steroid-induced increase in GH secretion, which, in turn, stimulates increased production of IGF-I, and, to a lesser extent, by the direct effects of increasing sex steroid concentrations. Ultimately, rising sex steroid levels limit adult height by stimulating epiphyseal fusion.

At midpuberty, gonadal estrogen production increases sufficiently to stimulate endometrial proliferation, ultimately resulting in the onset of menses (menarche). Postmenarcheal cycles are at first anovulatory. Gradually, as the estrogen positive feedback mechanism matures, ovulatory cycles increase in frequency and, in late puberty, become established (Table 9.3).

## TABLE 9.3 Serum Hormone Concentrations During Female Puberty<sup>157,158,159,160,161,162,163</sup>

<b>Tanner Stage</b>	<b>FSH (IU/L)</b>	<b>LH (IU/L)</b>	<b>Estradiol (pg/mL)</b>	<b>DHEA-S (ng/dL)</b>
Stage 1	0.9–5.1	1.8–9.2	<0.8	19–302

# COMMON PROBLEMS ASSOCIATED WITH PUBERTY

---

Some of the common physical manifestations of pubertal maturation may be viewed by patients or their parents as abnormal, including anemia, acne, psychosocial problems, myopia, and dysfunctional uterine bleeding. Adolescents also are at high risk for sexually transmitted infections (STIs).

Girls tend to eat less of foods high in iron content, such as meat, and a low heme iron intake increases the risk of low iron stores.<sup>164</sup> The third NHANES (1988–1994) observed a 9% prevalence of anemia among American girls between the ages of 12 and 15 years.<sup>165</sup>

Acne is a disorder of the pilosebaceous unit caused by androgen stimulation characterized by follicular occlusion and inflammation. During puberty, the number of acneiform lesions increases, at all stages.<sup>166</sup> In girls, acne tends to be more severe in the late stages of puberty, which are associated with higher serum concentrations of DHEA-S.<sup>167</sup>

The psychosocial changes during puberty predispose to an increased incidence of depression, which is twice as common in girls as in boys.<sup>168</sup> Many girls become unhappy with their physical appearance, resulting in a decrease in self-esteem that is more common in white girls than in black girls.<sup>169</sup> The problem is most common when pubertal development is not synchronous with that of peers.<sup>170</sup> Early-maturing girls are more likely to develop psychopathology,<sup>171</sup> to have older friends,<sup>172</sup> and to be vulnerable to peer pressures.<sup>173</sup>

The prevalence of myopia (nearsightedness), caused by growth in the axial diameter of the eye, is greatest during puberty. Dysfunctional uterine bleeding is a consequence of anovulatory cycles and is common in adolescent girls during the 1st year or 2 after menarche.

Adolescents represent the highest-risk age group for nearly all STIs.<sup>174</sup> The risk for acquiring an STI relates to age at first intercourse, the number of partners, the perceived risk, and attitudes about acquiring an STI.<sup>175</sup> The persistence of a columnar epithelium on the exocervix (ectropion) also may predispose to infection with Chlamydia<sup>176</sup> and human papillomavirus.<sup>177,178</sup>

# **PRECOCIOUS PUBERTY**

---

Precocious puberty describes pubertal development that begins at an earlier age than expected, based on established normal standards. Its causes are many, ranging from variants of normal development, such as premature adrenarche, to serious pathology, including malignant intracranial neoplasms. Children with precocious puberty warrant careful evaluation to define the cause and, when indicated, prompt treatment to avoid the psychosocial and growth consequences of abnormally early sexual development.

# Indications for Evaluation

Abnormally early or precocious puberty generally is defined as pubertal development occurring more than 2.5 standard deviations earlier than the average age. Traditionally, using 10 years as the average age of onset of puberty in girls, precocious puberty has been defined as secondary sexual development before the age of 8 years. However, as discussed in an earlier section of this chapter,<sup>138,139</sup> the age at onset of puberty has been declining over the past few decades, raising questions about when pubertal development should be considered precocious and warrants clinical evaluation.

The 1997 study conducted by the PROS network observed that 6.7% of American white girls and 27.2% of black girls had breast or pubic hair development before the age of 8 years.<sup>140</sup> These observations suggested that continued application of the traditional definition of precocious puberty would result in a large number of potentially normal girls having extensive, costly, and unnecessary testing. Consequently, new guidelines were proposed, lowering the age at which evaluation is indicated to age 7 in white girls and age 6 in black girls,<sup>179</sup> sparking a vigorous debate.

Some authorities questioned the new recommendations because the PROS study population was not a random sample drawn from the general population, because the study focused on premature thelarche and premature adrenarche and not on “true” precocious puberty (typically characterized by early breast and pubic hair development), and because no cause was determined in those having precocious puberty. Criticism centered on concerns that the recommended lower ages in the newly proposed guidelines might increase significantly the risk for underdiagnosis of important endocrine pathology.<sup>180,181,182,183</sup> Indeed, a subsequent large European study involving 443 girls with central precocious puberty identified 35 with an occult intracranial lesion (8%) and reported that application of the revised American guidelines lowering the age for evaluation for precocious puberty would have missed 4/35 girls (11%) with cranial pathology.<sup>184,185</sup> Others favoring the new recommendations emphasized that fewer than 2% of girls with precocious puberty over age 6 had an intracranial lesion and that unnecessary imaging has high financial and emotional costs.<sup>186</sup>

In another American study involving 223 patients (white girls aged 7–8 years and black girls aged 6–8 years) referred to a single tertiary center solely for evaluation of precocious puberty over a 5-year period, 105 (47%) exhibited both breast and pubic hair development, 83 (37%) had only pubic hair, 24 (11%) had only breast development, and 11 (5%) had no signs of early sexual development.<sup>183</sup> Ultimately, 186/212 (88%) with signs of early puberty had a diagnosis of idiopathic gonadotropin-dependent precocious puberty and 26 (12%) had a treatable endocrinopathy amenable

to early intervention, including acanthosis nigricans/hyperinsulinemia, hypothyroidism, neurofibromatosis, GH deficiency, pituitary adenoma, McCune-Albright syndrome, and congenital adrenal hyperplasia (CAH). More importantly, more than one-third of the girls with only breast development or with breast and pubic hair development had bone ages that were advanced significantly and were, therefore, at risk for diminished growth potential.<sup>183</sup> In a more recent study from New York City, Cincinnati, and San Francisco, 10% of White, 15% of Hispanic, and 23% of Black girls between the ages of 7 and 8 years had breast development (assessed by palpation).<sup>187</sup> A subsequent guidance published by the American Academy of Pediatrics concluded that it is reasonable for primary care physicians to consider referring most girls who have a breast development before 8 years of age.<sup>188</sup> The same report emphasized that most of these girls will not have treatable endocrine pathology and will represent the lower end for a new normal.

Clearly, more and larger prospective studies are needed because questions regarding the indications for evaluation for precocious puberty remain unsettled. However, taking all of the available data into consideration, we believe that the following guidelines offer a good balance between safety and cost-effectiveness:

**All girls under the age of 6 who have either breast or pubic hair development and girls under age 8 having both breast and pubic hair development merit a thorough evaluation to determine the cause.**

**Girls under 8 years of age having only early breast development (premature thelarche) or pubic hair growth (premature adrenarche or pubarche) warrant a careful history and physical examination and, at a minimum, an evaluation of bone age and close follow-up to determine their linear growth rate in efforts to identify those who may be at risk for decreased growth potential.**

**Between the ages of 6 and 8 years, clinicians must make individual judgments regarding the extent of evaluation, based on the results of the initial evaluation and, inevitably, on the level of anxiety in the patient and her parents.<sup>9</sup>**

**Factors associated with an increased risk for intracranial pathology that clearly warrant complete evaluation and imaging include onset of puberty before age 6, rapid pubertal progression, and associated symptoms of headache, seizures, or focal neurologic deficits.<sup>179,186</sup>**

# Classification of Precocious Puberty

Traditionally, precocious puberty has been classified according to the underlying pathophysiology. However, the classification has limited practical utility in clinical practice because it reflects the final diagnosis, after evaluation is completed.

**Gonadotropin-dependent precocious puberty**, also known as “central precocious puberty” or “true precocious puberty,” describes early maturation and activation of the hypothalamic-pituitary-gonadal axis and is characterized by both breast and pubic hair development in girls and by pubic hair development and testicular enlargement (>4 mL in volume or 2.5 cm in diameter) in boys. The early developing sexual characteristics are “isosexual,” meaning they are consistent with the child’s gender.

**Gonadotropin-independent precocious puberty**, also known as “peripheral precocious puberty” or “pseudoprecocious puberty,” describes early sexual development that is independent of GnRH and gonadotropins and generally results from exposure to sex steroid hormones that derive from the gonads, the adrenals, or the environment. Gonadotropin-independent precocious puberty is further subclassified as isosexual when sexual characteristics are consistent with gender and as “contrasexual” when inconsistent with gender (virilization in girls or feminization in boys).

**Incomplete precocious puberty** describes children with isolated premature thelarche or premature adrenarche. Both usually represent variants of normal pubertal development, but some will progress to complete precocious puberty that may be gonadotropin-dependent or gonadotropin-independent.

## Gonadotropin-Dependent Precocious Puberty

Gonadotropin-dependent precocious puberty results from early maturation of the hypothalamic-pituitary-gonadal axis and is much more common in girls than in boys.<sup>189</sup> Although puberty begins earlier than normal, the sequence of pubertal events generally is normal and proceeds at the normal pace.

Up to 90% of children with gonadotropin-dependent precocious puberty have no identifiable cause (idiopathic), a diagnosis made by exclusion.<sup>190,191</sup> However, the disorder can be associated with a variety of central nervous system lesions, including tumors, irradiation, hydrocephalus, cysts, trauma, inflammatory diseases, and midline developmental defects such as septo-optic dysplasia. **Consequently, head magnetic resonance imaging (MRI) is indicated even when there are no neurologic signs or symptoms.**<sup>184,191,192</sup>

Tumors associated with gonadotropin-dependent precocious puberty include hamartomas, astrocytomas, ependymomas, pineal tumors, and optic and hypothalamic

gliomas. Hamartomas are heterotopic neuronal masses containing GnRH neurons that typically attach to the tuber cinereum or floor of the third ventricle where they can function as an ectopic hypothalamic GnRH pulse generator, divorced from the central inhibitory mechanisms that normally restrain activity during childhood; they are the most common tumor associated with precocious puberty and can be associated with gelastic seizures (laughing, giggling)<sup>193,194</sup>; some produce transforming growth factor alpha, which mediates the release of GnRH.<sup>195</sup> The precocious puberty that can be observed in children with neurofibromatosis usually relates to an optic glioma.<sup>196</sup>

As described in an earlier section of this chapter, activating mutations in the gene encoding the GPR54 receptor (KISS1R), which mediates the actions of kisspeptin (an excitatory neuroregulator of GnRH secretion), can cause gonadotropin-dependent precocious puberty.<sup>53</sup>

**Children exposed to high circulating androgen or estrogen concentrations, as may occur with CAH, virilizing tumors, and the McCune-Albright syndrome, often exhibit early maturation of the hypothalamic-pituitary-gonadal axis, which then results in gonadotropin-dependent precocious puberty.**<sup>197,198,199</sup>

Although quite rare, girls with severe primary hypothyroidism can present with precocious puberty, exhibiting breast development, galactorrhea, and episodic menstrual bleeding. In most cases, the very high serum levels of TSH, which has structural similarity to FSH, appear to activate the FSH receptor.<sup>200</sup>

Rarely, gonadotropin-dependent precocious pubertal development has resulted from an autonomous pituitary gonadotropin-secreting tumor rather than from early maturation of the hypothalamic-pituitary-gonadal axis.<sup>201,202</sup>

## **Gonadotropin-Independent Precocious Puberty**

Gonadotropin-independent precocious puberty can result from excess sex steroid secretion from the gonads or adrenals or from exposure to exogenous estrogens.

**Autonomous functional ovarian follicular cysts are the most common cause of gonadotropin-independent precocious puberty in girls.** Transient breast development and vaginal bleeding are the most common presentation, which can be an isolated event or recur at unpredictable intervals.<sup>203,204,205</sup> Serum estrogen levels typically are elevated, but not always (due to regression of the cyst), and both basal and GnRH-stimulated gonadotropin concentrations are low. In most cases, bone age is not advanced. Ovarian ultrasonography usually demonstrates one or more unilateral or bilateral ovarian cysts greater than 15 mm in diameter.<sup>206</sup> The disorder is self-limited in most and requires no treatment. However, recurrent cysts resulting in prolonged or

repeated estrogen exposure can precipitate early maturation of the hypothalamic-pituitary-gonadal axis, resulting in gonadotropin-dependent precocious puberty.<sup>204</sup> Autonomous ovarian cysts also can be an early manifestation of McCune-Albright syndrome, arising before the emergence of the characteristic skin (“café au lait spots”) or bone lesions; affected patients therefore require careful longer-term follow-up.<sup>203,205</sup>

Ovarian tumors are rare causes of gonadotropin-independent precocious puberty in girls and include granulosa cell tumors, Leydig cell tumors, and gonadoblastomas.<sup>207,208,209</sup>

**McCune-Albright syndrome is a rare disorder characterized classically by precocious puberty, café au lait skin pigmentation, and polyostotic fibrous dysplasia of the bone, all caused by a somatic mutation of the alpha subunit of the G-protein (encoded by the GNAS1 gene), which results in a mosaic distribution of cells bearing constitutively active adenylate cyclase.**<sup>210,211,212</sup> The mutation results in continuous stimulation of endocrine function and, in addition to precocious puberty, also can cause gigantism, Cushing syndrome, adrenal hyperplasia, and thyrotoxicosis, in varying combinations. Although precocious puberty is the most common clinical manifestation,<sup>213</sup> the phenotype varies with the tissues that are affected by the mutation and can include hepatitis, intestinal polyps, and cardiac arrhythmias. As in other forms of gonadotropin-independent precocious puberty, the sequence of pubertal development may be abnormal; for example, vaginal bleeding frequently precedes breast development.<sup>214</sup> The skin and bone lesions can increase over time and may not be present at the initial presentation. Early and repeated exposure to elevated sex steroid levels can result in accelerated growth, advanced bone age, and reduced adult height; it also may induce early maturation of the hypothalamic-pituitary-gonadal axis, resulting in secondary gonadotropin-dependent precocious puberty. McCune-Albright syndrome is more common in girls than in boys. The diagnosis merits consideration in girls presenting with recurrent functional ovarian follicular cysts and episodic menses.<sup>215</sup> Partial forms of the syndrome also have been described.<sup>212</sup>

Adrenal pathology, such as androgen-secreting tumors and CAH, is another cause of gonadotropin-independent precocious pubertal development.

Exposure to exogenous estrogens or environmental pollutants having estrogenic activity (xenoestrogens) can result in premature sexual development in infants or toddlers.<sup>216,217,218</sup> Examples include accidental exposure to estrogens, xenoestrogens, or placental extracts contained in cosmetics or personal hair and skin care products and environmental pollutants that can act as endocrine disruptors by mimicking estradiol, such as polychlorinated biphenyls, herbicides, pesticides, and plasticizers, which may be found in water contaminated with industrial products.<sup>219</sup> Serum hormone levels in

affected children typically are in the normal range, but can vary widely depending on the nature, time, and frequency of use or exposure. **Children are extremely sensitive to the effects of estrogen and may respond with increased growth or breast development even at serum levels below the limits of detection.**<sup>220</sup>

## **Incomplete Precocious Puberty**

Incomplete precocious puberty includes premature adrenarche or premature thelarche and usually is a variant of normal puberty. Such cases present a clinical dilemma due to uncertainty regarding whether the condition is entirely benign, as usual, or might be the first indication of true precocious puberty.

### **Premature Adrenarche**

Premature adrenarche is the most common cause of premature pubarche, describing otherwise unexplained early growth of genital hair associated with increased levels of adrenal androgens.<sup>221</sup> **Generally, the best indicator of adrenarche is a serum DHEA-S concentration greater than 40 µg/dL, which is higher than that normally seen in children 1–5 years of age (5–35 µg/dL).** In children with premature adrenarche, the growth rate and bone age often are above average but still within normal ranges. **Exaggerated adrenarche** is the term used to describe the clinical extreme of premature adrenarche, wherein the serum DHEA-S level exceeds that typical of adrenarche or for age and usually, but not always, is associated with a somewhat early onset of true puberty.<sup>222</sup>

**The cause of premature adrenarche is unknown. The condition traditionally has been considered an early variant of normal development and, as such, generally has no serious consequences. However, up to 20% of girls with premature adrenarche may subsequently develop gonadotropin-dependent precocious puberty, and close follow-up therefore is recommended.**<sup>81,223</sup> Other evidence indicates that girls with premature adrenarche also are at increased risk for developing polycystic ovary syndrome, suggesting that premature adrenarche may be an early manifestation of the disorder.<sup>224,225,226,227,228,229</sup> In many, premature pubarche is preceded by low birth weight and is followed by hyperandrogenism, hirsutism, and oligomenorrhea in adolescence, often accompanied by hyperinsulinemia and dyslipidemia. These observations suggest that insulin resistance may be the underlying metabolic disorder, causing decreased growth during fetal life, premature pubarche, and hyperandrogenism that worsens during late puberty or the early postmenarcheal years.<sup>230</sup> In those affected, metformin treatment can decrease insulin resistance and hyperandrogenism, improve the lipid profile, often restore cyclic menses, and may help to prevent later development of

diabetes and cardiovascular disease.<sup>231</sup>

Premature pubarche usually results from a premature adrenarche but also has other causes. Idiopathic premature pubarche, unassociated with any demonstrable increase in adrenal androgen production, probably reflects an increased sensitivity of hair follicles to normal androgen concentrations. In select instances, this may be caused by increased androgen receptor (AR) activity due to shorter CAG repeats or AR methylation pattern.<sup>232,233</sup> Premature pubarche sometimes can be the only clinical manifestation of a mild form of CAH.<sup>234,235</sup> Other rare causes of ACTH-dependent childhood virilization include Cushing syndrome, glucocorticoid resistance, cortisone reductase deficiency, and androgen-producing neoplasms of the adrenal gland or ovary.

The evaluation of premature pubarche should focus first on determining whether the growth of pubic hair is an isolated phenomenon or may be associated with other signs and symptoms suggesting another of the diagnoses mentioned above. **The single most important and useful test is an x-ray of the left hand and wrist for bone age. If sexual hair is small in amount and slow-growing and bone age is normal, precocious puberty is unlikely and expectant management is appropriate, with re-evaluation at 6 months and periodically thereafter.** A limited endocrine evaluation should include measurements of serum testosterone and DHEA-S, for comparison to age-adjusted normal values. The presumptive diagnosis of premature adrenarche can be made when both are appropriate for pubarche, bone age is normal, and predicted adult height is within the range expected for the family.<sup>236</sup> More extensive endocrine evaluation can be reserved for those children having other signs suggesting true precocious puberty or a virilizing disorder.

**An ACTH stimulation test to exclude the diagnosis of CAH is indicated when bone age is advanced abnormally, the predicted adult height is abnormally low, or the serum testosterone and DHEA-S concentrations are elevated above the ranges typical of premature adrenarche.** The test is performed by obtaining blood samples before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 1 µg/m<sup>2</sup> or 0.25 mg). A stimulated serum 17-OHP concentration greater than 1,000 ng/dL generally indicates 21-hydroxylase deficiency.<sup>237</sup> In children with premature pubarche, diagnosis of the rare 3β-HSD deficiency requires a stimulated 17α-hydroxypregnenolone level greater than 9,790 ng/dL.<sup>235</sup>

Premature adrenarche is a benign condition and requires no specific treatment. Parents can be reassured that the condition is a normal variant relating to increased sensitivity of hair follicles to low levels of androgen or an early occurring incomplete form of puberty. However, children with a diagnosis of premature adrenarche merit periodic re-evaluation for evidence of progressive virilization.

## Premature Thelarche

Premature thelarche generally is defined as isolated breast development in girls before the age of 8 years. In girls, premature thelarche usually is a benign condition considered a variant of normal puberty. Early breast development is particularly common during the first year of life when the hypothalamic-pituitary-gonadal axis is still active.<sup>238,239</sup> Studies using ultrasensitive bioassays for estrogen have detected higher estrogen levels in many, but not all, girls with premature thelarche than in normal controls.<sup>240</sup> The breast also may be more sensitive to estradiol than normal in some girls.<sup>241</sup> Although most affected children subsequently experience normal puberty and growth,<sup>242,243,244</sup> a significant proportion experiences an earlier than average menarche.<sup>245</sup>

Physical examination typically reveals a light pink areola with an infantile appearance, with Tanner stage 2 or 3 breast development; frequently, the change may be unilateral or asymmetrical. There is no sign of androgen exposure.

**Exaggerated thelarche** describes those with premature thelarche who also exhibit increased growth velocity and/or advanced bone age and may represent an intermediate between premature thelarche and precocious puberty.<sup>240,246</sup> Even girls with exaggerated thelarche exhibit a prepubertal pattern of response to acute stimulation with GnRH or a GnRH agonist; FSH levels rise more than LH, which remains below 5 IU/L.<sup>247</sup> Some cases have been associated with the presence of functional ovarian cysts.<sup>203</sup> Genetic studies in girls with exaggerated thelarche have revealed that some harbor a mutation in the GNAS1 gene, suggesting that the disorder can be an early or the only sign of McCune-Albright syndrome.<sup>240,248</sup>

Premature thelarche also has been related to exposure to exogenous estrogen, including environmental chemicals that degrade slowly in the environment and can accumulate in the food chain, but no clear relationship with premature thelarche has been established.

The evaluation of premature thelarche, like that of premature adrenarche, should focus on determining whether breast development is an isolated phenomenon or associated with other signs of precocious puberty; here again, the most important initial test is an evaluation of bone age. **In children with Tanner stage 2 breast development and normal bone age, precocious puberty is unlikely and expectant management is appropriate, with re-evaluation at 6 months and periodically thereafter.**

**Approximately 15–20% of girls with premature thelarche subsequently develop gonadotropin-dependent precocious puberty, at a mean age of  $7.1 \pm 0.7$  years and a mean bone age of  $9.0 \pm 1.1$  years.**<sup>249,250</sup> A longitudinal study involving more than 150 girls with premature thelarche observed that 69% had complete regression of breast

development (13% of these later developing true precocious puberty), 21% had recurrent episodes of breast development (32% later developing true precocious puberty), and 10% had persistent breast development (57% later developing true precocious puberty).<sup>250</sup>

# Evaluation of Precocious Pubertal Development

The evaluation of early sexual development begins with a careful history and physical examination and measurement of bone age to determine whether there is any corresponding increase in linear growth. Subsequent evaluation is limited to those with precocious puberty and is aimed at determining the cause and at directing treatment.

The **medical history** should determine when the physical change(s) was first noticed, in the siblings and parents as well as in the patient, seek evidence of growth acceleration, exclude previous history of neurologic disease or trauma or exposure to sex steroids, and identify any associated symptoms of headache, seizures, or abdominal pain.

The **physical examination** should include height, weight, and calculation of growth velocity (cm/year), which often is an early indication of evolving precocious puberty.<sup>251</sup> A fundoscopic examination should be performed to detect papilledema, a sign of increased intracranial pressure. Evaluation of visual fields may reveal evidence to suggest a sellar mass lesion. A careful examination of the skin should be performed to identify any café au lait spots, which suggest the diagnosis of McCune-Albright syndrome.

**Tanner staging** of pubic hair and/or breast development should be performed. The diameter of the glandular breast tissue should be measured, taking care to distinguish it from adipose. Accurate assessments are important for determining whether additional evaluation is warranted.

A measurement of **bone age** is indicated when examination demonstrates signs of early sexual development (Table 9.4).

## TABLE 9.4 Tanner Staging

	Breast	Pubic Hair
Stage 1 (prepubertal)	Elevation of papilla only	No pubic hair
Stage 2	Elevation of the breast and papilla as small mound, increased areola diameter	Sparse, long, pigmented hair, primarily on the labia majora
Stage 3	Further enlargement without separation of the breast and areola	Dark, coarse, curled hair sparsely distributed over the mons
Stage 4	Secondary mound of the areola and papilla above the breast	Adult-type hair, abundant but limited to the mons
Stage 5	Recession of the areola to contour of the breast	Adult-type hair, extending onto the medial thigh

## Endocrine Evaluation and Imaging

**Children with advanced bone age and those having normal bone age accompanied by both breast and pubic hair development, or normal bone age with evidence of accelerated growth and breast or pubic hair development, warrant further endocrine evaluation and imaging.**

Basal and GnRH-stimulated serum gonadotropin levels differentiate gonadotropin-dependent from gonadotropin-independent precocious puberty, which then guides further evaluation. Serum gonadotropin concentrations should be measured using ultrasensitive assays having low detection limits for pediatric patients (approximately 0.1 IU/L).<sup>252,253,254</sup>

The **GnRH stimulation test** is performed by obtaining blood samples before and 30–40 minutes after a single dose of GnRH (100 µg), administered intravenously. Because synthetic GnRH currently is not available in the United States, a GnRH agonist can be used instead,<sup>255,256,257</sup> obtaining blood samples before and 60 minutes after a single dose of leuprolide acetate (20 µg/kg), administered subcutaneously.<sup>257</sup> **The stimulated serum LH concentration is the most useful diagnostic parameter; although a normal threshold value has not been firmly established, due to differences in assay methods and the limited amount of normative data, a stimulated LH value of 3.3–5.0 IU/L defines the upper limit of normal for prepubertal children (Tanner stage 1, T1) with most assays.**<sup>257</sup> Both basal and stimulated serum LH concentrations have high specificity and positive predictive value for diagnosis of gonadotropin-dependent precocious puberty. In a study comparing the results of GnRH stimulation tests performed in normal children (T1) with those obtained in children with gonadotropin-dependent and gonadotropin-independent precocious puberty, the mean basal serum LH concentration was 1.6 IU/L in the group with gonadotropin-dependent precocious puberty and less than 0.6 IU/L in the other two groups. The mean stimulated LH value in the group of children with gonadotropin-dependent precocious puberty was 21.6 IU/L, compared to 3.2 IU/L in normal children (T1) and 1.4 IU/L in the group with gonadotropin-independent precocious puberty.<sup>258</sup>

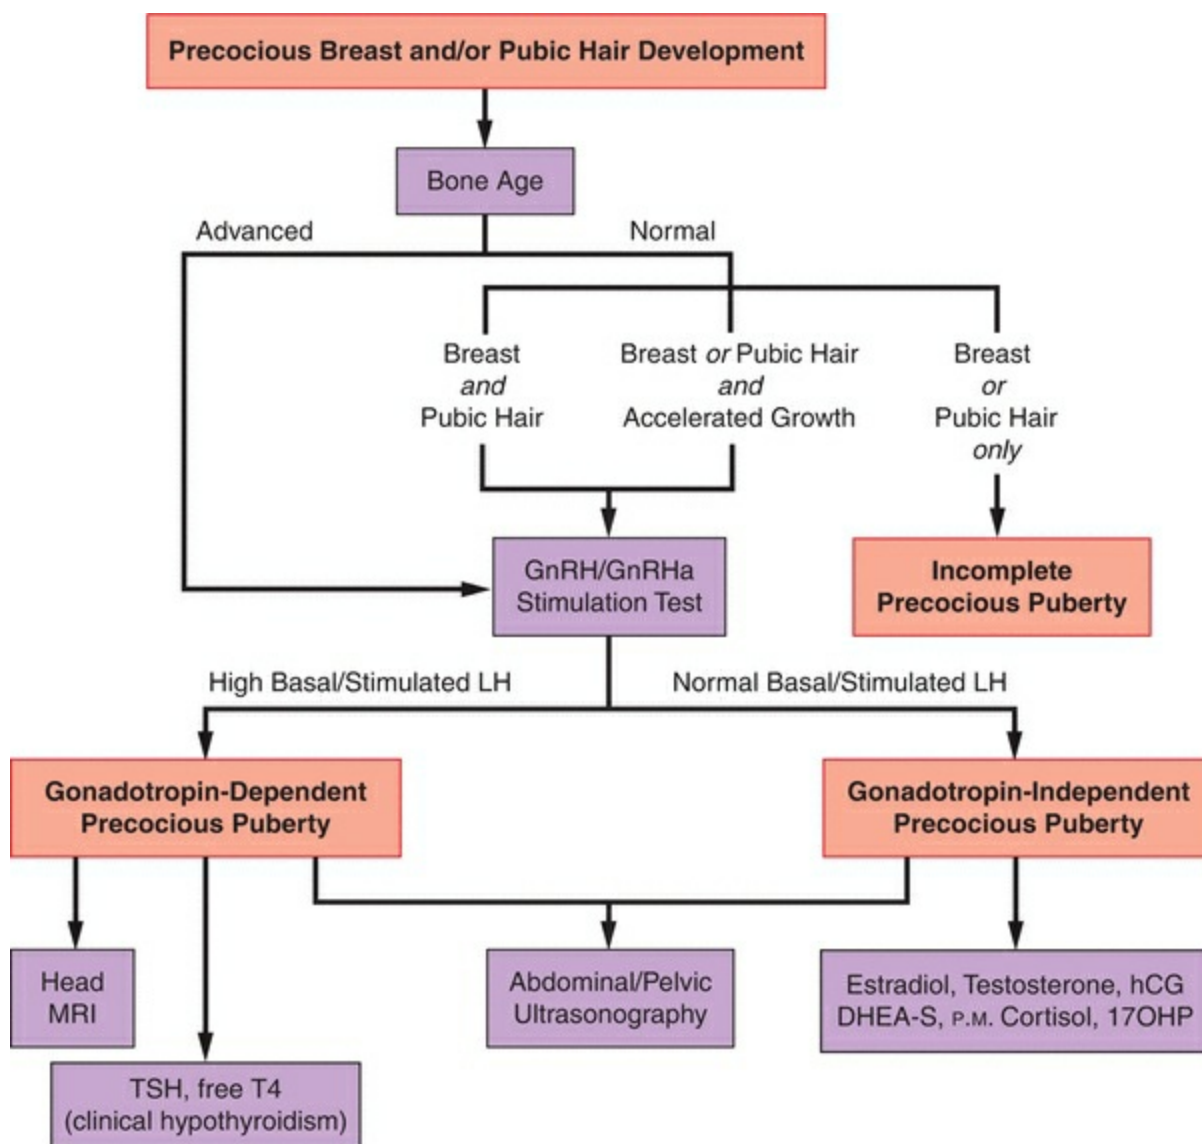

**In children with gonadotropin-dependent precocious puberty (as identified by elevated basal or stimulated serum LH levels), a head MRI is indicated to exclude an intracranial mass lesion.**<sup>257,259</sup> Thyroid function tests (TSH and free T4) should be obtained if there is any clinical evidence of hypothyroidism.

**In children with gonadotropin-independent precocious puberty (as identified by normal basal and stimulated serum LH levels), serum concentrations of estradiol, testosterone and hCG (functional ovarian cysts and tumors, functional adrenal**

tumors), late afternoon cortisol (Cushing syndrome), DHEA-S (premature adrenarche), and 17-OHP (CAH) should be obtained to determine the peripheral source of sex steroid production and the cause of early sexual development.

Abdominal and pelvic ultrasonography is indicated in all girls with precocious puberty to identify functional ovarian cysts or tumors. Ultrasonography is indicated even for those with gonadotropin-dependent precocious puberty because early and repeated or sustained exposure to sex steroids from autonomous peripheral sources can induce a secondary premature maturation of the hypothalamic-pituitary-gonadal axis (Figure 9.7).

**FIGURE 9.7**

# Treatment of Precocious Puberty

The treatment of precocious puberty differs according to whether it is gonadotropin-dependent or gonadotropin-independent and on the underlying cause, when that can be determined. **The principal goals of treatment are to stop or slow development until normal pubertal age, to maximize adult height, and to reduce the risk of psychosocial problems associated with early sexual maturation.**

## Treatment of Gonadotropin-Dependent Precocious Puberty

The decision to treat gonadotropin-dependent precocious puberty depends on the underlying pathology and on the speed of sexual development. In those having an identified intracranial lesion, treatment should be directed to the lesion, if that is possible. In those having no intracranial lesion, the decision to treat should be based primarily on the pace of progression and on the estimated adult height.

**Treatment for gonadotropin-dependent precocious puberty generally is indicated when sexual maturation progresses to the next stage within 3–6 months, when growth velocity is accelerated to greater than 6 cm/year (unless peak height velocity has already passed), when bone age is advanced by 1 year or more, or when predicted adult height is below the target range or is decreasing on serial determinations.**<sup>259</sup> Conversely, those with stable or regressing pubertal signs, normal growth velocity (for age), bone age within 1 year of chronologic age, and a predicted adult height within the target range may not require treatment. In most cases, growth velocity should be monitored for 3–6 months before making the decision to treat.<sup>259</sup> Treatment aimed only at avoiding the potential psychosocial consequences of precocious puberty should be carefully considered because there are few data regarding outcomes and effectiveness.

## GnRH Agonist Treatment

**Long-acting GnRH agonists have proven both safe and effective for the treatment of idiopathic gonadotropin-dependent precocious puberty.**<sup>260,261,262,263,264,265,266,267</sup>

GnRH agonist treatment causes a brief initial “flare” of gonadotropin release, followed by pituitary desensitization (exhaustion of available stores of releasable gonadotropins) and down-regulation (decrease in GnRH receptors). By suppressing the pituitary-gonadal axis, GnRH agonist therapy can prevent progressive pubertal development, and increase final adult height, compared to pretreatment predictions. **Young children and those who exhibit rapidly progressive development can be expected to have early**

**epiphyseal fusion, are at greatest risk for compromised adult height, and can benefit most from treatment.**<sup>257</sup>

In girls under 6 years of age with idiopathic gonadotropin-dependent precocious puberty, treatment with a GnRH agonist can be expected to add 9–10 cm to adult height. In older children already past their peak with slowing growth velocity, treatment can be expected to slow it further, to delay epiphyseal fusion, and to yield slow but steady increases in predicted adult height. In girls between 6 and 8 years of age, GnRH agonist treatment typically results in a gain of 4–7 cm in height, less if bone age is significantly advanced.<sup>257</sup> Girls already close to the age of normal puberty, those with slowly progressive maturation, and girls with a predicted height above 150 cm have less to gain and may not benefit significantly from treatment.<sup>268,269,270</sup>

The choice among the available GnRH agonist formulations depends mostly on physician preference and availability. Depot preparations generally are preferred because of improved compliance. Direct comparisons in randomized trials have not been made, but any of the following treatment regimens generally can be expected to suppress the pituitary-gonadal axis<sup>271,272,273</sup>

- Buserelin 6.3 mg every 2 months
- Goserelin 3.6 mg every month or 9.8 mg every 3 months
- Histrelin 50-mg implant every year
- Leuprolide 3.75–7.5 mg monthly or 11.25 mg every 3 months
- Triptorelin 3.0–3.75 mg monthly or 11.25 mg every 3 months

Nonetheless, the dose of GnRH agonist treatment required can vary significantly.<sup>274</sup> Inadequate treatment can permit progressive sexual development and bone maturation. Conversely, overtreatment can suppress endogenous GH and decrease growth velocity and bone mineral accumulation to levels below those normally expected during the prepubertal years.<sup>275</sup> The adequacy of GnRH agonist treatment can be monitored simply by measuring the serum LH concentration 30–60 minutes after each repeated injection of the agonist; the LH level should be less than 3.0 IU/L, consistent with prepubertal norms after acute GnRH agonist stimulation.<sup>276</sup>

**GnRH agonist treatment should be monitored at 3–6 month intervals with serial physical examinations to detect any progressive pubertal development; bone age also should be evaluated periodically.**<sup>257</sup> Breast development should cease and growth velocity and the pace of advancing bone age should decrease. Pubic hair development may continue due to normal adrenarche.<sup>277</sup> Although bone density may decline during longer durations of treatment, bone mass is regained after treatment ends and peak bone mass is normal; consequently, there is no reason or need to monitor bone

density.<sup>257</sup>

**Treatment with GnRH agonists does not appear to have any significant long-term adverse effects on function of the hypothalamic-pituitary-gonadal axis.<sup>278</sup> It can be continued until the epiphyses are fused or until the pubertal and chronologic ages are appropriately matched. Prompt reactivation of the pituitary-gonadal axis and pubertal development, in a pattern similar to that in normal adolescents, generally follows the discontinuation of treatment.<sup>279</sup> In one Japanese study of 63 girls and 11 boys who were treated with leuporelin for an average of 3.8 years, 96.8% of girls achieved menarche or remenarche within an average of 17.5 ( $\pm 11.2$ ) months after cessation of treatment.<sup>267</sup>**

GnRH agonist therapy also is recommended for treatment of GnRH-secreting hypothalamic hamartomas<sup>193,280</sup>; the tumor can be monitored by serial imaging and risky surgery can be avoided. Treatment for other hypothalamic, pituitary, cerebral, or pineal tumors must be individualized. Many that are small and do not extend around or into vital structures can be excised successfully.

## **Treatment of Gonadotropin-Independent Precocious Puberty**

The treatment of gonadotropin-independent precocious puberty is aimed at the underlying pathology. Girls with functional tumors involving the ovaries or adrenals are treated surgically; hCG-secreting tumors also may require adjunctive radiation or chemotherapy, depending on the type and location of the tumor. Solitary unilateral functional ovarian cysts also can be excised surgically. Children with CAH should receive treatment with glucocorticoids, and those with McCune-Albright syndrome generally are best treated with drugs that inhibit steroidogenesis or hormone action rather than surgery, to preserve fertility.

### **McCune-Albright Syndrome in Girls**

In girls with McCune-Albright syndrome, treatment can be aimed at blocking aromatization and estrogen production, but available evidence indicates that aromatase inhibitors, such as fadrozole, letrozole, and anastrozole, tend to lose their effectiveness over time.<sup>281,282,283,284</sup> The alternative is to block the effects of estrogens by treatment with an antiestrogen such as tamoxifen, which has been used successfully for treatment of associated vaginal bleeding.<sup>285</sup> Bisphosphonate treatment can be useful in the treatment of the fibrous dysplasia of the bone that causes pain and fractures.<sup>286</sup> Those who develop a gonadotropin-dependent component to their precocious development, due to chronic premature exposure to sex steroids, may benefit from adjunctive

treatment with a GnRH agonist, as in children with idiopathic gonadotropin-dependent precocious puberty.<sup>214</sup>

## **Management of Incomplete Precocious Puberty**

Although girls with isolated premature thelarche or premature adrenarche do not require treatment, they do merit regular examinations to detect other emerging evidence of precocious sexual development that may signal the need for further evaluation and possible treatment.

# DELAYED PUBERTY

---

Delayed puberty is defined by absent or incomplete sexual maturation by the age at which 95% of children of the same sex has started pubertal development. **In the United States, breast development, the usual first sign, begins by the age of 12 years in more than 95% of girls.**<sup>140</sup> Delayed puberty results from hypogonadism, which, in turn, can result from an inactive hypothalamic-pituitary axis (hypogonadotropic hypogonadism) or from primary gonadal failure (hypergonadotropic hypogonadism).

**The most common cause of hypogonadotropic hypogonadism is a functional GnRH deficiency, reflecting a constitutional delay in the reactivation of the hypothalamic-pituitary-gonadal axis or the suppressive effects of chronic stress due to illness, malnutrition, or excessive exercise.** GnRH deficiency also can result from genetic defects (e.g., Kallmann syndrome) or anatomical abnormalities (e.g., hypothalamic and pituitary tumors). Other causes of hypogonadotropic hypogonadism include pituitary failure, hypothyroidism, and hyperprolactinemia. Hypergonadotropic hypogonadism can result from idiopathic primary gonadal failure, from previous treatment of malignancy (gonadectomy, chemotherapy, gonadal radiation), or from a variety of congenital and genetic abnormalities or syndromes.

The distribution of diagnostic frequencies among girls with delayed puberty is shown in the table below, representing the findings in a series of 326 patients.<sup>287</sup> The series included all girls who were referred for evaluation of delayed pubertal milestones, including some with only primary amenorrhea relating to müllerian or other developmental anomalies or androgen insensitivity syndrome, who did not have true delayed puberty. In a subsequent study involving 74 females aged 18 years old and younger (mean age  $14 \pm 1.4$  year) referred to a tertiary center solely for the evaluation of delayed puberty, the final diagnosis was constitutional delay in 22 (30%), functional hypogonadotropic hypogonadism (chronic illness, eating disorders, excessive exercise) in 14 (19%), irreversible hypogonadotropic hypogonadism (genetic causes, CNS tumors) in 15 (20%), hypergonadotropic hypogonadism (previous chemotherapy, gonadal radiation, and congenital and genetic abnormalities) in 19 (26%), with 4 patients (5%) left unclassified<sup>288</sup> (Table 9.5).

## **TABLE 9.5 Relative Frequency of Delayed Pubertal Abnormalities**<sup>287</sup>

<b>Hypergonadotropic Hypogonadism</b>		<b>43.0%</b>
Ovarian failure, abnormal karyotype		26.0%
Ovarian failure, normal karyotype		17.0%
46,XX	15.0%	
46,XY	2.0%	
<b>Hypogonadotropic Hypogonadism</b>		<b>31.0%</b>
Reversible		18.0%
Physiologic delay	9.0%	
Weight loss/anorexia	3.0%	
Primary hypothyroidism	1.0%	
Congenital adrenal hyperplasia	1.0%	
Cushing syndrome	0.5%	
Prolactinoma	1.5%	
Irreversible		13.0%
GnRH deficiency	7.0%	
Hypopituitarism	2.0%	
Congenital CNS defects	0.5%	
Other pituitary adenomas	0.5%	
Craniopharyngioma	1.0%	
Malignant pituitary tumor	0.5%	
<b>Eugonadism</b>		<b>26.0%</b>
Müllerian agenesis		14.0%
Vaginal septum		3.0%
Imperforate hymen		0.5%
Androgen insensitivity syndrome		1.0%
Inappropriate positive feedback		7.0%

# Evaluation of Delayed Pubertal Development

The initial evaluation of delayed puberty begins in the same way as that for precocious puberty, with a careful history, physical examination, and a measurement of bone age.

The **medical history** should determine whether pubertal development has not yet started or began and then stopped. A careful evaluation of the previous growth pattern can provide important clues.<sup>289</sup> **Those with constitutional delay typically exhibit delayed growth, adrenarche, and sexual development, associated with declining growth velocity and delayed skeletal maturation.** Other important historical factors include dietary and exercise habits, previous serious illnesses, and medications that might delay the onset or slow the pace of pubertal progression.<sup>290</sup>

**Delayed puberty can be among the first clinical indications of an underlying metabolic disorder, such as inflammatory bowel disease or hypothyroidism.** Neurologic symptoms, including headache, visual disturbances, anosmia, dyskinesia, seizures, and mental retardation, suggest a CNS disease or disorder. Anosmia suggests strongly a genetic cause, such as a KAL1, FGF8, FGFR1, PROK2, or PROKR2 gene mutation (all associated with different forms of Kallmann syndrome). **A complete family history, with emphasis on the age at pubertal milestones in older siblings and parents, also provides useful information; in most patients with constitutional delay, other family members have a similar history.**<sup>288</sup>

The **physical examination** should include height, weight, arm span, and Tanner staging of breast and pubic hair development. Height should be compared to norms for age and for bone age and then carefully monitored for at least 6 months. A eunuchoid body habitus (arm span exceeds height by  $\geq 5$  cm) suggests delayed epiphyseal closure due to hypogonadism. In the presence of breast budding (Tanner stage 2), a normal spontaneous puberty generally can be expected and both the patient and family can be reassured. Congenital malformations such as midline defects and skeletal abnormalities (cleft lip/palate, scoliosis) suggest congenital GnRH deficiency resulting from genetic mutations involving elements of the fibroblast growth factor signaling pathway. As in patients with precocious puberty, a fundoscopic examination should be performed to detect papilledema and visual fields should be evaluated.

A measurement of **bone age** should be obtained for comparison with chronologic age and for assessment of the potential for future growth. **Patients with constitutional delay of puberty typically exhibit a bone age between 12 and 13.5 years, which generally does not progress further without the exposure to gonadal steroids that is required for epiphyseal closure.**

## Laboratory Evaluation and Imaging

The laboratory evaluation of girls with delayed puberty is aimed first at differentiating primary (hypergonadotropic) from secondary (hypogonadotropic) hypogonadism, which typically can be accomplished by measuring the serum FSH, LH, and estradiol concentrations.

By midadolescence, gonadotropin levels, particularly FSH, are grossly elevated in girls with primary gonadal failure.<sup>27</sup> In patients with hypogonadism, low basal gonadotropin levels are consistent with the diagnosis of constitutional delay of puberty, but also with congenital GnRH deficiency or pituitary gonadotropin deficiency. Ultrasensitive immunofluorometric assays for FSH and LH may help to distinguish the low but detectable concentrations typically observed in those with constitutional delay from the undetectable levels in patients with congenital GnRH deficiency, but these assays have not yet been widely validated for use in patients who are truly GnRH deficient.<sup>23</sup> **GnRH agonist stimulation testing generally is not helpful or necessary.** Whereas some have found that stimulation with a GnRH agonist (buserelin, nafarelin, triptorelin) can successfully discriminate constitutional delay of puberty from congenital GnRH deficiency in boys,<sup>291,292,293</sup> similar studies have not been conducted in girls with delayed puberty. Consequently, after excluding other causes, time and serial observations may be required to establish the correct diagnosis.

**When the estradiol level is clearly low, a serum FSH level in the low normal range has the same interpretation and clinical implication as a frankly low FSH concentration.** If the hypothalamic-pituitary-ovarian axis was intact and functioning normally, the FSH level should be high when estrogen levels are grossly low; therefore, a “normal” value is abnormally low in that clinical context and indicates hypothalamic-pituitary suppression or dysfunction. Moreover, although the level of immunoreactive FSH may be normal, the level of biologically active FSH may not be, because patients with hypogonadotropic hypogonadism may secrete gonadotropins having altered patterns of glycosylation and reduced biologic activity.<sup>294</sup>

Further laboratory evaluation is directed toward determining the cause of hypogonadotropic or hypergonadotropic hypogonadism, once that is established.

### Hypogonadotropic Hypogonadism

In girls with hypogonadotropic hypogonadism, measurement of the serum **prolactin** concentration is indicated to identify those with hyperprolactinemia, which can cause either delayed or arrested pubertal development, depending on when it arises. Hyperprolactinemia can result from excessive secretion by a pituitary lactotrope adenoma, from any other hypothalamic or pituitary tumor or disorder that interrupts the

normal delivery of hypothalamic dopamine via the tuberoinfundibular tract, or from medications that interfere with the actions of dopamine. **Therefore, hyperprolactinemia is an indication for imaging by MRI, except when it can be attributed confidently to medications.**

Measurement of the serum **TSH and free thyroxine (T4)** concentrations also is indicated to identify those who may have primary or secondary hypothyroidism, particularly if growth velocity has slowed and the bone age is grossly delayed.

The serum **DHEA-S** concentration may be helpful for distinguishing constitutional delay of puberty from congenital GnRH deficiency. Patients with congenital GnRH deficiency are more likely to have a normal adrenarche than those with constitutional delay, although values in the two groups frequently overlap.<sup>295</sup>

Other laboratory tests are aimed at identifying those who may have an occult chronic illness, such as chronic inflammatory bowel disease, liver disease, or anorexia nervosa, and should include a **complete blood count, erythrocyte sedimentation rate, and liver function tests.**

Although **pelvic ultrasonography** can be used to determine the presence or absence of a uterus in virginal girls, it must be interpreted cautiously because results can be misleading when the reproductive organs are immature and very small and generally are unnecessary. Whereas müllerian anomalies are a common cause of primary amenorrhea, they are not associated specifically with delayed puberty.

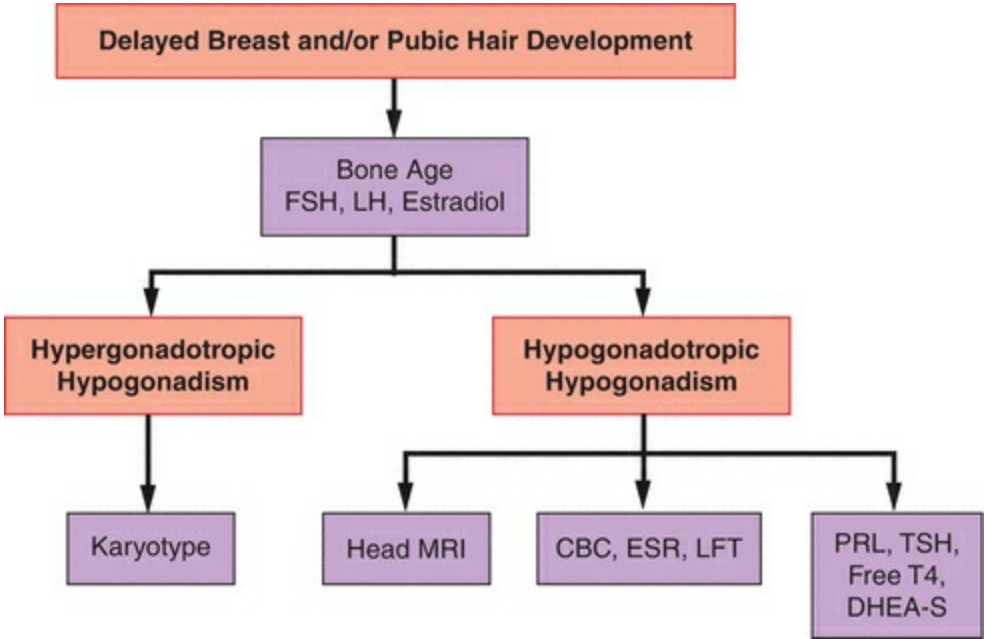

**A head MRI should be obtained in patients with hypogonadotropic hypogonadism and those with neurologic signs or symptoms.** In addition to detecting mass lesions, imaging can reveal the presence or absence of the olfactory bulbs and tracts (absent in Kallmann syndromes).

## **Hypergonadotropic Hypogonadism**

**A karyotype should be obtained in all girls with hypergonadotropic hypogonadism to detect chromosomal abnormalities, except when a history of previous chemotherapy or gonadal radiation provides an obvious explanation.** The most common disorder of this type is gonadal dysgenesis, with Turner syndrome (45,X) being the prototype. In addition to other structural X chromosome abnormalities (e.g., deletions, rings, and isochromosomes), karyotype will identify those harboring a Y chromosome (e.g., 46,XY, Swyer syndrome), in whom gonadectomy will be indicated due to the significant risk for malignant transformation in occult testicular elements (20–30%).

In patients with hypergonadotropic hypogonadism and a normal (46,XX) karyotype, the diagnostic possibilities include 17-hydroxylase deficiency, a rare steroidogenic

enzyme defect associated with sexual infantilism and hypertension, and other uncommon causes of primary ovarian failure, all of which are discussed in [Chapter 10](#) ([Figure 9.8](#)).

**FIGURE 9.8**

# Treatment of Delayed Puberty

The first priority in the treatment of delayed puberty is to correct the specific cause, when that is possible, such as thyroid hormone therapy for hypothyroidism, dopamine agonist therapy for hyperprolactinemia, and excision of a craniopharyngioma or other operable central lesion. In those with no such identifiable cause, congenital GnRH deficiency must be distinguished from constitutional delay of puberty, but in most, a final diagnosis can be established only after serial observations; however, treatment options are the same in either case.

Patients with congenital GnRH deficiency or constitutional delay of puberty can be managed expectantly, providing reassurance and psychological support, or with hormone therapy, which may be appropriate for those with severe pubertal delay or serious psychosocial concerns that cannot be resolved with reassurance and education. **In general, sex hormone therapy should be limited to girls over 12 years of age having few or no signs of sexual maturation causing significant distress or anxiety.**

**The goals of short-term hormone therapy are to foster age-appropriate secondary sexual development and to induce a growth spurt and a normal adolescent increase in bone density without causing premature epiphyseal closure, which requires that bone age be monitored at 6-monthly intervals during treatment.** In those who prove ultimately to have an isolated GnRH deficiency, the longer-term goals are to maintain sex hormone levels in the normal physiologic range and to induce ovulation with exogenous gonadotropin therapy when fertility becomes a priority. Oral or transdermal estrogen therapy can be used, beginning at doses well below those used for adults (e.g., 0.25–0.5 mg oral micronized estradiol or its equivalent), increasing gradually at intervals of 3–6 months according to response (Tanner stage, bone age), with the goal of completing sexual maturation over a period of 2–3 years. **A progestin should not be added to the treatment regimen until there is substantial breast development and full contour breast growth has plateaued, because premature progestin treatment can adversely affect breast growth or contours.** In general, progestin therapy can safely begin once menses have begun or after 12–24 months of estrogen treatment. Once breast development has been accomplished and menses are established, hormone therapy can be discontinued for 1–3 months, at intervals, to observe whether spontaneous menses will begin, as can be expected in girls with constitutional delay of puberty. Persistent hypogonadism beyond 18 years of age clearly suggests congenital GnRH deficiency.

In general, GH therapy is best limited to those with documented GH deficiency. Serum GH and IGF-I levels typically are low in patients with constitutional delay of puberty but increase after treatment with estrogen and usually are normal in those with

congenital GnRH deficiency.

# GROWTH PROBLEMS IN NORMAL ADOLESCENTS

---

Perhaps, the worst thing about an adolescent growth problem is that it makes the individual feel “different.” It is probably true that, more than anyone else, the adolescent does not like to be different. Therefore, concerns over unusually short or tall stature deserve attention and should not be dismissed.

Growth in height is a continuous but not a linear process. There are three distinct phases of growth. The first is the infantile phase, which is characterized by rapid growth amounting to a total of 30–35 cm during the first 2 years of life. The next phase is the childhood phase, during which growth proceeds at a relatively constant pace of 5–7 cm/year, often slowing in late childhood. The last is the pubertal phase, which is characterized by a growth spurt at a rate of 8–14 cm/year, reflecting the effects of increasing levels of both GH and sex steroid hormones.<sup>296,297</sup>

The contribution of heredity to final adult height is difficult to predict accurately, but a child’s height potential can be estimated by calculating the **midparental height**; for girls, midparental height is calculated as follows:

$$\frac{(\text{father's height} - 13 \text{ cm}) + (\text{mother's height})}{2}$$

**Target height** represents a range of heights encompassing the 3rd to 97th percentiles for expected adult height, equating with the midparental height  $\pm 8.5$  cm.<sup>298</sup> For children with delayed or accelerated growth, height should be adjusted to the appropriate percentile based on bone age, rather than chronologic age, to permit a more accurate judgment regarding whether growth is consistent with genetic potential.

**The basic and essential laboratory test in the evaluation of perceived abnormal growth is a left hand/wrist x-ray for bone age.** The Bayley-Pinneau tables (found at the end of this chapter) can be used to determine a **predicted adult height**, based on current height and bone age, in reference to the Greulich-Pyle Atlas.<sup>299</sup> The predicted adult height is the number found where the column corresponding to the patient’s current height intersects the row corresponding to her bone age. If bone age is within 1 year of chronologic age, the table for average girls should be used. If bone age is accelerated or delayed by 1 year or more, the tables for children with accelerated or delayed growth should be used, with one exception. Height predictions for girls with idiopathic GnRH-dependent precocious puberty are more accurate when using the table for average girls.<sup>300</sup>

# Short Stature

Short stature is defined as height 2 or more standard deviations below the mean height for children of the same sex and chronologic age, as determined by plotting height on an appropriate growth chart. **Accurate serial measurements of height and growth velocity are perhaps the most useful tool in the evaluation of children with growth failure.**<sup>301</sup> **The pattern of growth is more important than any single point measurement.** Slowing growth that increasingly deviates from a previously defined pattern (percentile) is the key finding. **Children should grow at a rate of at least 5 cm/year from age 4 year to the onset of puberty.**

The most common causes of short stature are familial (genetic) and constitutional delay of growth; both are characterized by a normal growth velocity. If growth velocity is abnormally low (less than fifth percentile for age), a thorough evaluation for the many potential causes is warranted, as described below.

Short stature is a feature of a variety of chromosomal (Down syndrome, Turner syndrome) and other genetic disorders (Noonan syndrome, Russell-Silver syndrome) and commonly is associated with intrauterine growth restriction or infections and maternal exposures during pregnancy such as smoking and alcohol. Children with short stature relating to endocrine disorders such as Cushing syndrome, GH deficiency, and hypothyroidism usually are overweight for height. In contrast, those with malnutrition due to an eating disorder, excessive exercise, malabsorption, or other systemic illness typically are underweight for height and merit evaluation for gastrointestinal,<sup>302,303</sup> heart, pulmonary,<sup>304</sup> and renal disease.<sup>305</sup>

**Idiopathic short stature** describes children whose height is more than 2 standard deviations below the mean for age with no identifiable endocrine, metabolic, or other cause. Such children generally exhibit low normal growth velocity and have normal serum IGF-I levels. Those with genetic or familial short stature typically have normal bone age and a predicted adult height within the target range, whereas those with constitutional delay of growth have delayed bone age. Recent evidence has suggested that 2–15% of children with idiopathic short stature may have mutations in the SHOX (Short Stature Homeobox) gene, located at the distal tip of the short arm of the X chromosome (Xp22.33).<sup>306,307,308</sup> Affected children tend to have short forearms and lower legs, Madelung deformity of the forearm (a congenital subluxation or dislocation of the distal ulna), cubitus valgus (wide carrying angle of the arm), a high-arched palate, and muscle hypertrophy, compared to those without such mutations.<sup>309</sup> Additional mutations with similar phenotype have been found on various autosomal chromosomes like FGFR3 (4p16.3), ACAN (15q26.1), NPPC (2q37), and NPR2 (9p13).<sup>310</sup>

## Evaluation

Although it is unlikely that a patient with congenital hypothyroidism will present undiagnosed and untreated as an adolescent, thyroid function always should be evaluated. Because both primary and secondary hypothyroidism can cause growth failure, both the serum TSH and free T4 concentrations should be measured. Cushing syndrome (hypercortisolism) is rare in children, except when it results from excess glucocorticoid treatment. Children with congenital GH deficiency generally are not difficult to recognize, usually presenting as young children with severe growth failure, delayed bone age, and very low serum concentrations of IGF-I and its major binding protein, IGFBP-3. Provocative tests of GH secretion are required to establish the diagnosis.

The evaluation of children with short stature should include the following:

- Bone age
- A complete blood count and erythrocyte sedimentation rate
- Electrolytes, creatinine, bicarbonate, calcium, phosphate, alkaline phosphatase, and albumin
- TSH, free T4, IGF-I (and IGFBP-3 in children under 3 years of age)
- Antiendomysial antibodies (a serologic screen for celiac disease)
- Karyotype (to exclude Turner syndrome or other X chromosome abnormalities)

A head MRI is not required to establish the diagnosis of idiopathic short stature, but should be considered in children with known GH deficiency and those with signs or symptoms of hypothalamic-pituitary dysfunction.

## Treatment

GH therapy for idiopathic short stature was approved by the U.S. Food and Drug Administration in 2003 and is considered indicated for girls whose height is more than 2.25 standard deviations below the mean for age whose epiphyses are not closed and whose predicted adult height is less than 59 inches. **However, GH treatment of children with idiopathic short stature is controversial, because the response to therapy is unpredictable and typically quite modest<sup>311,312,313,314</sup> and because evidence that short stature has significant psychosocial consequences is lacking.<sup>315,316,317</sup>**

Most children with idiopathic short stature, particularly those with constitutional delay of growth, exhibit catch-up growth during puberty without treatment.<sup>311,318</sup> Moreover, the average increase in height is only approximately 4–6 cm after more than

5 years of treatment.<sup>313</sup> The optimal age for starting treatment is between age 5 years and early puberty.<sup>319</sup>

GH treatment has relatively few potential adverse effects.<sup>311,313,320</sup> Although high-dose treatment has been reported to advance the onset of puberty and epiphyseal closure,<sup>321</sup> lower doses do not.<sup>322</sup> Current evidence suggests that the impact of treatment correlates with serum IGF-I levels and that treatment can be optimized when the dose of GH is adjusted to maintain a normal IGF-I concentration.<sup>319</sup> **However, GH therapy generally should be limited to children whose short stature is a significant disability and whose self-image and socialization are judged likely to improve significantly with an increase in height.**<sup>323,324</sup> The associated costs and potential benefits must be weighed carefully because the costs of GH therapy are extremely high. In the United States, the cost has been estimated to exceed \$50,000 per inch gained in adult height!<sup>325</sup>

An alternative approach to treatment involves the use of a long-acting GnRH agonist to delay pubertal development and epiphyseal fusion. However, the modest impact of such treatment (ranging up to only 4 cm in increased height) comes at the cost of a substantial decrease in bone mineral density accretion.<sup>326</sup> Although treatment with an aromatase inhibitor might also seem logical, such therapy actually slows growth in girls via profound inhibition of estrogen production.

# Tall Stature

Tall stature is defined as height 2 or more standard deviations above the mean height for children of the same sex and chronologic age. Although tall stature is nearly as common as short stature, it is perceived as more socially acceptable and less commonly perceived as a problem. Most children with tall stature, like those with short stature, represent the extremes of a normal distribution of heights and only a few have a specific growth abnormality.<sup>327</sup>

Abnormally rapid growth during childhood and adolescence can result from precocious pubertal development, GH excess,<sup>328</sup> hyperthyroidism,<sup>329</sup> sex hormone deficiency or insensitivity,<sup>330,331</sup> or rare autosomal recessive disorders such as familial glucocorticoid deficiency<sup>332</sup> or resistance<sup>333</sup> and congenital total lipodystrophy.<sup>334</sup> Patients with Marfan syndrome,<sup>335</sup> homocystinuria,<sup>336</sup> and neurofibromatosis type I also can be unusually tall.<sup>337</sup>

The diagnosis of familial or constitutional tall stature generally is established by family history and the absence of dysmorphic features, distinguishing it from disorders of excessive growth. **In most tall but otherwise normal children, a careful family history, physical examination, and bone age generally are all that is required to establish the diagnosis and to provide reassurance.** Serial measurements of growth at 6–12-month intervals can help to confirm that growth is in the high normal range but not excessive. The Bayley-Pinneau tables (found at the end of this chapter) can be used to predict adult height in tall girls and become more accurate after the age of 12 years; in younger children, they may tend to overestimate adult height.<sup>338</sup>

## Treatment

As in otherwise normal short children and adolescents, the treatment of tall children and adolescents is controversial, generally discouraged, and should be limited to those whose tall stature is the cause of significant psychosocial problems.<sup>339,340,341</sup>

Sex steroids have been used to treat tall girls and boys for decades, the goal being to promote early epiphyseal fusion.<sup>342,343</sup> **The earlier treatment is started, the greater the likelihood that adult height will be diminished.** The stage of secondary sexual development is relevant because the adolescent growth spurt precedes menarche, and treatment must begin before menarche to be optimally effective.<sup>327</sup> Although that implies that treatment could begin as early as age 8 or 9 years, the usual age to begin treatment is between 10 and 12 years. However, treatment that begins after menarche can still achieve up to an inch of growth reduction.<sup>344,345</sup> A typical starting dose is 15–30 µg of ethinyl estradiol, which can be administered in a low-dose oral contraceptive

pill. Treatment should continue until the epiphyses are closed, as can be determined by serial measurements of bone age at 6–12-month intervals during treatment.<sup>346</sup> The mean adjusted reduction in height ranges up to 6 cm, but averages a more modest 1–2.5 cm,<sup>338</sup> and treatment is not without potential complications and future consequences. Common side effects include nausea, water retention and weight gain, and menorrhagia. Whereas an early study found no adverse effects of treatment on future fertility,<sup>347</sup> a more recent study involving 1,243 adult women with hereditary tall stature observed that the risk for future infertility was significantly increased and that cycle fecundability was decreased by approximately 40% in those treated with estrogen as adolescents, compared to those who received no treatment.<sup>348</sup> This was further confirmed in a subsequent study from the Netherlands involving 125 tall women aged 20–42 years, of whom 52 women had been treated with 100 µg and 43 with 200 µg of ethinyl estradiol in adolescence.<sup>349</sup> In that study, 80% of untreated women achieved pregnancy within 1 year, compared to 69% of women treated with 100 µg and 59% of women treated with 200 µg ethinyl estradiol; there was a significant correlation between the estrogen dose and time to pregnancy. The mechanism responsible for the effect is still unknown, but it might be related to ovarian function and follicular depletion. In a study from the same Dutch group comprising 285 tall women (157 treated and 128 untreated), treated women had significantly higher odds of being diagnosed with imminent ovarian failure (OR 2.83, 95% CI = 1.04–7.68).<sup>350</sup> Serum FSH levels in these women were significantly increased, whereas antral follicle counts and serum antimüllerian hormone levels were decreased<sup>350</sup> (Tables 9.6, 9.7, 9.8).

# Amenorrhea

Few problems in gynecologic endocrinology can present a diagnostic challenge to clinicians like that of amenorrhea. The number, variety, and complexity of diseases and disorders that must be considered can seem daunting and, in many instances, include unfamiliar organ systems. Moreover, some of the diagnostic possibilities can have serious consequences, if not recognized and treated effectively. Consequently, otherwise confident and experienced clinicians may view the problem as too complicated and time-consuming or may question their ability to perform or interpret the evaluation. However, when approached logically and systematically, the diagnostic evaluation of amenorrhea truly is straightforward, involving thorough history taking and a finite number of laboratory tests and procedures already familiar to almost all clinicians. With few exceptions, an evaluation can be completed quickly and without great expense.

The purpose of this chapter is to provide a systematic strategy for the evaluation of amenorrhea that will yield an accurate diagnosis, no matter how common or uncommon the cause. Once a diagnosis is established, additional corroborating evidence and the assistance of appropriate specialists (e.g., neurosurgeon, internist, endocrinologist, or psychiatrist) can be obtained, when necessary. However, the large majority of women with amenorrhea have relatively simple problems—polycystic ovary syndrome (PCOS), hypothalamic amenorrhea, hyperprolactinemia, and ovarian failure—all of which can be managed easily by the primary health providers after an initial consultation with a specialist.

The diagnostic evaluation described here is not new. With minor modifications, it has been applied successfully for several decades. Before describing the evaluation in detail, amenorrhea first must be defined, so as to identify the patients who warrant an evaluation. A brief preliminary review of the physiologic mechanisms involved in menstruation (discussed in detail in [Chapter 5](#)) provides the framework necessary to understand and follow the logical design of the diagnostic evaluation.

# DEFINITION OF AMENORRHEA

---

The age at which menarche should be expected varies with individual differences in the age at the onset of puberty. The normal pubertal progression is discussed in detail in [Chapter 9](#) and is only briefly summarized here. In general, the first menses should occur within 2–3 years after the initiation of pubertal development. In most young girls (approximately 80%), the first sign of puberty is an acceleration of growth (the growth spurt), followed by breast budding (thelarche) and the appearance of pubic hair (adrenarche). In the remainder (approximately 20%), adrenarche precedes thelarche by a brief interval, but the two events typically are closely linked. Consequently, menarche can occur as early as age 10 (when puberty begins at age 8) and rarely occurs later than age 16 (when puberty begins at age 13). On average, the mean ages for thelarche, adrenarche, and menarche in girls of African ancestry are 6–12 months earlier than in Caucasian girls. Once normal menstrual cycles have been established, menses should occur at regular intervals ranging between 25 and 35 days. The term amenorrhea refers to “absence of menses.” **Patients fulfilling any of the following criteria should be evaluated for amenorrhea:**

- **No menses by age 14 in the absence of growth or development of secondary sexual characteristics**
- **No menses by age 16 regardless of the presence of normal growth and development of secondary sexual characteristics**
- **In women who have menstruated previously, no menses for an interval of time equivalent to a total of at least three previous cycles or no menses over a 6-month period**

Having affirmed the traditional definition of amenorrhea, it is important to point out that unduly strict adherence to these criteria with a disregard to the overall clinical picture can result in a delay in identifying serious underlying health conditions. For example, there is no reason to defer the evaluation of a young girl who presents with the classical phenotype of Turner syndrome. Similarly, a 14-year-old girl who has no vagina should not be advised to return in 2 years before initiating evaluation and offering intervention. All patients deserve a considerate evaluation at initial presentation. Finally, the possibility of pregnancy as a reason for amenorrhea must always be considered.

Traditionally, amenorrhea has been categorized as primary or secondary. Primary amenorrhea describes patients who have never menstruated, and secondary amenorrhea describes those who have menstruated previously but now do not. The differential diagnoses of primary and secondary amenorrhea differ. For example, when evaluating a case of primary amenorrhea, the clinician must consider a wide range of possibilities;

these should include consideration of possible absence of hypothalamic gonadotropin-releasing hormone (GnRH) (such as in cases of Kallmann syndrome), disorders of the pituitary (ranging from hyperprolactinemia, secondary hypothyroidism to abnormalities in the secretion of growth hormone [GH] and gonadotropins), abnormalities of the ovaries that could range from gonadal dysgenesis to functional abnormalities such as PCOS, and abnormalities of the müllerian system that could range from complete absence of the uterus to various forms of obstructive anomalies such as imperforate hymen, transverse vaginal septum, or vaginal agenesis. In contrast, when encountering secondary amenorrhea, developmental absence of GnRH or presence of obstructive uterine anomalies of the müllerian system as a mechanism for amenorrhea is highly unlikely. While these classic distinctions between primary and secondary amenorrhea can help narrow the scope of diagnostic possibilities, such preliminary categorization can sometimes be misleading. For example, premature ovarian insufficiency (POI), PCOS, and pregnancy can present as either primary or secondary amenorrhea. In any case, the diagnostic approach recommended here can be applied effectively in all women with amenorrhea.

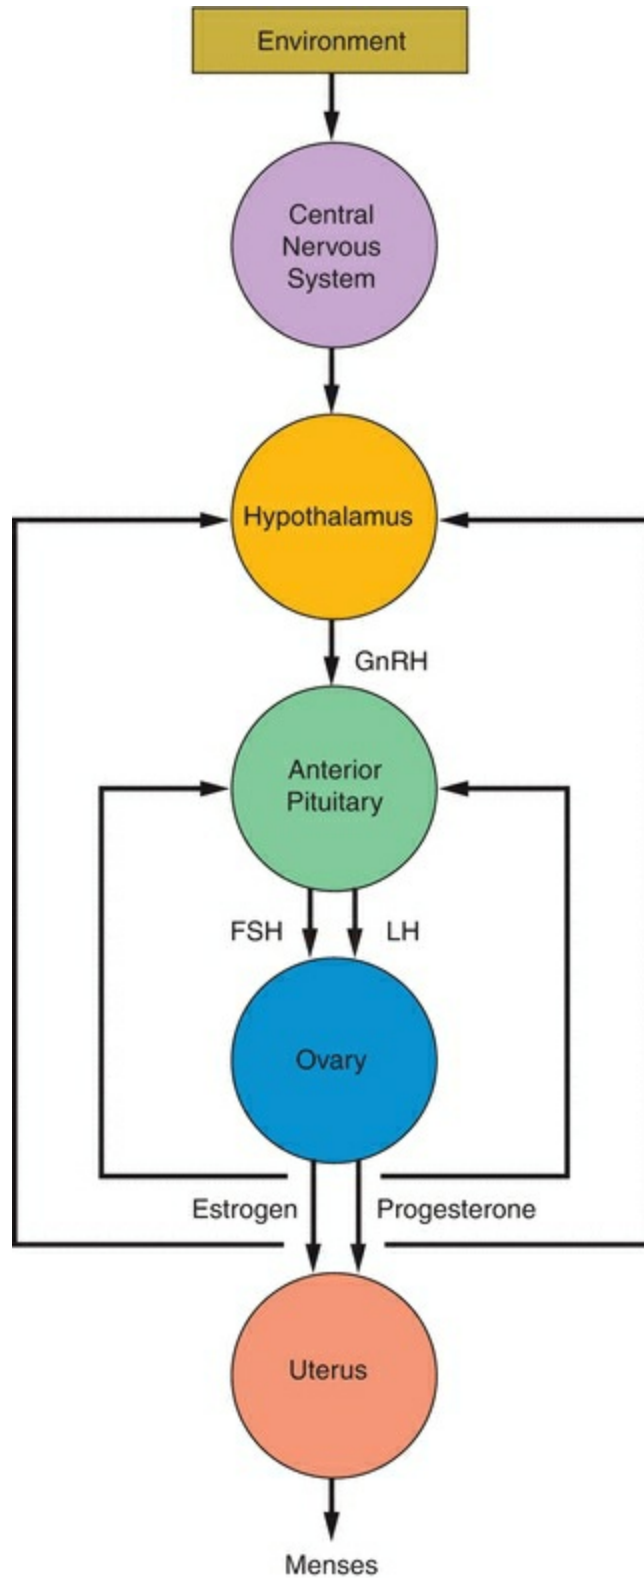

# BASIC PRINCIPLES IN MENSTRUAL FUNCTION

---

A functioning hypothalamo-pituitary-ovarian (HPO) axis along with a normal uterovaginal anatomy is a requisite for menstrual function. The ovaries must contain viable follicles that can respond to stimulation by the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), released from the anterior pituitary. In turn, pituitary gonadotropin secretion depends on the action of GnRH, secreted from the medial basal hypothalamus into the portal vascular network that bathes the anterior pituitary. Finally, the pulsatile pattern of hypothalamic GnRH secretion is governed by input from higher centers that interpret and translate environmental stimuli and modulated by the feedback effects of ovarian sex steroids. Finally, the uterus must contain a functional endometrium that can respond to the actions of ovarian sex steroid hormones, estrogen and progesterone, across the ovarian cycle of follicle development, ovulation, and corpus luteum function, and the genital outflow tract must be anatomically intact with continuous connection between the vaginal orifice, the vaginal canal, the endocervix, and the uterine cavity, to allow egress to the menstrual flow that marks the beginning of each menstrual cycle. The entire system is highly regulated by a complex interplay of mechanisms that integrate biophysical and biochemical information composed of interacting hormonal signals, autocrine/paracrine factors, and target cell reactions.

The basic requirements for normal menstrual function thus include four anatomically and functionally distinct structural components—(1) the genital outflow tract including the uterus, cervix, and vagina; (2) the ovary; (3) the pituitary; and (4) the hypothalamus—thus providing a natural and useful hierarchy for organizing the diagnostic evaluation of amenorrhea (**Figure 10.1**).

**FIGURE 10.1**

Therefore, the many causes of amenorrhea can be categorized according to the site or level of the disorder or disturbance:

- **Disorders of the genital outflow tract and uterus**
- **Disorders of the ovary**
- **Disorders of the anterior pituitary**
- **Disorders of the hypothalamus or central nervous system**

Amenorrhea can result from congenital or acquired disease or dysfunction at any level in the system and can involve more than one mechanism. For example, PCOS involves a number of interrelated pathophysiologic mechanisms operating at multiple levels including the ovarian, the pituitary, and the hypothalamus.

# EVALUATION OF AMENORRHEA

---

Like any other complaint, evaluation begins with a careful medical history followed by a detailed physical examination, which always provide valuable diagnostic clues. Information gained from the medical history and physical examination clearly can exclude certain differential diagnoses; however, hasty first impressions also can be deceiving and can lead to errors in judgment and to inappropriate, costly, and needless testing. A methodical, systematic approach to evaluation to help arrive at the most plausible diagnosis therefore is best.

Logically, the recommended evaluation for amenorrhea is designed to separate the reproductive physiology and function into its distinct structural components—the genital outflow tract and uterus, the ovary, the pituitary, and the hypothalamus—and to test the functional integrity of each, beginning at the lowest level and progressing systematically to the higher levels of the system until the cause is determined.

# Medical History

The menstrual history is, of course, key. Primary amenorrhea speaks for itself, but cyclic pelvic or lower abdominal pain or urinary complaints can be caused by developmental anomalies resulting in obstructed menstrual flow (cryptomenorrhea), such as may be caused by an imperforate hymen, transverse vaginal septum, or cervical atresia. In women with secondary amenorrhea, the history surrounding the onset of amenorrhea can provide important diagnostic clues. Onset of amenorrhea following endometrial curettage or other uterine surgery involving the endometrial cavity (e.g., resection of a submucous uterine fibroid) clearly suggests the possibility of damage to the endometrium as a mechanism for amenorrhea (e.g., Asherman syndrome resulting from endometrial curettage undertaken for removal of products of conception in management of a nonviable early pregnancy). Amenorrhea, either secondary or even primary, in the setting of symptoms of hyperandrogenism (acne, excess facial and bodily hair, or thinning of scalp hair) is highly suggestive of PCOS. Galactorrhea in the setting of amenorrhea identifies hyperprolactinemia, PCOS, or pregnancy as plausible mechanisms for amenorrhea. Women with PCOS classically present with infrequent and irregular menses dating from menarche or early adulthood and often report long-standing symptoms of hyperandrogenism. In most with hypothalamic amenorrhea, the onset of amenorrhea temporally relates to events resulting in severe nutritional, physical, or emotional stress. Picture of POI can vary with some women presenting as primary amenorrhea, others reporting varying durations of menstrual irregularity before amenorrhea, to sudden cessation of menses in the absence of any prior menstrual disturbances. While symptoms of hypoestrogenism, such as hot flashes and night sweats, are often experienced by women with POI presenting as secondary amenorrhea, these symptoms may not be experienced when POI develops prior to onset of puberty.

Questions relating to past medical history, general health, and lifestyle can identify a severe or chronic illness such as diabetes, renal failure (which is often associated with elevated prolactin levels, primarily reflective of altered renal clearance), or inflammatory bowel disease, previous head trauma, or evidence of physical or psychological stress. Specific history relating to weight loss or weight gain and to the frequency and intensity of exercise is highly relevant and often revealing. Headaches, seizures, vomiting, behavioral changes, or visual symptoms may suggest a disorder of the central nervous system. Vaginal dryness or hot flashes are evidence of estrogen deficiency and suggest ovarian insufficiency. Progressive hirsutism or features of virilization are unusual in PCOS and concerning for either nonclassical (late-onset) congenital adrenal hyperplasia (CAH) or an androgen-producing tumor of the ovary or adrenal gland; possibility of exposure to exogenous androgens as a mechanism for worsening hyperandrogenism must also be considered. Symptoms of galactorrhea obviously suggest hyperprolactinemia, but may require directed questioning as this

symptom may not be spontaneously divulged by some women. History relating to the time and duration of any treatment with oral contraceptive pills (OCP), progestins (e.g., depot medroxyprogesterone acetate [MPA], progestin implants, or intrauterine system), GnRH agonists (often used for management of common gynecologic disorders such as endometriosis, uterine fibroids, and premenstrual syndrome), or other medications or drugs that can affect central neurotransmitter secretion and thereby disrupt hypothalamo-pituitary signals that are critical to normal menstrual function (phenothiazines, reserpine derivatives, amphetamines, benzodiazepines, antidepressants, dopamine antagonists, opiates) also can provide important diagnostic clues. Pregnancy as a mechanism for amenorrhea must always be considered, regardless of patient's age.

# Physical Examination

The overall body habitus often provides important information. Height, weight, and body mass index (BMI) should be determined and recorded. A combination of sexual infantilism and short stature (<60 inches, or 152.4 cm) is a hallmark of gonadal dysgenesis. Hypothalamic amenorrhea is often seen in conditions associated with poor nutrition (eating disorders such as anorexia nervosa, malabsorption syndromes) or physical, psychological, or emotional stress. Obesity and an increased waist-hip ratio (>0.85) are commonly encountered in women with PCOS.

Both hypothyroidism and hyperthyroidism can be associated with amenorrhea. Examination of the skin can reveal a soft, warm, and moist texture as seen in hyperthyroidism; a rapid pulse, exophthalmos or lid lag, a fine tremor, and hyperreflexia suggest the diagnosis of Graves disease; goiter may not always be appreciated. Conversely, dry, coarse skin, a slow pulse, diminished reflexes, and thinning of the hair, particularly involving eyebrow hair, are suggestive of hypothyroidism. A goiter or thyroid nodule is further evidence of a thyroid disorder. Orange discoloration of the skin, without scleral icterus, can result from hypercarotenemia associated with excessive ingestion of low-calorie carotene-containing fruits and vegetables in chronically dieting women. Acanthosis nigricans (velvety hyperpigmented skin observed most commonly at the nape of the neck, in the axillae and groin, and beneath the breasts) strongly suggests severe insulin resistance, hyperinsulinemia, and the possibility of type II diabetes. Features of hyperandrogenism, such as acne and hirsutism, are common symptoms of PCOS, but can also be the presenting symptoms of nonclassical CAH, or result from exposure to androgenic anabolic steroids. When accompanied by any sign of frank virilization (deepening of the voice, frontotemporal balding, decrease in breast size, increased muscle mass, clitoromegaly), the possibility of ovarian hyperthecosis or an ovarian or adrenal neoplasm must be considered.

Examination of the breasts deserves careful attention. **Breast development is a reliable indicator of endogenous estrogen production or exposure to exogenous estrogens.** The Tanner stage of breast development should be noted ([Chapter 9](#)). A secondary arrest of breast development suggests a disruption of the HPO axis. When menarche has not followed breast development at the expected time (ideally, within 2 years of thelarche), a developmental anomaly of the reproductive tract as a mechanism for primary amenorrhea should be high in the list of differential diagnoses. Breast examination should be systematic and thorough yet gentle, and examination of the nipple must be undertaken to evaluate for expressible galactorrhea. **Secretions that result from hormonal stimulation of the breast tissue typically emerge from multiple duct openings at the nipple, whereas a discharge relating to breast pathology usually arises from a single duct.** Macroscopic characteristics of any expressed nipple

discharge can point to the underlying etiology; bilateral nipple discharge that appears milky or opaque is a classic manifestation of hyperprolactinemia; unilateral bloody or greenish discharge should raise concerns for a focal ductal pathology and should be further evaluated with imaging studies (mammography, ultrasound, or even breast MRI). Microscopic examination of any expressed cloudy or white nipple secretions demonstrating lipid droplets confirms galactorrhea and suggests hyperprolactinemia. Evidence of chronic chest wall lesion(s) (such as eczema) may even identify a mechanism for hyperprolactinemia.

Abdominal examination rarely may reveal a suprapubic mass, as may result from hematometra or an eccentric mass suggestive of an ovarian neoplasm. Excessive growth of terminal hair in the infraumbilical region and extension of pubic hair in a male escutcheon pattern are suggestive of hyperandrogenism. Purple hue abdominal striae raise the possibility of Cushing syndrome (discussed in [Chapter 13](#)); more commonly, however, pale pink stretch marks along the abdominal wall often result from progressive obesity or a previous pregnancy.

Careful examination of the external genitalia and the lower genital tract is key, particularly when evaluating for primary amenorrhea. **The presence of pubic hair growth reliably reflects androgen production or exposure.** Because breast development and growth of pubic hair typically progress in a symmetrical manner, their Tanner stages should be consistent. Absent or scant growth of sexual hair can be expected in otherwise sexually infantile girls, but also is a classical sign of androgen insensitivity syndrome (AIS) when breast development may be asymmetrically advanced. Clitoromegaly is a concerning sign of virilization and should prompt evaluation for hyperandrogenemia; obvious and severe enlargement of the clitoris may suggest ambiguous genitalia, and in this case, assessment of karyotype may be the next step in evaluation. Attempts at office examination of the vagina in sexually infantile girls or those with a small hymenal ring are generally non-informative and often even counterproductive; such an examination can be effectively undertaken under anesthesia, at which time either a speculum examination or vaginoscopy can be performed to document the presence and appearance of the cervix. A patent vagina and normal cervix exclude müllerian/vaginal agenesis, AIS, and obstructive causes of primary amenorrhea such as an imperforate hymen or a transverse vaginal septum. In those with primary amenorrhea having an absent or infantile vaginal orifice, rectal examination can provide meaningful information as a distended hematocolpos can be easily palpated proximal to the site of obstruction from a transverse vaginal septum, when the uterus is present and functional. Atrophic appearance of the external genitalia and loss of rugosity of the vaginal epithelium are features that would suggest a diagnosis of POI.

# Evaluation of the Genital Outflow Tract and Uterus

Evaluation of the genital outflow tract and uterus can be organized easily based on the menstrual history and physical examination of the genital anatomy. Primary amenorrhea in the setting of adequate development of secondary sex characteristics but with a blind or absent vagina points directly to a developmental anomaly of the genital outflow tract as a mechanism for amenorrhea. Primary or secondary amenorrhea with a patent vagina and visible cervix excludes abnormalities of the genital outflow tract, except in those with history of previous cervical or uterine surgery or infection in whom the possibilities of cervical stenosis and intrauterine adhesions or other endometrial damage must be considered.

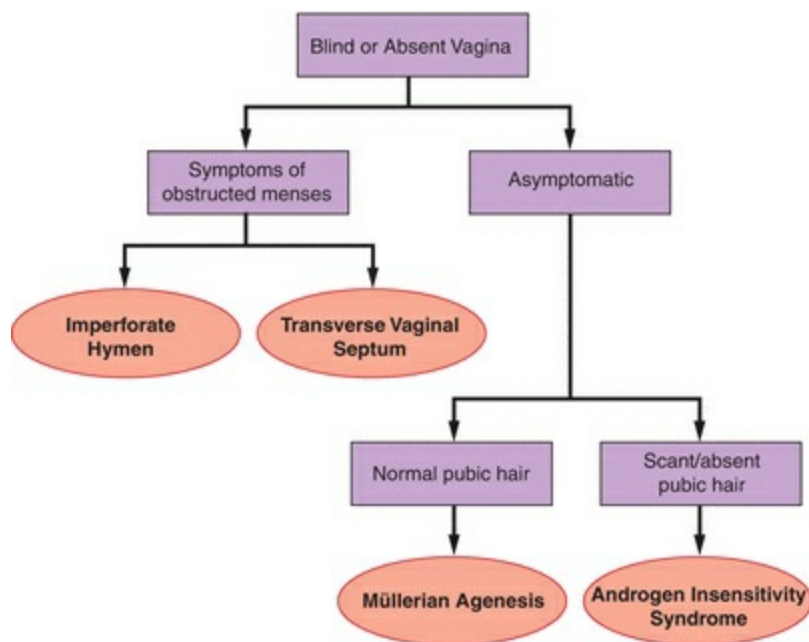

In premenarchal-age girls with the incidental finding of an absent vaginal orifice, diagnosis can be more difficult but also is seldom urgent. Although pelvic ultrasonography generally can determine whether a uterus is present, imaging must be interpreted cautiously because even abdominal/pelvic magnetic resonance imaging (MRI) can be misleading when the reproductive organs are immature and very small. Remaining alert to the diagnostic possibilities, careful observation over time is preferable to invasive investigations otherwise unnecessary in the asymptomatic prepubertal girl.

## Abnormal Genital Anatomy

The embryology of the female genital tract is complex but generally well defined and is described in detail in [Chapter 3](#). Briefly summarized, it involves both the medial migration and midline fusion of the müllerian (paramesonephric) ducts to form the uterus and fallopian tubes, cervix, and upper vagina and the vertical fusion of the developing müllerian ductal system with the invaginating urogenital sinus that forms the lower vagina and the introitus. Outflow tract abnormalities that result from failure of müllerian duct development include a spectrum of anatomical abnormalities that range from vaginal/müllerian agenesis to cervical agenesis, transverse vaginal septa, and imperforate hymen ([Figure 10.2](#)). Although all are uncommon and the clinician may have only limited or no previous experience with any of these anatomical malformations, each has unique and distinguishing features that, in most cases, point to the correct diagnosis at the time of the initial visit. Only limited additional evaluation, described in a later section of this chapter, is required to firmly establish the diagnosis and to plan treatment. AIS must be considered as a differential diagnosis in any girl presenting as primary amenorrhea and diagnosed with vaginal agenesis; the presence or absence of pubic hair distinguishes AIS from an isolated müllerian anomaly in a

genetically normal female.

**FIGURE 10.2**

## Normal Genital Anatomy

In those with primary or secondary amenorrhea having a patent vagina and visible exocervix, the likelihood of a genital outflow tract abnormality is very small. The only possibilities that need be considered are cervical stenosis and endometrial damage that may result from surgical trauma (Asherman syndrome) or infection (such as genital tuberculosis). Since these are acquired conditions, they result in secondary amenorrhea with an onset that typically correlates closely with the time of the previous insult. Both receive separate and thorough discussion in the later section of this chapter devoted to specific disorders of the genital outflow tract and uterus.

# Evaluation of Ovarian Function

In women with secondary amenorrhea, obstructive developmental disorders of the genital tract can be excluded. Similarly, in those with normal genital tract anatomy and no relevant history to suggest the possibility of acquired cervical stenosis or Asherman syndrome, disorders of the genital outflow tract and uterus can similarly be excluded. Further stepwise evaluation is then required to determine the underlying cause of amenorrhea, and attention now may be focused on the next level of the reproductive system, the ovary.

Abnormalities of ovarian function are the most common overall cause of amenorrhea (primary and secondary) and include a wide variety of disorders ranging from simple chronic anovulation as in women with PCOS to ovulatory dysfunction associated with obesity, thyroid disorders, and hyperprolactinemia, to ovarian failure or POI. Several conditions are associated with POI including genetic abnormalities (these can be chromosomal abnormalities or single gene disorders such as fragile X [FMR1] premutations or genetically inherited metabolic disorders such as galactosemia) or autoimmune disease, or following exposure to radiation or chemotherapy. These and other specific causes of ovarian failure and the mechanisms involved are discussed at length in a later section of this chapter. The focus here is on the evaluation of ovarian function and on the diagnosis and treatment of common chronic anovulatory disorders.

The most obvious measure of ovarian function is estrogen production. Unfortunately, one cannot rely just on symptoms and signs of estrogen deficiency to identify hypogonadal women. **Genitourinary atrophy develops only gradually and is not observed commonly in young women, even when estrogen levels are clearly low, and vasomotor symptoms typically are absent in women with hypothalamic dysfunction.** Other methods for assessing the level of ovarian estrogen production include measurement of the serum estradiol concentration and “bioassays” based on clinical observations of the amount and character of cervical mucus, the results of a “progesterin challenge test,” or measurement of endometrial thickness by transvaginal ultrasonography. **Although each method is informative to varying degrees, each also has pitfalls, no one method is definitive, and more than one measure therefore is recommended.** Overall, the duration of amenorrhea, other symptoms, medical history, and clinical examination all contribute to the overall assessment relating to ovarian function.

## Serum Estradiol Concentration

A serum estradiol measurement is easy to obtain, is relatively inexpensive, and provides some degree of objective assessment of ovarian steroidogenic function.

Reasonably, one would expect to find relatively normal estrogen levels (in premenopausal early follicular phase range) in women with normal ovaries whose amenorrhea results simply from mild dysregulation and chronic anovulation, as in obese women and those with PCOS, and to find low estrogen levels (in the menopausal range) in women with ovarian failure, pituitary disease, or more severe hypothalamic dysfunction. Unfortunately, serum estradiol concentrations can fluctuate erratically in all conditions, normal or low on any given day, and therefore can be misleading. A random estradiol concentration greater than approximately 40 pg/mL suggests the presence of functional ovarian follicles; such levels of estradiol however can also be encountered in women with POI, those in perimenopause, and sporadically in women with hypothalamic amenorrhea. Conversely, a low random estradiol concentration may suggest ovarian failure, but also is commonly encountered in women with hypothalamic amenorrhea, and may be observed in those with less severe forms of chronic anovulation.

## Bioassays of Estrogen Production

The observation of **estrogenic cervical mucus**—clear, watery, stretchable, and relatively abundant—suggests a normal level of ovarian estrogen production, but its absence cannot be interpreted confidently because many normal women exhibit such mucus only during the late follicular phase of the cycle when estrogen levels are relatively high, or not at all.

The **progestin challenge test** is based on the premise that progestin treatment (e.g., 5–7 days of exposure to MPA 10 mg daily or norethindrone acetate 1 mg daily) will induce a withdrawal bleed only in those whose endometrium has been exposed to circulating estrogen concentrations in premenopausal range. **A pure progestational agent must be used because endogenous estrogen status cannot be inferred from the response to an OCP that contains both estrogen and progestin.** The more potent synthetic progestins such as MPA are a better choice than oral micronized progesterone, which must be administered in relatively high doses (e.g., 200–300 mg daily) to achieve a response.<sup>1</sup> A positive test—bleeding within 2–7 days after completion of progestin treatment—implies endogenous estrogen production and is reassuring for residual ovarian function. A negative progestin challenge test—no withdrawal menses—suggests hypogonadism. Scant withdrawal bleeding or spotting suggests marginal levels of endogenous estrogen production. Despite the reassurance provided by a positive progestin challenge test, the overall correlation between withdrawal bleeding and estrogen status is far from perfect; both false-positive (withdrawal bleeding despite generally low levels of estrogen production) and false-negative (absent bleeding despite significant estrogen production) results are relatively common. Up to 40–50% of women whose amenorrhea relates to stress, exercise, weight loss,

hyperprolactinemia, or ovarian failure, in whom estrogen levels generally are low, exhibit some degree of withdrawal bleeding.<sup>2,3</sup> In contrast, up to 20% of amenorrheic women with significant estrogen production (such as women with PCOS who exhibit elevated circulating androgen levels) experience no withdrawal bleeding<sup>4</sup>; rationale for false-negative response lies in an endometrium that is rendered unresponsive by chronic exposure to high circulating androgen levels.

The **endometrial thickness**, determined by transvaginal ultrasonography (the maximum two-layer thickness in the midsagittal plane), is a measure of endometrial proliferation, which reflects the level of estrogen production. Endometrial thickness correlates with both the serum estradiol concentration and with the response to a progestin challenge in women with amenorrhea. In one study involving 44 women with secondary amenorrhea, endometrial thickness was significantly greater in 32 women who had withdrawal bleeding ( $10.3 \pm 4.1$  mm) than in 12 who did not ( $5.0 \pm 1.3$  mm); the serum estradiol level also was significantly greater ( $45.3 \pm 19.4$  vs.  $18.6 \pm 8.0$  pg/mL), and an endometrial thickness measuring 6.0 mm or greater predicted withdrawal bleeding with 95% accuracy.<sup>2</sup> An added potential benefit of endometrial thickness as a measure of ovarian estrogen production is that it can help to identify individuals with chronic anovulation at low risk for having associated pathology such as hyperplasia or cancer. In addition to thickness, the sonographic appearance of the endometrial echo is also informative of tissue estrogenization. A trilaminar-appearing endometrial echo correlates with proliferative effects of estrogen on the endometrium.

## **Serum Follicle Stimulating Hormone (FSH) Concentration**

The serum FSH concentration is a useful, but indirect, measure of ovarian function. A normal or low serum FSH level indicates the presence of functional ovarian follicles and may be observed in a variety of conditions associated with amenorrhea, including chronic anovulation (e.g., PCOS), pituitary disease, and hypothalamic dysfunction. Low FSH levels are also commonly seen in women using hormonal contraceptive regimens. **A high serum FSH concentration in the presence of amenorrhea is a reliable indicator of ovarian follicular depletion or ovarian failure.** Exceptions to this interpretation are rarely encountered and include inactivating mutations involving the FSH or LH receptor, enzyme deficiencies (17 $\alpha$ -hydroxylase, aromatase), and functional pituitary and ectopic FSH-secreting tumors; in these conditions, disproportionately elevated FSH levels will be seen despite the presence of ovarian follicles. **Because the clinical implications of an elevated FSH level are serious, one or more repeated measurements are warranted to confirm the finding (Table 10.1).**

**TABLE 10.1 Placing Serum Gonadotropin Levels in Clinical Perspective**

Clinical State	Serum FSH	Serum LH
Normal adult female	5–20 IU/L (midcycle peak ~ 2 times the basal level in ovulatory women)	5–20 IU/L (midcycle peak ~ 3 times the basal level in ovulatory women)
Hypogonadotropic state: Prepubertal, hypothalamic, or pituitary dysfunction	<5 IU/L	<5 IU/L
Hypergonadotropic state: Postmenopausal, castrate, or ovarian failure	>20 IU/L	>40 IU/L

Although certainly not inappropriate, generally it is neither necessary nor helpful to also measure serum LH because levels of the two gonadotropins typically move in parallel. The one notable and highly relevant exception in women with amenorrhea—the “monotropic” rise in FSH that signals a more advanced stage of follicular depletion—can be detected by measuring FSH alone. In women who are menstruating regularly, serum levels of FSH tend to be higher than of LH at all times in the cycle except for the periovulatory period. During the midcycle gonadotropin surge in ovulatory cycles, LH levels increase more than those of FSH, but that has little relevance in women with amenorrhea. A “reversed” LH/FSH ratio (FSH lower than LH), like that seen in prepubertal girls, suggests, but does not prove, hypothalamic dysfunction.<sup>5</sup> A moderately increased serum LH concentration frequently is observed in women with PCOS, but is

not a diagnostic criterion. Other conditions in which levels of the two gonadotropins diverge significantly are truly rare and include ectopic gonadotropin secretion by tumors outside the reproductive tract, single gonadotropin deficiencies resulting from mutations in genes encoding the  $\beta$ -subunit of LH or FSH, and the very rare functional gonadotroph adenoma that secretes clinically important amounts of one gonadotropin (FSH) but not the other.

Measurement of the serum FSH level traditionally has been recommended only for those having demonstrable evidence of hypogonadism (e.g., a negative progestin challenge), to help differentiate between patients with gonadal failure (in whom FSH levels will be elevated) and those with functional hypothalamic or pituitary causes of amenorrhea (in whom FSH levels will be in low or normal range). Measurement of serum FSH contributes to a more confident clinical assessment of ovarian function and helps differentiate patients with common chronic anovulatory conditions from those with more severe hypogonadism who otherwise may go unrecognized and who require further specific evaluation, counseling, or treatment. For example, when evaluation suggests marginal levels of estrogen production (e.g., serum estradiol levels of 30–40 pg/mL or lower or when scant bleeding follows a progestin challenge), a low serum FSH can identify those who merit further evaluation to exclude pituitary and hypothalamic disorder or disease, as described below. Conversely, in women with normal levels of estrogen production, a moderately elevated FSH level (e.g., 10–15 IU/L) is concerning for diminished ovarian reserve, and this information can be helpful in guiding women toward proactively exploring opportunities for fertility planning and preservation before the opportunity gets lost. Like the other measures of ovarian function, the serum FSH concentration must be interpreted carefully, in its clinical context. FSH levels can fluctuate unpredictably, particularly during the years immediately preceding the menopause, regardless whether it occurs prematurely or at the usual age. It is important to appreciate that a sharp rise in FSH occurs during the estrogen-induced LH surge; unless serum estrogen levels are also tested along with FSH, elevated FSH if drawn at the time of an LH surge can be erroneously interpreted to represent diminished ovarian reserve, a label that generates significant psychological distress.

## **Serum Antimullerian Hormone (AMH) Concentration**

A member of the TGF $\beta$  family of growth factors, AMH is secreted by the ovarian granulosa cells of the preantral and small growing follicles measuring less than 4 mm in diameter. Circulating levels of AMH are now recognized as a more reliable marker of ovarian reserve status compared to FSH. In contrast to FSH, where high levels are concerning for diminished ovarian reserve, higher AMH levels are reassuring. Undetectable AMH level in the setting of amenorrhea is highly concerning for ovarian

failure as a mechanism for amenorrhea. In contrast, levels greater than 5 ng/mL in association with amenorrhea are suggestive of PCOS as a plausible reason for amenorrhea. Measurement of AMH is reliable on any day in an individual's menstrual cycle, although prolonged periods of ovarian suppression, such as with use of hormonal contraceptives, can result in spuriously lower circulating AMH levels.<sup>6</sup>

## Chronic Anovulation

**When evaluation reveals clear evidence of adequate ovarian estrogen production and serum FSH and AMH levels are also normal, a diagnosis of chronic anovulation is established.** Hyperprolactinemia is one of the most common causes of anovulation and amenorrhea, and, although less common, thyroid disorders are easily identified and treated. **Measurement of serum prolactin and thyroid-stimulating hormone (TSH) concentrations is therefore justified in all women with amenorrhea.** For efficiency, both can be measured along with the serum FSH and estradiol levels, at the outset of the evaluation. When all are normal, no further evaluation is required.

Besides thyroid and prolactin disorders, common and likely causes of chronic anovulation include PCOS, obesity, psychological stress or intense exercise, and reproductive aging. In all but the last, anovulation can be attributed to a dysfunctional HPO axis in which gonadotropin secretion is sufficient to stimulate follicular development and estrogen production to varying degrees, but the system lacks the coordination required to achieve successful ovulation. Women with classical PCOS usually are easily recognized because they commonly exhibit signs of hyperandrogenism (such as acne and/or excessive facial and bodily hair or thinning of scalp hair), unlike those whose chronic anovulation relates solely to weight gain or obesity; the pathophysiology of the two disorders is complex and is discussed at length in [Chapter 11](#) (PCOS) and [Chapter 19](#) (obesity). Severe hirsutism ([Chapter 12](#)) or signs of virilization warrant additional specific evaluation to exclude steroidogenic enzyme deficiencies, androgen-secreting tumors, and Cushing syndrome, as described in [Chapter 13](#) (reproduction and the adrenal). The diagnosis of anovulation relating to emotional, nutritional, or physical stresses is often suggested by the medical history and the chronology of events, but is arrived at only after systematic exclusion of the conditions discussed above. Management of chronic anovulation associated with the commonly encountered thyroid disorders and hyperprolactinemia is summarized here.

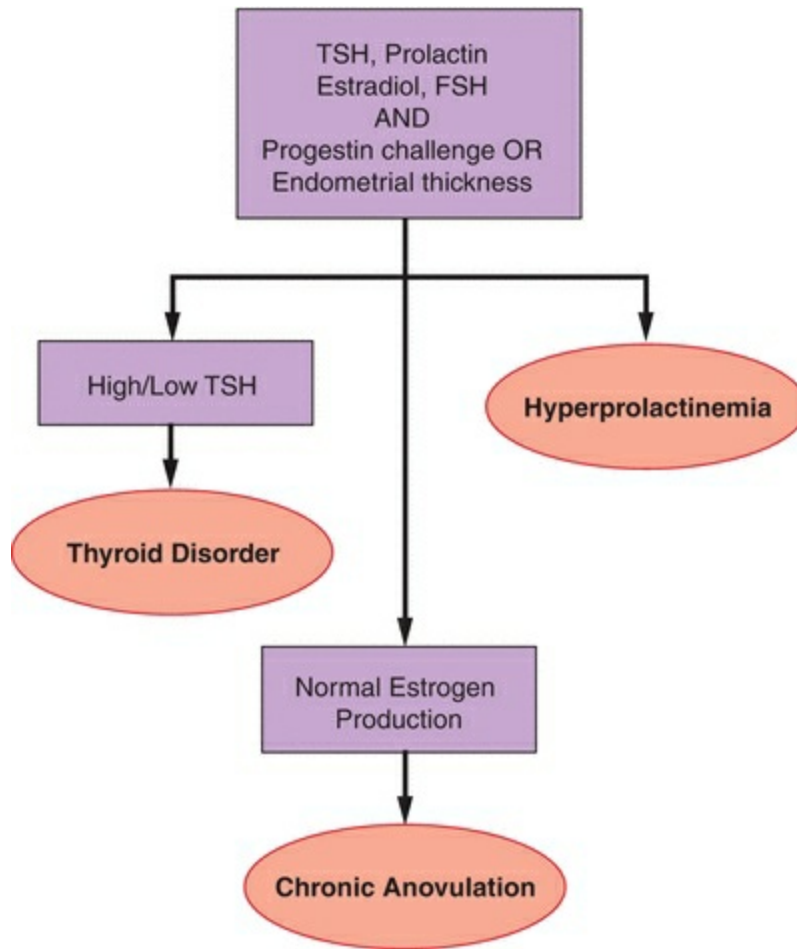

## Thyroid Disorders

The newest ultra-sensitive TSH assays now in common use detect both primary hypothyroidism (elevated TSH) and primary hyperthyroidism (low TSH); either may result in chronic anovulation and amenorrhea. Although only a few patients presenting

with amenorrhea will have a thyroid disorder that is not clinically apparent, their exclusion and treatment are so simple that routine measurement of TSH in the evaluation of menstrual disturbances is justified; a return of ovulatory cycles typically follows the restoration of normal thyroid hormone levels. Any abnormal TSH value should be confirmed by repeat testing that includes measurement of serum thyroxine (tetraiodothyronine; T4 or free T4) levels to better define the nature (primary vs. secondary) and the extent of the thyroid disorder. Elevated TSH with normal free T4 concentration indicates subclinical hypothyroidism, best viewed as a compensated state wherein normal levels of T4 are maintained, but only under increased levels of pituitary TSH stimulation. **Although observation and periodic reevaluation are reasonable in patients with subclinical hypothyroidism, because not all will develop frank hypothyroidism, treatment is warranted in those with menstrual dysfunction or infertility.** In those with a low TSH and a normal free T4 level, serum triiodothyronine (T3) should be measured; an elevated T3 can identify hyperthyroidism that otherwise might escape detection. When the T3 also is normal, subclinical hyperthyroidism is likely and should be followed carefully through vigilant clinical surveillance and periodic monitoring of TSH levels. On rare occasions, both TSH and free T4 levels are low, suggesting secondary hypothyroidism of pituitary origin; this requires further assessment to determine the cause of pituitary dysfunction. Evaluation of serum levels of other pituitary hormones, such as gonadotropins, prolactin, and ACTH, should be considered if secondary hypothyroidism is suspected, as this information will help guide further management.

A few women with hypothyroidism will develop secondary hyperprolactinemia and may even experience galactorrhea. The likelihood of hyperprolactinemia increases with the duration of hypothyroidism; galactorrhea is more common in young women with higher prolactin levels.<sup>7</sup> The mechanism probably involves both the gradual depletion of hypothalamic dopamine (the putative prolactin-inhibiting factor) and constant stimulation of pituitary lactotropes by the hypothalamic thyrotropin-releasing hormone (TRH), which may cause pituitary hypertrophy or hyperplasia and sometimes even enlargement or erosion of the sella turcica.<sup>8,9</sup> Although prolactin levels rapidly normalize with appropriate treatment of the accompanying hypothyroidism, the disappearance of breast secretions in those with galactorrhea is gradual and can take several months. Patients with primary hypothyroidism and hyperprolactinemia may present with either primary or secondary amenorrhea<sup>10</sup> (**Figure 10.3**).

**FIGURE 10.3**

## Hyperprolactinemia

Hyperprolactinemia is among the most common causes of secondary amenorrhea. Hyperprolactinemia occurring in premenarchal years may even present as delayed puberty and primary amenorrhea. **Checking serum prolactin level is therefore justified in all women with amenorrhea.** A normal random measurement (<15–20 ng/mL in most clinical laboratories) excludes hyperprolactinemia. Circulating prolactin levels are fairly stable throughout the day but can increase transiently during sleep, and with exercise, breast stimulation, and meals. **To avoid otherwise unnecessary and costly imaging, mildly elevated prolactin levels (20–40 ng/mL) are best repeated and confirmed before the diagnosis of hyperprolactinemia is made.**

The mechanism by which hyperprolactinemia results in anovulation and amenorrhea relates to a disruption or inhibition of the normal hypothalamic GnRH pulse rhythm, resulting in ineffective or even frankly low levels of gonadotropin secretion. It may be that increased circulating prolactin levels stimulate a generalized increase in hypothalamic dopaminergic neuronal activity, intended to suppress prolactin secretion,

but also inhibiting the GnRH neurons. Consequences of the disturbed GnRH pulsatility due to prolactin excess can range from subtle ovulatory dysfunction to anovulation or even profound hypogonadotropic hypogonadism, depending on the extent to which the gonadotropin secretion is suppressed. Mild hyperprolactinemia (levels in the range of 20–50 ng/mL) may cause only a short luteal phase, resulting from poor preovulatory follicular development.<sup>11,12</sup> Moderate hyperprolactinemia (50–100 ng/mL) frequently causes oligomenorrhea or amenorrhea, and higher prolactin levels (>100 ng/mL) typically result in frank hypogonadism with low estrogen levels and their clinical consequences (e.g., genitourinary atrophy, and loss of bone mass).<sup>13,14</sup>

Despite galactorrhea being a recognized consequence of prolactin excess, the symptom or finding of galactorrhea cannot reliably identify those whose amenorrhea results from hyperprolactinemia. Only about one-third of women with hyperprolactinemia exhibit galactorrhea, probably because breast milk production requires estrogen and hyperprolactinemia often results in anovulation or a more severe secondary hypogonadotropic hypogonadism and, consequently, low circulating estrogen levels. The structural heterogeneity of prolactin offers another possible explanation. Prolactin circulates in various forms that have varying bioactivity (manifested by galactorrhea) and immunoactivity (recognition by immunoassay).<sup>15,16,17</sup> The predominant circulating form of prolactin (80–95%) is monomeric (molecular weight 23 kDa), which is more biologically active than the larger glycosylated variants that may combine to form dimers or trimers (“big prolactin,” 50–60 kDa) and other even larger varieties (macroprolactin, >100 kDa), which result from the aggregation of smaller prolactin molecules bound together with immunoglobulins.<sup>18</sup> The larger molecular forms are cleared more slowly, predominate in women with hyperprolactinemia having normal menses, and result in minimal or no galactorrhea.<sup>19</sup> If suspected, the diagnosis of macroprolactinemia can be confirmed by requesting the laboratory to pretreat the patient’s serum with polyethylene glycol to precipitate the macroprolactin before performing the prolactin assay.<sup>20</sup> In women with mildly elevated prolactin levels, diagnosis of macroprolactinemia avoids unnecessary and costly imaging aimed at excluding pituitary and hypothalamic mass lesions.

Hyperprolactinemia has many causes that are discussed in detail in the chapter dedicated to the breast ([Chapter 16](#)) and briefly summarized here.<sup>21</sup> Hyperprolactinemia may result from hypothyroidism, prolactin-secreting pituitary adenomas, and other pituitary or hypothalamic tumors that may compress the pituitary stalk and disrupt the delivery of dopamine. A variety of drugs that lower dopamine levels or inhibit dopamine action may cause hyperprolactinemia, including amphetamines, benzodiazepines, butyrophenones, metoclopramide, methyl dopa, opiates, phenothiazines, reserpine, and tricyclic antidepressants. Breast or chest wall surgery,

cervical spine lesions, or herpes zoster (affecting the dermatome that includes the breast) may activate the afferent sensory neural pathway that stimulates prolactin secretion in a manner similar to suckling. Renal insufficiency may cause hyperprolactinemia, due to decreased clearance. Rarely, hyperprolactinemia may result from ectopic prolactin secretion by bronchogenic and renal cell carcinomas, or by a gonadoblastoma or prolactinoma that may arise in benign or malignant ovarian teratomas, or from aberrantly located pituitary tissue in places such as the pharynx.<sup>22,23,24,25,26</sup> All possible causes must therefore be considered and excluded; a careful history can eliminate most of the possibilities. When iatrogenic mechanism for prolactin excess is deemed as a plausible cause, a trial of drug discontinuation or use of an alternative medication can be considered, in consultation with the prescribing physician. When discontinuation or drug substitution is not possible, further evaluation to exclude a pituitary or hypothalamic mass lesion is required before concluding that prolactin excess is entirely of iatrogenic origin.

**Women with amenorrhea and hyperprolactinemia that cannot be attributed confidently to medication or another specific cause require further evaluation with imaging to exclude pituitary tumors and hypothalamic mass lesions.** (See “Evaluation of Pituitary Function” section.) Pituitary adenomas and their management are discussed in detail in a later section of this chapter devoted specifically to pituitary causes of amenorrhea. Discussion here is limited to the treatment of hyperprolactinemia unassociated with any demonstrable sellar abnormality.

Treatment with a dopamine agonist restores ovulatory function and menses within several weeks in the large majority of women with hyperprolactinemia. Although improvement in galactorrhea is anticipated with decline in circulating prolactin levels, the absolute resolution of milk leakage following normalization of prolactin levels often lags by weeks to even months.<sup>27</sup> Bromocriptine and cabergoline are two commonly utilized dopamine agonists in the management of hyperprolactinemia; both are highly effective. Bromocriptine has a relatively short half-life, often necessitating a frequency of administration of 2 to 3 times daily; gastrointestinal side effects such as nausea are common, and bedtime dosing is better tolerated. Cabergoline is a selective dopamine receptor type 2 agonist having fewer side effects than bromocriptine, greater potency, and a longer duration of action requiring less frequent administration (twice weekly) and can be effective in those who cannot tolerate or prove resistant to bromocriptine<sup>28,29</sup>; due to its better tolerance and convenience of dosing, cabergoline is increasingly being utilized as the preferred of the two dopamine agonists. Long-term use of dopamine agonists in relatively high doses, such as used in the management of Parkinson disease (>3 mg daily), has been associated with hypertrophic valvular heart disease; mitogenic stimulation of normally quiescent valve cells via activation of the serotonin receptors is a suspected mechanism for this uncommon but serious risk of

long-term use of dopamine agonists in high doses.<sup>30,31</sup> Although the doses required for effective treatment of hyperprolactinemia are much lower than used for treatment of Parkinson disease, concerns remain that long-term use of even relatively low doses of dopaminergic drugs may increase the risk of valvular heart disease.<sup>32,33</sup> Treatment should begin with a low-dose regimen, and dosing should be gradually adjusted in increments to achieve normalization of prolactin levels; the goal should be to utilize the lowest dose of cabergoline or bromocriptine required to normalize serum prolactin concentrations. Given the concerns relating to long-term use of dopaminergic drugs, a trial discontinuation of treatment should be attempted if prolactin levels have been normal for 2 or more years.<sup>34</sup> In those who cannot tolerate oral treatment, vaginal administration is effective and associated with fewer side effects.<sup>35,36</sup> Either drug may be used in women planning to conceive since both appear to be safe in early pregnancy.<sup>37,38</sup>

Treatment with a dopamine agonist is the obvious choice when the objective is ovulation induction and pregnancy or the elimination of troublesome galactorrhea. However, for those with neither specific indication, alternative treatments deserve careful consideration. **Although treatment with a dopamine agonist certainly is a logical choice, it is by no means the only choice or necessarily the best choice for all women with hyperprolactinemia and amenorrhea. It is important to remember that treatment should be focused on the patient and not on the prolactin level.** Hyperprolactinemia itself poses no particular health risks. In women not at risk for an unwanted pregnancy, cyclic progestin therapy will prevent the clinical consequences of chronic unopposed estrogen exposure in those who are not frankly hypogonadal. For those manifesting signs and/or symptoms of hypoestrogenism, cyclic or combined estrogen/progestin treatment in physiologic doses, such as used for managing menopausal symptoms ([Chapter 17](#)), will prevent the consequences of chronic estrogen deficiency. In women who need contraception, treatment with a low-dose combination hormonal contraceptive achieves the same goals. In the past, treatment with exogenous estrogen was considered contraindicated for women with hyperprolactinemia due to a fear that this might aggravate the underlying pathophysiology or promote the growth of an underlying pituitary tumor; however, experience has shown that estrogenic formulations (used as menopausal hormone therapy or as combination hormonal contraceptives) pose no such risks.<sup>39,40</sup> The same treatments are useful in the management of women with medication-induced hyperprolactinemia and hypogonadism when the drug cannot be discontinued or an alternative substituted. Dopamine agonists are best avoided in patients with medication-induced hyperprolactinemia, because they may interfere with or counteract the dopamine antagonist properties of their primary treatment. Unfortunately, amenorrhea and galactorrhea often promptly recur within weeks after discontinuation of dopamine agonist treatment and most therefore require

long-term therapy.

## General Management

All patients with chronic anovulation require management, and following a limited evaluation, as described here, treatment can be implemented immediately. Clinicians are keenly aware that normal endometrium that is chronically exposed to an estrogenic environment without antagonistic influences of periodic progesterone exposure as occurs in ovulatory cycles can progress to hyperplasia, atypia, and cancer within a relatively short interval of time. However, too often they believe the problem is relevant only in older age women. **The critical factor in determining the risk for these endometrial pathologies is not the age but the duration of exposure to unopposed estrogen stimulation.** Young women who remain anovulatory for long periods of time can, and do, develop endometrial cancer.<sup>41,42,43,44</sup> Although endometrial sampling is not indicated for all women with chronic anovulation, it should be given serious consideration for those at greatest risk for endometrial pathology. Obesity, hyperinsulinemia, and diabetes are recognized risk factors for endometrial cancer, and these risks are especially prevalent in women with PCOS, a population that is especially deemed at risk for endometrial hyperplasias and cancer.<sup>45,46</sup> Although endometrial thickness, as assessed by transvaginal ultrasound, can offer valuable prognostic yield in identifying postmenopausal women at risk for endometrial hyperplasia and cancer, it is of little value in prognosticating a similar risk profile in premenopausal amenorrheic populations. No studies correlating endometrial thickness and histology in premenopausal women with amenorrhea have been performed. However, in premenopausal women with abnormal uterine bleeding, no serious pathology was found in those having an endometrial thickness less than 8 mm,<sup>47</sup> and in asymptomatic postmenopausal women, an endometrial thickness less than 5–6 mm has greater than 99% negative predictive value for endometrial disease.<sup>48,49</sup> A thin endometrium (<4 mm) may be useful in identifying those amenorrheic women in whom an invasive intervention such as an endometrial biopsy may be safely omitted; their risk for endometrial pathology is likely negligible. Whereas some studies have suggested that amenorrheic women also may be at an increased risk for developing breast cancer,<sup>50</sup> others have demonstrated an inverse association between breast cancer risk and chronic anovulation (discussed in [Chapter 16](#)).<sup>51</sup>

Given the recognized risk of endometrial hyperplasia and cancer from chronic endometrial exposure to estrogen, at a minimum, women with chronic anovulation require periodic treatment with a progestin, to negate the proliferative endometrial effects of estrogen and thereby reduce the risk of developing endometrial pathology. For example, a synthetic progestin such as MPA in doses of 5–10 mg daily can be

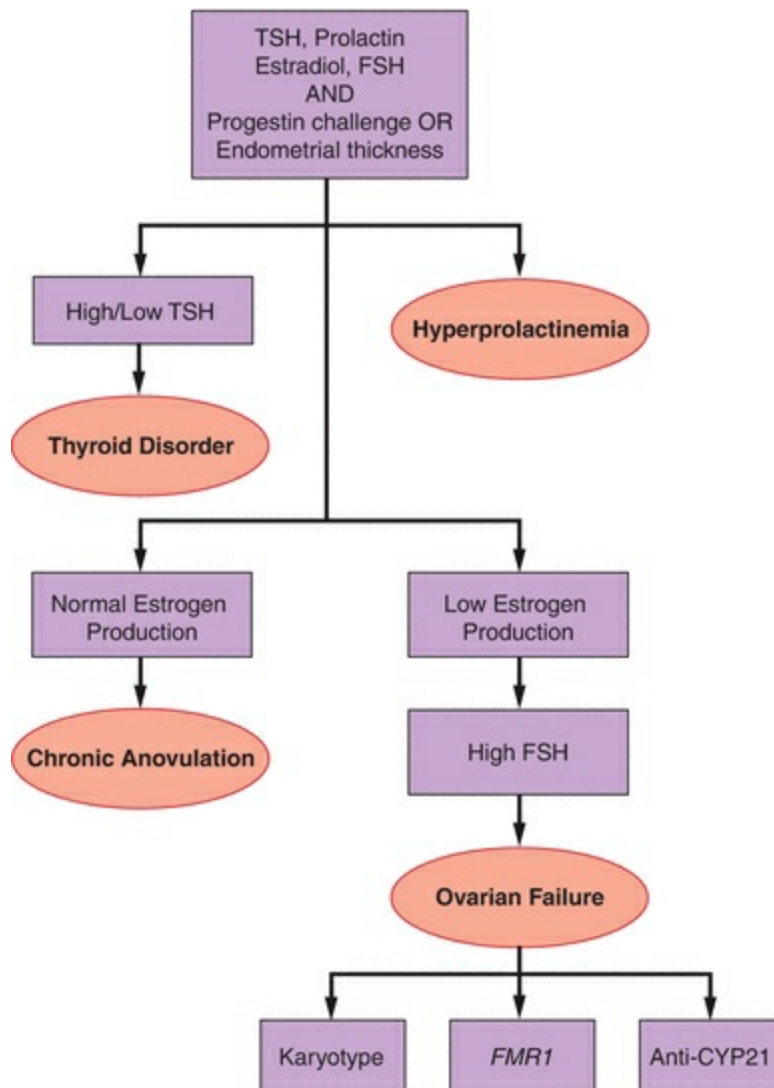

administered for the first 12–14 days of each month; for some women, the frequency of progestin exposure can be stretched to every alternate month. Experience with varying hormone regimens has demonstrated that duration of treatment, as well as type and dose of progestin formulation, are relevant to ensuring endometrial protection. At minimum, treatment with a potent progestin, such as MPA, for an interval greater than 10 days is required to effectively counteract the growth-promoting effects of continuous exposure to endogenous estrogens. A higher dose and longer treatment duration may be considered in obese women who are innately at a higher risk for endometrial cancer. **It is important to note that cyclic treatment with a progestin, at physiologic doses, does not change the intrinsic rhythm of the HPO axis and will not prevent a sporadic ovulation.** Therefore, if menses do not occur at the expected time, pregnancy must be considered and excluded. Absent bleeding after a course of progestin treatment also may indicate that estrogen production has fallen to grossly low levels and signal the need for further evaluation, as described in the section that follows. When reliable contraception is required, cyclic treatment with a low-dose hormonal contraceptive, or consideration for a progestin-only regimen (pill, implant, or intrauterine system), is an obvious and better choice. There is no evidence that use of hormonal contraception has any impact, either positive or negative, on menstrual cyclicity after treatment is discontinued.

For women with chronic anovulation who are desirous of achieving pregnancy, treatment should be aimed at inducing ovulatory cycles. For women with thyroid disorders, specific treatment to restore normal thyroid function is indicated. For those with hyperprolactinemia, initiating a dopamine agonist is the treatment of choice. Those experiencing anovulation in the setting of psychological stress or excess weight gain may achieve resumption of spontaneous ovulation from stress and weight reduction, respectively, whereas those experiencing amenorrhea in the setting of nutritional deprivation and low body mass, resumption of ovulation may be achieved through improved diet and weight gain. For the majority who are without an obvious mechanism for their ovulatory dysfunction, successful ovulation can be achieved with the use of ovulation induction agents such as clomiphene citrate or aromatase inhibitors. Exogenous gonadotropins can be considered for those failing to respond to oral medications. Methods for ovulation induction are described in detail in [Chapter 27](#).

## **Ovarian Failure and Ovarian Insufficiency**

**When evaluation reveals evidence of low ovarian estrogen production and serum FSH level is consistently high, a diagnosis of ovarian failure is established.** Amenorrheic women, if younger than age 40 years, with evidence of persisting hypergonadotropic hypogonadism are diagnosed with premature ovarian failure (POF), a condition that in recent years is preferentially referred to as POI; the terms POF and

POI are used interchangeably in this chapter. Although premature follicular depletion is the cause in almost all cases, additional specific evaluation is indicated to exclude conditions (such as chromosomal and other genetic abnormalities and autoimmune disease) that may have potential health implications for the patient and other members of her family. The elements and purpose of the expanded diagnostic evaluation of POI cases are summarized here (Figure 10.4). The known causes of ovarian failure and the disorders deserving specific consideration and exclusion are discussed at greater length in a later section of this chapter.

**FIGURE 10.4**

## Karyotype

In all patients under age 30 with a diagnosis of POI, a karyotype should be obtained to exclude chromosomal translocations, deletions, and mosaicism that might offer an

obvious explanation for premature failure of the ovaries. A karyotype will identify those missing an entire X chromosome in all (Turner syndrome) or some (Turner mosaic) of the tested cells. Chromosomal analysis will similarly identify those phenotypic... phenotypic females having a Y chromosome in whom gonadectomy is indicated due to the significant risk for malignant transformation in occult testicular gonadal tissue elements (20–30%). Signs of virilization cannot reliably identify the subset of women at risk because many carrying a Y chromosome exhibit no signs of androgen excess. In women over age 30, ovarian failure reasonably can be regarded as premature menopause. Karyotype after age 30 generally is unnecessary because most tumors in patients with a Y chromosome arise before age 20 and virtually all before the age of 30.<sup>52,53</sup> After age 30, women with short stature or a family history of early menopause still merit a karyotype to exclude X chromosome deletions and translocations that may affect other family members.<sup>54,55,56,57</sup> Pelvic ultrasonography can exclude the rare tumor not recognized previously. Genetic underpinnings to POI are further discussed later in this chapter.

## **Fragile X (FMR1) Premutations**

Fragile X syndrome is the most common inherited cause of mental retardation and autism and results from the abnormal expansion of an unstable trinucleotide (CGG) repeat sequence in the FMR1 (Fragile X Mental Retardation) gene that is located on the long arm of the X chromosome (Xq27.3). The FMR1 gene normally contains about 30 or less CGG repeats, but in those with FXS, the number of these trinucleotide repeats exceeds 200. Convincing evidence has demonstrated an association between POI and fragile X “premutations,” in the range of 55–200 CGG repeats. Whereas the full mutation silences the FMR1 gene, resulting in little or no production of the corresponding mRNA or gene product (fragile X mental retardation protein, FMRP), POI associated with premutations may reflect FMR1 mRNA gain-of-function toxicity.<sup>58</sup> Women with premutations often exhibit endocrine evidence of early ovarian aging (such as low circulating levels of AMH and inhibin B and higher FSH levels) in comparison to age-comparable women with normal FMR1; up to one-third of the premutation carriers experience early menopause (at age < 45 years). The prevalence of premutations is approximately 14% in women with familial POF and between 1% and 7% in sporadic cases of POF.<sup>58,59</sup> **Women with POI therefore should be offered testing for FMR1 premutations.**<sup>60</sup> Women who carry fragile X premutations (and any affected children or siblings) are at risk for having a child with Fragile X syndrome, because the length of the CGG repeat sequence is unstable and may expand to a full mutation when passed from mother to offspring. The inheritance and the implications of premutations are complex, and affected women therefore should receive formal genetic counseling. The FMR1 premutation–related POI is further discussed later in this

chapter.

## Autoimmune Screening

A number of autoimmune disorders have been linked with POI.<sup>61</sup> Addison disease (autoimmune adrenocortical insufficiency) has the strongest association with POF. The presence of autoantibodies to steroid-producing cells and observations of a lymphocytic infiltrate in the ovaries of the affected individuals suggest the underlying mechanism (autoimmune oophoritis).<sup>62</sup> The prevalence of other autoimmune diseases (e.g., thyroid autoimmunity, type I diabetes, and myasthenia gravis) is higher among women with POF than in the general population; however, there is no direct or compelling evidence to indicate a cause and effect relationship. Autoimmune ovarian failure generally occurs as part of a specific autoimmune polyendocrine syndrome (APS) that includes adrenal insufficiency. However, because POF may precede the onset of adrenal insufficiency by several years, the autoimmune cause may not be recognized when the diagnosis of POF is first made.<sup>61</sup> Women with POF should be screened for antiadrenal antibodies (most easily demonstrated against the 21-hydroxylase enzyme, CYP21) and for antithyroid antibodies (antithyroid peroxidase and antithyroglobulin antibodies) to help quantify their lifetime risk for respective end-organ damage. **The presence of antiadrenal antibodies strongly implies autoimmune oophoritis as the cause of POF and identifies women who should be carefully evaluated and should undergo periodic surveillance for early detection of adrenal insufficiency. The presence of thyroid autoantibodies does not prove autoimmune ovarian failure but identifies women at risk for developing autoimmune thyroid disorders, and these women should similarly undergo periodic surveillance for early detection of thyroid dysfunction.** Routine screening for other autoimmune endocrine disorders is unnecessary and can be reserved for those with clinical indications.<sup>63</sup> Autoimmunity-related POF is further discussed later in this chapter.

# Evaluation of Pituitary Function

The normal feedback relationship between ovarian estrogen production and pituitary gonadotropin secretion dictates that low estrogen levels, as in the early follicular phase of the menstrual cycle, should cause a compensatory increase in FSH release in attempts to stimulate ovarian follicular development and estrogen secretion. In the setting of amenorrhea, low serum FSH (<5 IU/L) and low estrogen concentrations identify inadequate or ineffective gonadotropin secretion as the mechanism and indicate that even the basic central feedback mechanisms in the HPO axis are not functioning. **When estrogen levels are clearly low (<20 pg/mL), a serum FSH level in the low normal range (5–10 IU/L) has the same interpretation and clinical implication**, for two reasons. First, given the recognized feedback relationship, the FSH level should be high when the estrogen levels are low, and thus a “normal” FSH value is, in fact, abnormally low in that clinical context. Second, although the measured level of immunoreactive FSH may be normal, the level of biologically active FSH clearly is not; if it were, follicular growth and estrogen production would be maintained. The biologic activity of glycoprotein hormones varies with their carbohydrate moieties (discussed in [Chapter 1](#)). Evidence indicates that women with hypogonadotropic hypogonadism may secrete gonadotropins having altered patterns of glycosylation and reduced biologic activity.<sup>64</sup> Indeed, most women with hypogonadotropic hypogonadism have normal serum gonadotropin concentrations; extremely low or undetectable gonadotropin levels typically are observed only in those with large nonsecreting pituitary tumors or in patients with anorexia nervosa.

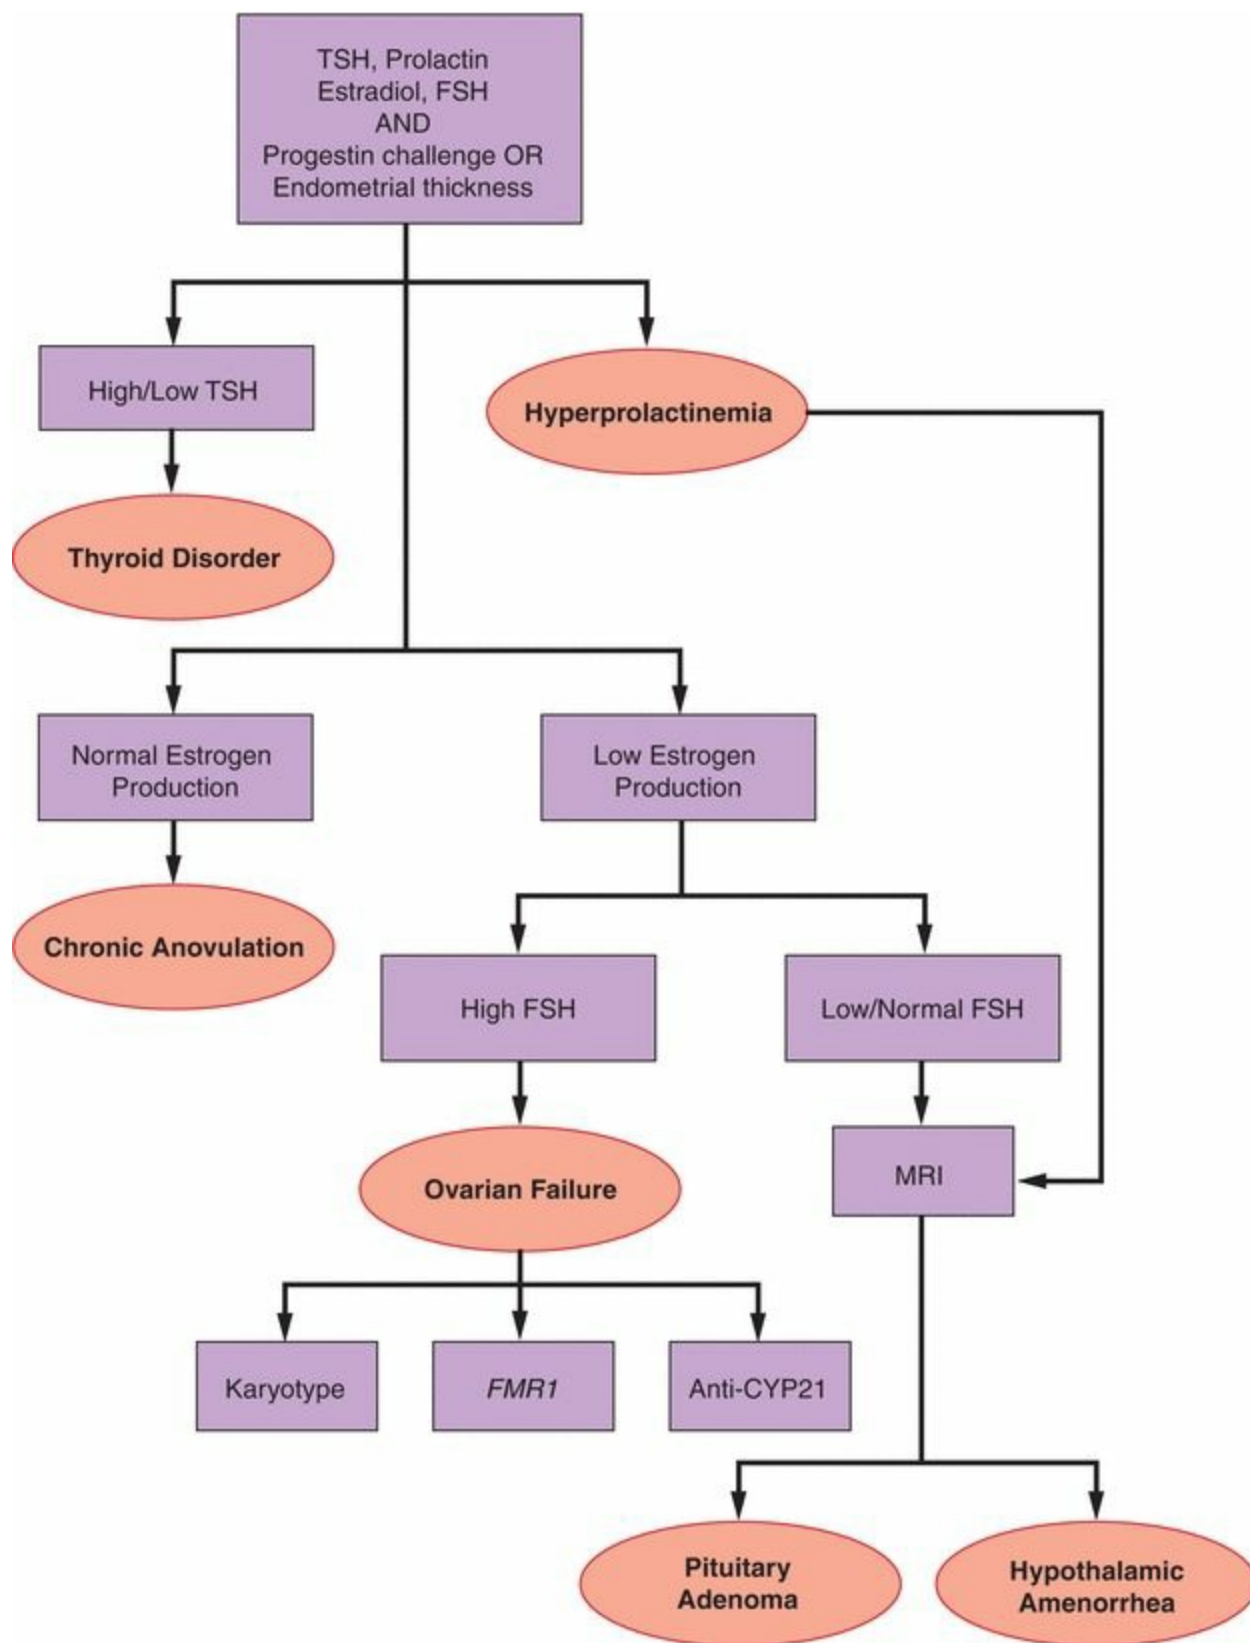

## Imaging

**When there is no clear explanation for hypogonadotropic hypogonadism (e.g., absence of significant physical, nutritional, or emotional stress) or for persistent hyperprolactinemia (e.g., use of medications), further evaluation with imaging is indicated to exclude intracranial tumors and to help distinguish between pituitary and hypothalamic causes.** The method of choice for imaging of the hypothalamic and pituitary regions is an MRI (with gadolinium contrast); brain MRI with contrast is more sensitive and accurate than other imaging techniques for the detection of abnormalities within and near the sella turcica.<sup>65</sup> Pituitary MRI can demonstrate the nearby optic chiasm, differentiate between hemorrhage and vascular abnormalities, and distinguish these from other sellar mass lesions. Pituitary adenomas are the most common sellar masses, which account for 10% of all intracranial neoplasms. Other less common mass lesions in or near the sella include benign tumors (craniopharyngioma, hamartoma, meningioma), pituitary hyperplasia (thyrotroph or gonadotroph hyperplasia due to long-standing primary hypothyroidism or gonadal failure, respectively, and corticotroph

hyperplasia that commonly follows bilateral adrenalectomy), malignant tumors (germ cell, sarcoma, chordoma, carcinoma, lymphoma), metastases (lung, breast), cysts (Rathke cleft, arachnoid, dermoid), pituitary abscess, lymphocytic hypophysitis, sarcoidosis, tuberculosis, and carotid arteriovenous fistula.

Although mass lesions are the most obvious abnormality to be excluded as a mechanism for HPO dysfunction in women with amenorrhea, other rare possibilities include Sheehan syndrome (pituitary infarct resulting from hypotension associated with postpartum hemorrhage; medical history is highly informative in these cases), infiltrative hemosiderosis relating to frequent transfusions or hereditary hemochromatosis, traumatic brain injury,<sup>66</sup> and mutations in the GnRH receptor.<sup>67</sup>

**In the absence of any radiologically demonstrable mass lesion in the sellar region or relevant history suggesting another specific cause for pituitary damage, there is no need to perform any additional specific pituitary function tests (Figure 10.5).** The clinical signs and symptoms associated with different types of functional and nonfunctional pituitary tumors and other specific pituitary causes of gonadotropin deficiency are discussed in a later section of this chapter.

**FIGURE 10.5**

## Evaluation of Hypothalamic Function

When brain imaging reveals no mass lesion and there is no reason to suspect other specific pituitary pathology, the diagnosis by exclusion is that of **functional hypothalamic amenorrhea** (FHA). The pathophysiology of FHA relates to a suppressed or otherwise abnormal pattern of pulsatile hypothalamic GnRH secretion, resulting in decreased gonadotropin secretion, absent follicular development with consequent anovulation, and low serum concentrations of estradiol. Serum levels of FSH (and LH, if measured) are low or in the normal range; often, but not always, the FSH level is higher than LH, a pattern that is reminiscent of the prepubertal period.

Unfortunately, there is no simple way to test, manipulate, or directly measure the hypothalamic function in clinical settings to prove the existence of GnRH deficiency in FHA. Whereas one might anticipate that the LH response to a bolus of exogenous GnRH (e.g., 100 mg, administered subcutaneously) would be revealing, experience has shown that it may be normal (>10 IU/L) or low in women with pituitary or hypothalamic disease. The response to repeated bolus GnRH administration (e.g., 24 hours after the first) may be somewhat more informative, due to the recognized self-priming effect that GnRH has on its own receptor.<sup>68</sup> Administration of exogenous GnRH in a pulsatile manner using a programmable infusion pump can effectively restore normal gonadotropin secretion and menstrual function and induce ovulation in women with hypothalamic amenorrhea,<sup>69,70</sup> but the considerable costs and logistical challenges of such treatment make it impractical and impossible to justify this approach as a diagnostic test.

In most cases, the probable cause of hypothalamic amenorrhea can be identified, such as extreme emotional stress, acute weight loss or chronic malnutrition, or strenuous physical exercise. However, in others with hypothalamic amenorrhea, no obvious cause or precipitating event may be identified. Rare individuals with idiopathic hypogonadotropic hypogonadism may present with primary amenorrhea and infantile sexual development due to a congenital GnRH deficiency, resulting from the failure of GnRH neuronal development during embryogenesis or from mutations in the GnRH receptor. Beyond the workup discussed, any specific evaluation to identify such rare abnormalities is not clinically necessary nor indicated, except perhaps when other family members are affected. The various causes of hypothalamic amenorrhea and its management are discussed at length in a later section of this chapter devoted to specific disorders of the hypothalamus.

# **SPECIFIC CAUSES OF AMENORRHEA**

---

With only modest effort, time, and expense, the problem of amenorrhea has been dissected by systematic evaluation of the organ systems that are critical to normal menstrual function—the genital outflow tract and uterus, the ovary, the anterior pituitary, and the hypothalamus. Once the anatomic level of dysfunction has been identified, further management can be tailored to a specific diagnosis. This section of the chapter considers each of the major causes of amenorrhea and their management, organized by organ system.

# Disorders of the Genital Outflow Tract and Uterus

Anatomical disorders of the genital outflow tract and the uterus are relatively uncommon causes of amenorrhea. Congenital developmental anomalies of the genital outflow tract and uterus that result from a failure of müllerian duct development (vaginal/müllerian agenesis, AIS) and failure of vertical fusion (imperforate hymen, transverse vaginal septum, or cervical atresia) present at or near the expected time of menarche as primary amenorrhea. Acquired disorders of the genital outflow tract or uterus that can present as secondary amenorrhea include intrauterine adhesions, resulting from surgical trauma or infection (Asherman syndrome), and cervical stenosis, often resulting from surgical procedures undertaken for management of cervical dysplasias and cancer, such as LEEP or cone biopsy. These acquired conditions present as secondary amenorrhea with an onset that typically correlates closely with the time of previous insult; clinical history is therefore a critical component of evaluation and helps guide the next steps of management.

## Imperforate Hymen

The hymen is formed by invagination of the posterior wall of the urogenital sinus and usually undergoes spontaneous dissolution during the perinatal period. Although most cases of imperforate hymen occur sporadically, reports of families with several affected members suggest that some cases may have a genetic and heritable cause.<sup>71</sup>

Imperforate hymen commonly occurs as an isolated anatomical defect, although in a minority, additional müllerian anomalies involving higher levels of the outflow tract may coexist. The HPO axis is intact, and the uterine endometrium is responsive to cyclic ovarian hormonal fluctuations with cyclic shedding of the menstrual endometrium. There is a progressive buildup of the menstrual blood in the vagina (hematocolpos) and the endometrial cavity (hematometra). Typically, the clinical presentation is that of primary amenorrhea in the setting of normal secondary sexual characteristics. Proximate to the time of anticipated menarche, patients with an imperforate hymen start experiencing worsening cyclic perineal, pelvic, or abdominal pressure or pain that results from the gradual accumulation of obstructed menstrual flow (cryptomenorrhea). Patients may present with acute urinary retention due to compression of the urethra and bladder by a grossly distended lower vagina.<sup>72</sup> With delay in diagnosis and intervention, imperforate hymen with resulting hematometra imposes a real risk for the development of severe endometriosis due to the ongoing retrograde spill of uterine blood into the peritoneal cavity through the patent fallopian tubes. **Examination of the external genitalia reveals no obvious vaginal orifice and a thin, often bulging, blue perineal membrane**

**at the inferior limit of a palpable, fluctuant mass (hematocolpos).** This blue bulging membrane at the introitus becomes prominent during a Valsalva maneuver. The treatment of girls with an imperforate hymen centers on providing relief of symptoms related to the accumulated menstrual fluid and debris. Definitive surgery should be accomplished as soon as possible because delay can lead to infertility due to inflammatory changes and to the development of severe endometriosis. Surgical correction of an imperforate hymen is straightforward. The classical procedure is to make a simple cruciate incision in the bulging hymen extending to the base of the hymenal ring and to excise its central portion to allow drainage of the sequestered menstrual fluid and subsequent normal menstrual egress. Alternatively, to avoid any risk of damage to the hymenal ring (a sign of virginity that is important to some individuals and in some cultures), a sterile puncture can be made in the center of the distended membrane and enlarged to approximately 0.5 cm in diameter to allow insertion of a 16-F Foley catheter. After thorough drainage of the vagina via irrigation with sterile saline, the catheter is left in place for approximately 2 weeks to allow further drainage from the vagina and the upper genital tract. A single dose of prophylactic antibiotics is prudent, and estrogen cream applied locally to the hymenal ring helps to encourage re-epithelialization.<sup>73</sup> If the latter approach is undertaken, use of tampons should be encouraged until sexual activity is initiated so as to minimize a plausible risk of scarring-related stricture of the surgically created vaginal opening.

## **Transverse Vaginal Septum/Cervical Atresia**

A transverse vaginal septum results when the vaginal plate, formed from the fused sinovaginal bulbs, fails to break down or canalize during embryogenesis. As could be expected, girls with a transverse vaginal septum or cervical atresia, like those with an imperforate hymen, generally present at or soon after the age of expected menarche with primary amenorrhea and complaints of cyclic pelvic or abdominal pain due to obstructed menses and exhibit symmetrical, age-appropriate secondary sexual development. **Physical examination reveals a normal vaginal orifice, a shortened vagina of varying length, no visible cervix, and a palpable hematocolpos in the proximal vaginal segment above the obstruction and/or a pelvic mass resulting from hematometra and hematosalpinges.** A Valsalva maneuver will cause distension at the introitus in those with an imperforate hymen, but not in those with a transverse vaginal septum or cervical atresia, and can help to distinguish the two. Imaging is necessary to define the anatomy of the disorder, but laboratory investigation generally is not required. Pelvic ultrasonography can reveal the level and extent of the hematocolpos and any associated hematometra or hematosalpinges. However, abdominal/pelvic MRI provides greater anatomical detail and is recommended to more clearly define the length of the atretic segment between the lower and upper vaginas,<sup>74,75</sup> information that

is essential to planning surgical treatment. **The temptation to insert a needle for diagnostic purposes must be resisted to avoid the risk of seeding the contents with infection and converting a hematocolpos into a pyocolpos.** In rare instances, laparoscopy may be required to clarify the anatomy of the developmental anomaly. Transverse vaginal septum and cervical atresia may be accompanied by abnormalities of the upper reproductive tract, such as absent segments or atresia of the fallopian tubes or unilateral absence of the fallopian tube and ovary.<sup>76</sup> The chronic retrograde menstruation seen with transverse vaginal septum and cervical atresia is more exaggerated compared to imperforate hymen and frequently results in pelvic endometriosis and adhesions, which can be particularly severe.

Simply described, the procedure involves excision of the septum or dissection of the atretic segment and primary anastomosis of the margins of the lower and upper vaginal canals over the site of the defect. Atretic segments of greater length may require application of a graft to bridge the gap between the lower and upper vaginas. In all instances, every effort should be made to incise and drain the sequestered menstrual fluid from below, at the level of the obstruction. Even in complicated circumstances, continuity of the lower genital tract usually can be achieved successfully. Operative excision of painful masses from above risks damage to the bladder, ureters, and rectum and unnecessarily removes distended but otherwise healthy reproductive organs. Surgical management of a transverse vaginal septum can be challenging and, because they also are infrequently encountered, often requires consultation with specialists having the necessary training and experience. **Because septa that appear relatively thin by physical examination and MRI may be significantly larger after decompression of the proximal hematocolpos, preparations for surgery should consider the possibility that a graft may be required.**

The optimal surgical approach for the management of rare cases of cervical atresia is controversial. Ideally, the goal would be to preserve the uterus and fertility while creating a functional outflow for menstruation. But experience has proven that such heroic efforts may be associated with serious postoperative complications such as peritonitis and sepsis, recurrent obstruction, and persistent infertility, prompting many to view hysterectomy as the best management option. However, conservative surgical treatment is reasonable to consider in selected individuals. The best candidates are those recognized early, before they develop severe pelvic endometriosis and adhesions, having a well-developed lower vagina,<sup>77</sup> although successful reconstruction and pregnancy can be achieved even in those who also require vaginoplasty.<sup>78,79</sup>

## **Müllerian Agenesis (Mayer-Rokitansky-Küster-Hauser Syndrome)**

The failure of müllerian development is a relatively common cause of primary amenorrhea, much more frequently encountered than AIS discussed in the next section of this chapter, and second only to gonadal dysgenesis in prevalence.<sup>80</sup> In Finland, the incidence is approximately 1 in 5,000 newborn girls.<sup>81</sup> Although usually sporadic, some cases of müllerian agenesis are associated with chromosomal translocations or occur in familial aggregates, suggesting a genetic basis for the disorder.<sup>82</sup> Although the exact mechanisms remain unknown, studies on discordant monozygotic twins have offered some meaningful insights, implicating genes relevant to remodeling of the extracellular matrix and neoangiogenesis.<sup>83</sup> Logically, müllerian agenesis might be attributed to an activating mutation in the gene encoding antimüllerian hormone (AMH) or its receptor, causing excess AMH activity. Inactivating mutations in these genes causing persistence of müllerian structures in otherwise normally virilized males have been described.<sup>83,84,85</sup> However, no activating mutations have been identified in patients with müllerian agenesis. The prevalence of a mutation in the galactose-1-phosphate uridylyltransferase (GALT) gene (different from that associated with classical galactosemia) is increased in daughters with müllerian agenesis and their mothers.<sup>86</sup> This observation suggests that errors in fetal or maternal galactose metabolism resulting in increased intrauterine galactose exposure may have adverse effects on müllerian development and is consistent with studies in rodents wherein a high galactose diet during pregnancy delayed vaginal opening in the female offspring.<sup>87</sup> Given the relationship between classical galactosemia and POI (discussed later in this chapter), patients with müllerian agenesis who carry such a variant GALT gene mutation may be at increased risk for the same.<sup>88</sup>

Patients with müllerian agenesis typically present in late adolescence or as young adults, well after menarche was expected, with primary amenorrhea as their only complaint. **They exhibit normal, symmetrical breast and pubic hair development, have no visible vagina, and have no symptoms or signs of cryptomenorrhea because the rudimentary uteri contain no functional endometrium.** However, in approximately 10%, functional islands of endometrium may result in hematometra and symptoms of cyclic pain like described earlier in association with transverse vaginal septum or cervical agenesis.<sup>88,89</sup> Two forms of the disorder have been described. Type A is characterized by symmetrical, muscular, rudimentary uteri and normal fallopian tubes and type B by asymmetrical rudimentary uteri and absent or hypoplastic fallopian tubes.<sup>90</sup> In the great majority of patients with müllerian agenesis, the ovaries are entirely normal histologically and functionally, although their location in the pelvis may be higher, positioned at or even above the level of the pelvic brim; one or both also may be hypoplastic or associated with an inguinal hernia. Urologic anomalies are relatively common (15–40%), particularly in type B müllerian agenesis, and include unilateral

renal agenesis, ectopic or horseshoe kidney, and duplication of the collecting system(s).<sup>88,89</sup> Skeletal malformations involving the vertebrae, the ribs, or the pelvis are observed in 10–15% of patients with müllerian agenesis; some of the more common abnormalities include hemivertebrae leading to scoliosis and the Klippel-Feil syndrome, characterized by a short neck, low hairline, limited range of motion, and sometimes pain and neurologic symptoms, all relating to one or more fused cervical vertebrae.

Although the diagnosis of müllerian agenesis is suggested by clinical history and physical examination alone, additional evaluation is warranted to establish this diagnosis and to identify any of the associated urologic (renal ultrasonography) and skeletal anomalies (spinal x-rays) that may be relevant to the overall well-being of the patient. **Because patients with müllerian agenesis can exhibit characteristics similar to those observed in some types of male pseudohermaphroditism, a karyotype is justified and definitive.** In the absence of a karyotype, serum testosterone concentration in the normal female range effectively excludes AIS (discussed below). Pelvic imaging is indicated to quantify the anatomical defects when müllerian agenesis is suspected. Pelvic ultrasonography may help to define the size and symmetry of any pelvic reproductive organs, but pelvic MRI is more accurate and is indicated when doubt remains.<sup>91,92</sup> Laparoscopy usually is not necessary for establishing the diagnosis of müllerian agenesis. Although imaging frequently does not agree completely with surgical observations, detailed knowledge of the pelvic anatomy is not often needed.<sup>93</sup> Surgery generally is indicated only in those with symptoms relating to hematometra, endometriosis, or a hernia into the inguinal canal.

The primary goal of treatment in women with müllerian agenesis—creation of a functional vagina—can be accomplished with a variety of methods, when the time is appropriate. In the large majority of cases, progressive vaginal dilation as originally described by Frank<sup>94</sup> and later by others<sup>95</sup> is an appropriate and effective first choice. In motivated patients, the technique is highly successful and can create a functional vagina within 3–6 months.<sup>96</sup> The procedure involves applying pressure to the point of moderate discomfort for an interval of 20–30 minutes daily, using commercially available vaginal dilators. Initially, pressure is directed posteriorly, to create a shallow pouch. After approximately 2 weeks, pressure shifts to the usual axis of the vagina. After the desired depth is achieved, dilators of increasing diameter will expand the vagina to a functional size. A variation on the technique uses a tight-fitting garment to hold the dilator in place, maintaining pressure by leaning forward on a bicycle seat mounted on a stool, or even on a bicycle.<sup>97</sup>

Operative treatment of women with müllerian agenesis generally can be reserved for those who are unable or unwilling to dedicate themselves to a program of

progressive vaginal dilation and for those in whom earnest efforts fail. The traditional McIndoe procedure for surgical creation of a neovagina involves dissection of the rectovaginal space and placement of a skin graft, held in place with a soft mold until the graft becomes established.<sup>98</sup> Subsequently, regular intercourse or vaginal dilation must be maintained to avoid risk of fibrosis and loss of function. The alternative Vecchiotti operation involved internal stretching of the vaginal dimple after surgical abdominal and vaginal dissection of the vesicorectal space.<sup>99</sup> A modification of the Vecchiotti operation, performed laparoscopically, has emerged as an attractive and effective option for surgical creation of a neovagina.<sup>100,101</sup> The procedure employs a specially designed system including a spring-loaded traction device, positioned on the abdomen; connected to the tip of a dilator; positioned at the introitus, via paired threads introduced with a needle inserted through small incisions in the lower abdomen; and guided beneath the peritoneum to penetrate the introitus in the midline. Tension on the threads is adjusted to maintain traction on the dilator, which is drawn upward gradually, invaginating the tissue to produce a neovagina 7–8 cm in depth over an interval of 7–10 days. Thereafter, standard vaginal dilators are employed to further extend and expand the vagina to functional dimensions over a period of a few weeks. Evidence indicates that the procedure results in a quality of sexual experience comparable to that in a sample of healthy, age-matched women of equivalent cultural and social status.<sup>102</sup>

Reassurance and support are important elements of the management of vaginal/müllerian agenesis. Affected women should be counseled that normal sexual function can be expected. Advances in assisted reproductive technologies with the use of gestational surrogacy option have allowed attainment of genetic offspring by in vitro fertilization (IVF) using oocytes retrieved from their own normal ovaries and the sperm of their chosen partner, with subsequent transfer of embryos to a gestational surrogate.<sup>102,103,104</sup> Existing data on neonatal outcomes of IVF with autologous eggs from patients with müllerian agenesis and use of gestational surrogates offer reassurance against any evidence of a dominant pattern of inheritance.<sup>104</sup> In the past decade, uterine transplantation has moved leaps and bounds, from concept to a reality, and may even eventually emerge as a first-line approach for addressing reproductive needs for patients with müllerian agenesis.<sup>105,106</sup>

## **Androgen Insensitivity Syndrome (AIS)**

Complete AIS (testicular feminization) is a form of male pseudohermaphroditism, the term referring to the gonadal sex (male) and the contrasting phenotype (female).<sup>107,108</sup> The disorder, discussed in greater detail in [Chapter 8](#) as a cause of abnormal sexual development, is the third most common cause of primary amenorrhea, after gonadal dysgenesis and müllerian agenesis. Patients with AIS have a normal male karyotype

(46,XY) and testes as gonads that produce both testosterone and AMH. However, an inactivating mutation in the gene encoding the intracellular androgen receptor (AR) (located on the long arm of the X chromosome, Xq) results in an end-organ insensitivity to androgen actions that prevents normal masculinization of the internal and external genitalia during embryonic development. Consequently, in the absence of androgen action, differentiation of the external genitalia follows the “default” female pattern of development. However, given AMH signaling is intact in AIS, the internal genitalia follow the male pattern of differentiation with regression of the müllerian structures; individuals with AIS are phenotypic females with absent cervix and uterus (due to normal AMH action); the vagina is short and ends blindly (derived only from the urogenital sinus).

Patients with complete AIS appear as normal females at birth. Growth and development during childhood also are generally normal, although overall height usually is above average and the body habitus somewhat eunuchoid (long arms, large hands and feet). At puberty, the breasts develop, driven by estrogen derived from the peripheral conversion of high circulating testosterone levels, unopposed by the actions of androgen. The breasts may become relatively large and have subtle abnormalities; lacking the actions of progesterone, they have little glandular tissue, small nipples, and pale areolae. The labia minora usually are underdeveloped and the vagina is short and ends blindly. Pubic and axillary hair do not develop, due to the absence of androgen action. The gonads are testes, and their location may be intra-abdominal, but often are partially descended into the inguinal canal; more than half of patients with complete AIS have an inguinal hernia, and the testes are frequently palpable in the inguinal canals, most commonly at the level of the external inguinal ring. Histologically, the gonads generally resemble any cryptorchid testes but may be nodular. After puberty, the testes contain immature seminiferous tubules lined by immature germ cells and Sertoli cells, with no evidence of spermatogenesis.

Patients with complete AIS most commonly present after the age of puberty in late adolescence or as young adults with primary amenorrhea. **They exhibit asymmetrical secondary sexual development (breast development with absent or scant pubic hair), have a short vagina with no visible cervix, and have no other symptoms or complaints.** Uncommonly, AIS may be recognized at birth or in childhood during workup for an inguinal mass or hernia, particularly when the disorder is reasonably suspected because other family members such as a sister or maternal aunt are affected. Diagnosis usually is not difficult. Patients with complete AIS generally are easily distinguished from those with müllerian agenesis by the absence of pubic and axillary hair and from those with an imperforate hymen or transverse vaginal septum by the absence of a uterus and lacking symptoms relating to obstructed menstrual flow. In some cases, the presence of some pubic hair, due to incomplete penetrance, can be confusing

or misleading. **Serum testosterone concentration easily distinguishes patients with AIS from those with müllerian agenesis because levels are normal or modestly elevated well above the normal range for females and often above the range observed in normal males.** Serum LH levels also are elevated, reflecting androgen insensitivity at the hypothalamo-pituitary level. A karyotype (46,XY) firmly establishes the diagnosis.

In rare cases of **incomplete androgen insensitivity**, varying degrees of androgen signaling remain. Consequently, depending on the magnitude of androgen sensitivity, the condition may present as ambiguous genitalia at birth; in more subtle cases, at puberty, pubic hair growth may accompany breast development and the clitoris may enlarge.<sup>107</sup> In other rare individuals, inherited deficiency of the enzyme **17-hydroxysteroid dehydrogenase** (type 3), which catalyzes the conversion of androstenedione to testosterone in the testicular Leydig cells, may mimic AIS; in this case however, the mechanism is one of impaired testosterone production rather than abnormalities in the AR and androgen signaling. When necessary, the two disorders can be differentiated by molecular analysis of the genes encoding the AR and the enzyme (17HSDB3).<sup>109</sup>

The management of patients with complete AIS has two major components, one focusing on creation of a functional vagina to allow attainment and optimization of potential for sexual relations and another relating to the risk for developing malignancy in the cryptorchid testes. In patients with AIS, the options for creation of a neovagina are the same as discussed earlier for those with müllerian agenesis—progressive vaginal dilation and vaginoplasty. The short but distinct vagina observed in most patients with AIS speeds the progress of efforts at vaginal dilation. Good results also can be expected with surgical treatment, when necessary.<sup>110</sup> Gonadectomy is indicated because the incidence of neoplasia in cryptorchid testes is relatively high. In one early series of 50 cases, 11 malignancies, 15 adenomas, and 10 benign cysts were observed: a 22% incidence of malignancy and a 52% overall incidence of neoplasia.<sup>111</sup> More recent series suggest a lower 5–10% overall incidence of gonadal tumors.<sup>52,112,113</sup> Whereas gonadectomy is recommended at the time of diagnosis in other intersex states such as XY gonadal dysgenesis (Swyer syndrome), it is better delayed in those with AIS, for two reasons. First, the smooth pubertal development that results from endogenous gonadal hormone production is difficult to achieve with exogenous hormone treatment, and second, gonadal tumors develop less often in patients with AIS and rarely before puberty. Therefore, gonadectomy and hormone therapy (physiologic estrogen treatment) generally are best postponed until after pubertal development is complete, by approximately age 16–18. **Complete AIS is the only exception to the rule that gonads with a Y chromosome should be removed as soon as the diagnosis is made.** Gonadectomy usually can be accomplished endoscopically with relative ease when the

testes reside within the abdomen and via inguinal incisions when they are partially descended.<sup>114,115</sup> In patients with the incomplete form of AIS, surgery should not be postponed because prompt gonadectomy will prevent further unwanted virilization that can occur at puberty.

In years now past, conventional wisdom warned against unthinking and “needless” disclosure of the true gonadal and chromosomal sex to patients with complete AIS for fear of undermining gender identity; this attitude has changed in favor of disclosure. Although infertile, patients with AIS have a completely female gender identity that must be reinforced, and not questioned. Candid disclosure based on facts and communicated with extreme sensitivity is advocated. Patients as well as parents must be offered psychological counseling and allowed access to educational resources to facilitate a fuller understanding of the disorder. One excellent resource is the Androgen Insensitivity Syndrome Support Group, headquartered in the United Kingdom (<http://www.aissg.org/>). Another resource is available through the NIH U.S. Library of Medicine (<https://ghr.nlm.nih.gov/condition/androgen-insensitivity-syndrome>).

## **Cervical Stenosis**

Severe cervical stenosis with complete outflow obstruction is a rare complication of cervical conization procedures or other surgical treatments for cervical intraepithelial neoplasia. When cervical stenosis causes symptoms, worsening dysmenorrhea and prolonged light staining or spotting after menses are the most common complaints; amenorrhea is a rare occurrence. Compared to other methods for limiting blood loss during conization, elective suturing appears to increase the risk for subsequent cervical stenosis and amenorrhea.<sup>116</sup> In women with amenorrhea who have had a previous conization or other cervical surgery or ablative treatment, simple uterine sounding will establish the diagnosis of cervical stenosis, and transvaginal ultrasonography will reveal any associated hematometra. The treatment for cervical stenosis is careful dilation, ideally performed under ultrasound guidance, although cervical dilation under fluoroscopic guidance has also been described.<sup>117</sup> Temporary placement of a urinary or specialized balloon catheter for an interval of approximately 2 weeks provides ongoing drainage of the uterine cavity and may help to prevent recurrence.<sup>118</sup>

## **Asherman Syndrome (Intrauterine Adhesions)**

Asherman syndrome, first described by Joseph Asherman in 1948 and called “amenorrhoea traumatica,”<sup>119</sup> results from intrauterine adhesions that obstruct or obliterate the uterine cavity, because of trauma. Disruption of the full thickness of the endometrium including the zona basalis, commonly resulting from instrumentation of the uterine cavity, is the most common mechanism for intrauterine scarring. Risk for

developing intrauterine adhesions is increased by inflammation, as may result from endometritis or retained products of conception, and when the endometrium is relatively thin and inactive, as it is during the early postpartum period. Consequently, most cases arise in close temporal proximity to a pregnancy and are associated with surgical trauma, primarily curettage.<sup>120</sup> In the original series of 29 cases described by Asherman, 11 had a previous postpartum hemorrhage, 15 experienced spontaneous abortion, 2 had undergone an elective pregnancy termination, and in 1, the antecedent event was a hydatidiform mole.<sup>119</sup> Asherman syndrome is an uncommon but recognized complication of cesarean section, abdominal or hysteroscopic myomectomy or metroplasty, and uterine artery embolization.<sup>121</sup> Elective endometrial ablation procedures that utilize various modalities to achieve endometrial damage such as electrocautery, laser, thermal ablation, or cryoablation for the management of menorrhagia frequently result in amenorrhea, by intent. End-organ endometrial damage and intrauterine adhesions also may result from intrauterine infections such as tuberculosis and schistosomiasis, which are rare in the United States but not in other regions of the world.<sup>122,123</sup>

Although Asherman syndrome from any cause may result in amenorrhea, most women with intrauterine adhesions present with dysmenorrhea, hypomenorrhea, infertility, or recurrent pregnancy loss, rather than absence of menses. **The diagnosis of Asherman syndrome is based primarily on a high index of suspicion, based on history. In women whose history suggests this possibility, scant or no withdrawal bleeding after sequential treatment with exogenous estrogen (e.g., conjugated equine estrogens 1.25 mg daily for 21 days) and progestin (e.g., MPA 10 mg daily for the last 5–7 days of estrogen dosing) reflects end-organ endometrial failure and corroborates the clinical suspicion.** However, some form of imaging ultimately is required to establish the diagnosis. Transvaginal or transabdominal ultrasonography may reveal a hematometra, but such findings are surprisingly rare. The clinical impression is further strengthened by ultrasound evidence of a thin, hyperechoic, and often irregular endometrial echo. Saline infusion sonogram (SIS) or hysterosalpingography (HSG) provides more specific information regarding the location and extent of intrauterine adhesions that partially or completely obliterate or obstruct the endometrial cavity or the cervical canal.<sup>124</sup> Hysteroscopy provides a definitive diagnosis. A variety of classification schemes have been proposed to describe the extent of intrauterine adhesions and to predict treatment outcomes,<sup>125,126,127,128,129,130</sup> but none has been validated. Diagnosis of genital tuberculosis is made by endometrial biopsy (histopathology or culture) or with a nucleic acid–based test performed on an endometrial aspirate. Diagnosis of schistosomiasis is made by identifying the eggs of the parasite in urine, feces, rectal scrapings, menstrual discharge, or the endometrium.

Operative hysteroscopy is the primary method for treatment of intrauterine

adhesions. Hysteroscopic adhesiolysis can be performed using hysteroscopic scissors, electrodissection, or with a laser; most prefer sharp dissection, which may have less risk for causing further injury. Simultaneous laparoscopy or transabdominal ultrasonography provides useful guidance when dense scar tissue makes it difficult to enter the uterine cavity and can help to maintain orientation within a grossly distorted cavity, reducing the risk of uterine perforation. Postoperative risk for rescarring is high; most advocate the insertion of an intrauterine balloon catheter (left in place for approximately 7–10 days) after adhesiolysis to keep the walls of the uterine cavity separated during the healing process to decrease the risk of recurrence.<sup>131</sup> Treatment with a broad-spectrum antibiotic (e.g., doxycycline 100 mg twice daily or Augmentin 500 mg twice daily) to minimize risk of infection during the period that balloon is retained and a nonsteroidal anti-inflammatory drug to reduce uterine cramping while the catheter remains in place are commonly utilized. High-dose exogenous estrogen treatment (2.5 mg conjugated equine estrogens 2–3 times daily or its equivalent) for approximately 4 weeks after surgery is generally recommended to encourage rapid endometrial re-epithelialization and proliferation; treatment with a progestin during the final week, if followed by menses, demonstrates a return of functional endometrium. Despite these measures, recurrence rates are relatively high, ranging from 20% to over 60% in severe cases,<sup>132</sup> and repeated procedures often are required to restore a normal uterine cavity.<sup>133</sup> The surgical outcome can be assessed by postoperative SIS or HSG or by early “second-look” hysteroscopy, which also provides the means to lyse any early recurring adhesions when still filmy.<sup>120</sup> Menstrual function can be restored in most cases (52–88%),<sup>132</sup> and among infertile women, live birth rates after hysteroscopic adhesiolysis generally have ranged between 25% and 35%.<sup>133</sup> As might be expected, outcomes tend to correlate with the severity of adhesions.<sup>127,132,134</sup> In those who do achieve pregnancy, the risks of preterm labor, placenta accreta, placenta previa, and postpartum hemorrhage are increased.<sup>127,134</sup> A recent development in the management of Asherman syndrome involves efforts at restoration of the endometrial uterine stem cell population through strategies that have ranged from systemic mobilization of the bone marrow–derived stem cells with the use of GCSF (granulocyte colony–stimulating factor) to intrauterine and intravascular injection of bone marrow aspirate into uterine vessels. Although experimental evidence is highly promising and anecdotal successes with endometrial restoration have also been achieved in clinical settings, the concept and technique both need to be refined before this approach can be made available for routine clinical applicability.<sup>135,136</sup>

# Disorders of the Ovary

Disorders of the ovary include the most common causes of amenorrhea and can present as primary or secondary amenorrhea. Those resulting only from chronic anovulation and relating to PCOS, obesity, and thyroid or mild prolactin excess disorders were discussed earlier in the section of this chapter devoted to the evaluation of ovarian function. The focus here is on specific disorders that result in ovarian failure and their management.

Ovarian failure occurs when few or no follicles remain that are capable of producing estradiol in response to pituitary gonadotropin stimulation. Follicular depletion may occur during embryonic life with no follicles remaining by infancy or early childhood, after puberty has begun but before menarche, or at some later time before menopause normally would be expected. Consequently, depending on when the available supply of ovarian follicles is functionally depleted, puberty may not occur, it may begin normally but stop before the first menses, or it may progress normally to and beyond menarche with the development of secondary amenorrhea at some later point in time. Regardless of age at onset, hypergonadotropic hypogonadism is the biochemical hallmark of ovarian failure. In a few women with rare genetic disorders however, a picture of hypergonadotropic hypogonadism results from a functional ovarian failure due to abnormalities in gonadotropic signaling and of ovarian follicular development, rather than from ovarian follicular depletion.

## Gonadal Dysgenesis

Gonadal dysgenesis is defined as an incomplete or defective formation of the gonads, resulting from a disturbance in germ cell migration or organization. Commonly caused by structural or numerical sex chromosome abnormalities or mutations in the genes involved in formation of the urogenital ridge and sexual differentiation of the bipotential gonad, gonadal dysgenesis is among the most common causes of primary amenorrhea (approximately 30–40%). Due to the absence of ovarian follicles or their accelerated depletion during embryogenesis or the first few years of life, the gonads in cases of pure gonadal dysgenesis contain only stroma and appear as fibrous streaks. The large majority of women with gonadal dysgenesis have an obvious abnormality involving an X chromosome. Approximately 25% of the affected individuals however have a normal 46,XX karyotype; this population may harbor a more subtle abnormality involving one or more specific genes on the X chromosome that are required for normal ovarian function. Some with 46,XX gonadal dysgenesis also have neurosensory deafness; the combination is known as Perrault syndrome. By far, the most common known form of gonadal dysgenesis is seen in cases of Turner syndrome.

# Turner Syndrome

Turner syndrome is a well-known and thoroughly studied genetic disorder, classically associated with a 45,X karyotype, but also with an assortment of other structural X chromosome abnormalities (deletions, ring, and isochromosomes), any of which may be present in all or only in some of the somatic cells (mosaicism), depending on the stage of embryonic development at the time the genetic defect arises. The disorder is discussed thoroughly in [Chapter 8](#), as a cause of abnormal sexual development, and is briefly summarized here.

The classical phenotype of Turner syndrome, first described in 1938 by Dr. Henry Turner, includes short stature, absent sexual development, a webbed neck, low-set ears and posterior hairline, widely spaced nipples (“shield chest”), short fourth metacarpals, and an increased carrying angle at the elbow (“cubitus valgus”). Evidence indicates that the specific phenotype of patients with Turner syndrome relates, in part, to the parental origin of their single X chromosome; most with a 45,X karyotype retain the maternal X.<sup>137</sup>

**If not recognized by phenotype or poor growth during childhood, patients with Turner syndrome generally present at or near the time of expected puberty with primary amenorrhea and absent secondary sexual development.** The diagnosis of Turner syndrome generally can be made easily, based on the phenotype and findings of hypergonadotropic hypogonadism. A karyotype is definitive, and specifically indicated, in part because it may reveal a cell line containing a Y chromosome otherwise not suspected or identified (e.g., 45,X/46,XY); approximately 5% of women with Turner syndrome have a karyotype containing all or part of a Y chromosome.<sup>138</sup> Further analysis with fluorescence in situ hybridization (FISH) using one or more probes specific for segments of the Y chromosome will identify another 5% having occult Y chromosome material.<sup>138,139</sup> Whereas it is important to identify a Y chromosome because affected individuals are at significant increased risk for developing gonadoblastoma (20–30%), that risk appears lower (5–10%) in women with Turner syndrome and limited to those having detectable Y chromosome on karyotype. **FISH analysis is most clearly indicated for those exhibiting any evidence of virilization or having a chromosomal fragment of uncertain origin** (discussed in [Chapter 8](#)).<sup>139,140</sup>

Mosaicism in women with Turner syndrome has important clinical implications besides those relating to a cell line containing a Y chromosome. In those with a mosaic 46,XX cell line (e.g., 45,X/46,XX), the gonad may contain functional ovarian cortical tissue, resulting in some degree of sexual development, or even menses and the possibility of pregnancy. Approximately 15% of patients with Turner syndrome begin but do not complete pubertal development and approximately 5% complete puberty and

begin menstruation.<sup>141</sup> As might be expected, given the genetic heterogeneity, the phenotype varies, with some appearing normal without obvious phenotypic stigmata and even attain normal stature before experiencing ovarian failure.

Women with Turner syndrome are at risk for a wide variety of medical problems having health implications that are equal if not more important than those relating to or resulting directly from hypogonadism.<sup>138</sup> Approximately one-third manifest one or more of a spectrum of cardiovascular anomalies that have been described in women with Turner syndrome and include bicuspid aortic valve, coarctation of the aorta, mitral valve prolapse, and aortic aneurysm. Spontaneous aortic dissection is a real risk in women with Turner syndrome, which gets exaggerated if pregnancy occurs, and is associated with a high incidence of mortality. Renal anomalies are also common and include horseshoe kidney, unilateral renal agenesis or pelvic kidney, rotational abnormalities, and partial or complete duplication of the collecting system(s). The prevalence of autoimmune disorders is common in Turner syndrome including autoimmune thyroiditis, type I diabetes, autoimmune hepatitis, thrombocytopenia, and celiac disease.<sup>142,143,144</sup> Hearing loss also is also common in this population and sensorineural loss is the most common form of hearing impairment in this population.<sup>145</sup> **Consequently, additional and periodic medical evaluation is indicated and should include the following<sup>140,145</sup>:**

- **Echocardiography (at diagnosis, at least once between the ages of 12 and 15 years, and every 5 years if normal; more often if abnormal)**
- **Renal ultrasonography (once if normal, every 3–5 years if abnormal)**
- **TSH and free T4 (at diagnosis and every 1–2 years)**
- **Complete blood count, fasting glucose, lipid profile, renal function tests, and liver enzymes (every 2 years)**
- **Antiendomysial antibodies, to detect celiac disease (at diagnosis)**
- **Audiometry (at diagnosis, at least once during the teen years or young adulthood, and every 10 years if normal)**

Average intellectual performance is within the normal range, although the prevalence of attention-deficit/hyperactivity disorder (ADHD) is increased in girls with Turner syndrome.<sup>146,147</sup> Overall mortality is increased approximately threefold and relates primarily to circulatory disease (e.g., hypertension), diabetes, and liver and renal disease.<sup>148</sup> Overall cancer risks in women with Turner syndrome are similar to those in the general population, but the incidence of CNS tumors, bladder cancer, and endometrial cancer may be increased<sup>149</sup>; the risk of breast cancer is decreased compared to the general population and may be attributable to the early deprivation of

ovarian hormones.<sup>149</sup> With early diagnosis and treatment with growth hormone (GH), a final height greater than 150 cm (59 inches) can be achieved in most patients with Turner syndrome. The most important determinants of final height are the dose of GH and the duration of treatment before estrogen therapy begins. Treatment with GH generally should begin as soon as growth curve falls below the fifth percentile of normal female growth, and the regimen must be individualized, according to response.<sup>140</sup>

Treatment with estrogen must be timed carefully, with the goals of minimizing its adverse effects on growth and adult height and inducing puberty at an approximately normal age. Ideally, estrogen therapy should begin no later than age 15 and not before age 12 when growth is a priority, unless height already has been maximized. Estrogen therapy should begin at a low dose (e.g., 0.25–0.5 mg micronized estradiol or its equivalent), increasing gradually at intervals of 3–6 months according to response (Tanner stage, bone age), with the goal of completing sexual maturation over a period of 2–3 years. When vaginal bleeding first occurs, or after 12–24 months of estrogen therapy, a progestin (e.g., MPA) should be added to the treatment regimen to prevent dysfunctional bleeding, to achieve differentiation of breast tissue, and to protect the endometrium from long-term adverse effects of unopposed estrogen.<sup>140</sup> Natural pregnancies are described in women with Turner syndrome, but they are rare and are associated with a relatively high risk for sex chromosome aneuploidy and spontaneous abortion. For the majority of women with Turner syndrome, oocyte donation offers a realistic possibility of biologic parenting. Any pregnancy in a woman with Turner syndrome must be considered as high risk given the innately increased cardiovascular risk related to structural cardiac anomalies that this population is predisposed to. The increased cardiovascular demands of pregnancy pose unique and potentially life-threatening risks that must be carefully considered before attempting pregnancy. **The risk of death during pregnancy is increased as much as 100-fold, primarily due to complications of aortic dissection or rupture.** This risk is greatest for those with preexisting cardiac abnormalities such as a bicuspid aortic valve or a dilated aortic root, but even those without obvious cardiac abnormalities remain at risk. **Turner syndrome generally should be regarded as a relative contraindication to pregnancy.** Those expressing serious interest in oocyte donation must receive thorough evaluation and counseling, and those with evidence of any significant cardiac abnormality must be strongly discouraged.<sup>150</sup> Advances in the field of fertility preservation, such as oocyte or ovarian tissue cryopreservation, now can offer a realistic possibility for preservation of fertility potential for a subset of girls and women with Turner syndrome who demonstrate evidence of residual ovarian function<sup>151</sup>; eggs and embryos of these patients are at a higher risk for sex chromosome aneuploidy, and preimplantation genetic screening technology can be utilized to minimize the risk of aneuploidy in the progeny.

Despite the promise, these technologic advancements in the field of assisted reproduction are likely to offer benefit to only a fraction of patients with Turner syndrome, the majority are destined for prepubertal or peripubertal ovarian failure. Consideration for use of gestational surrogate should be strongly encouraged for women considering use of donor eggs or by those who have autologous cryopreserved eggs or ovarian tissue.

## Swyer Syndrome (46,XY Gonadal Dysgenesis)

Swyer syndrome is a distinctly different and less common form of gonadal dysgenesis that is characterized by a 46,XY karyotype. Despite the presence of a Y chromosome, the phenotype is female because the dysgenetic (streak) gonads produce neither AMH nor androgens. Consequently, the vagina, cervix, uterus, and fallopian tubes develop normally and the internal and external genitalia fail to masculinize.<sup>152</sup> In at least 10–15% of the affected individuals, a mutation of the SRY (Sex-determining Region of the Y chromosome) gene that is located on the short arm of the Y chromosome (Yp11.3) is the cause.<sup>153</sup> In the remainder, no cause can be determined, although mutations in the SRY regulatory elements or in other genes involved in the testis-determining pathway have been implicated (SF1, SOX9, WT1, CMRT1).<sup>154,155,156</sup>

**Patients with Swyer syndrome generally present after the expected time of puberty with delayed sexual maturation and primary amenorrhea.** The presence of pubic hair reflects a normal adrenarche and hence rules out complete AIS as a possible diagnosis. Evaluation reveals hypergonadotropic hypogonadism, prompting a karyotype that establishes the diagnosis. **Gonadectomy is indicated soon after diagnosis is made due to the significant risk for malignant transformation in occult testicular elements (20–30%).** Gonadoblastoma is a premalignant germ cell tumor, unique to intersex states like Swyer syndrome, and may contain or give rise to other highly malignant tumors, including dysgerminoma, endodermal sinus tumor, embryonal carcinoma, and choriocarcinomas; evidence suggests that the tumors originate from clonal expansion of surviving germ cells in areas of undifferentiated gonadal tissue.<sup>157</sup>

Patients with Swyer syndrome exhibit normal growth and intellectual development, are otherwise healthy, and require no specific monitoring or treatment beyond that relating to hormone therapy aimed at inducing sexual maturation. The same sequential sex steroid treatment regimen described above for patients with Turner syndrome can be applied successfully in those with Swyer syndrome. Despite the male karyotype, the patients with Swyer syndrome must be assured of their female gender identity and reassured regarding their ability to achieve and sustain a pregnancy with the use of donor egg IVF. Unlike the situation with Turner syndrome patients, pregnancy in patients with Swyer syndrome has not been associated with any specific risks or

complications.<sup>158</sup>

## **46,XX Gonadal Dysgenesis**

Some individuals with primary amenorrhea and gonadal dysgenesis (streak gonads) have a normal 46,XX karyotype, providing indirect evidence that autosomal genes also play a critical role in ovarian differentiation. In contrast to those with Turner syndrome, affected women are normal in stature and, in most cases, have no apparent somatic anomalies. A wide variety of candidate genes has been identified, primarily via experiments involving murine knockout models, including several that encode DNA- and RNA-binding proteins and transcription factors expressed during oogenesis.<sup>159</sup>

## **Premature Ovarian Failure or Premature Ovarian Insufficiency**

POF is traditionally defined as hypergonadotropic hypogonadism and amenorrhea arising before the age of 40. This is a heterogeneous disorder that varies widely in cause and phenotype. Whereas the term POF is well-entrenched in the medical literature, an alternative term—“premature ovarian insufficiency” or POI—has been proposed and increasingly adopted to more accurately reflect the continuum of decreased ovarian function observed in the affected women<sup>160</sup> while acknowledging that many may exhibit intermittent ovarian function and ovulation and that 5–10% may even conceive and achieve successful live birth.<sup>161,162</sup> In this chapter, terms POF and POI are used interchangeably.

Although POI can manifest at any age, the majority of cases present as secondary amenorrhea at some time after puberty is completed; it however also may occur at any time before menarche and is then distinguished from gonadal dysgenesis on the basis of ovarian morphology and histology; instead of streak gonads, the ovaries more closely resemble those of menopausal women. Approximately 1% of women will develop POI before the age of 40 years. In a cross-sectional survey of women aged 40–55 conducted at seven sites in the United States to determine eligibility for a community-based, multiethnic longitudinal study of the perimenopause (the Study of Women Across the Nation, SWAN), premature menopause was reported by 1% of Caucasians, 1.4% of African Americans and Hispanics, 0.5% of Chinese, and 0.1% of Japanese women.<sup>163</sup>

Important known causes of POI include numerical and structural chromosomal abnormalities, fragile X (FMR1) premutations, autoimmune disorders, radiation therapy, and chemotherapy. Whereas history alone can identify the latter two, the first three merit specific consideration and exclusion. In these and other rare disorders associated with ovarian failure such as galactosemia, the basic pathophysiology

involves accelerated follicular atresia. In other rare genetic disorders, mutations in genes encoding intraovarian regulators, steroidogenic enzymes, gonadotropins, or their receptors result in impaired or abnormal follicular development, but the end result is much the same—functional ovarian failure. In most women with POF, a specific cause cannot be identified, but evidence implicating a number of genetic factors is growing rapidly.<sup>159</sup>

## **Numerical and Structural Chromosomal Abnormalities**

A wide variety of numerical and structural chromosomal abnormalities may be identified in women presenting with POI. A review of karyotypes obtained in women with secondary amenorrhea revealed the spectrum of possibilities and demonstrates the importance of a karyotype in women with POF.<sup>164</sup> Half of the observed abnormalities were numerical, involving X chromosome mosaicism (including 45,X, 46,XX, and 47,XXX cell lines) or Y chromosome mosaicism (including 46,XY, 47,XYY, and 47,XXY cell lines); the remainder included an assortment of X chromosome translocations, deletions, and other structural abnormalities and even some with a pure 46,XY karyotype.

Chromosomal deletions and translocations involving either the short (Xp) or the long arm (Xq) of the X chromosome may be identified in women with POF. Only about half of those with deletions involving the short arm of the X chromosome present with primary amenorrhea and gonadal dysgenesis; the remainder achieve menarche and exhibit cyclic ovarian function reflected in menstruation for variable lengths of time before experiencing POF and secondary amenorrhea. Presumably, the short arm of the X chromosome contains genes essential for ovarian germ cell function. Although the specific genes involved are unknown, likely candidates include BMP15 (Bone Morphogenetic Protein) and other members of the TGF $\beta$  (Transforming Growth Factor Beta) superfamily.<sup>159</sup> The long arm of the X chromosome also contains genes crucial for normal ovarian function. Likely candidate genes, identified by the phenotypes associated with deletions and translocations involving Xq, include XIST (the X-inactivation gene), DACH2 (encoding a transcription factor), and QM (encoding a ribosomal protein).<sup>159,165</sup>

## **Fragile X (FMR1) Premutations**

A spectrum of clinically important disorders, including POI, involves a dynamic trinucleotide (CGG) repeat sequence mutation in the X-linked FMR1 gene, located near the terminal end of the long arm of the X chromosome (Xq27.3). As mentioned earlier in this chapter, the normal FMR1 gene contains approximately 30 repeats. The fully expanded form of the mutation, characterized by 200 or more CGG repeats, results in

FXS, the most common known genetic cause of mental retardation and autism. The premutation, characterized by between 55 and 200 trinucleotide repeats, is associated with two disorders that are distinct from FXS. One is the fragile X-associated tremor/ataxia syndrome (FXTAS), a neurologic disorder that affects males primarily, as might be expected for an X-linked disorder. The other is POF, affecting approximately 15% of women who carry the premutation.<sup>59,60</sup>

In the full mutation, the expanded number of trinucleotide repeats in the 5' untranslated region of the FMR1 gene results in hypermethylation that extends into the promoter region and silences the gene. Consequently, there is little or no production of mRNA and its product, the FMRP, which is an RNA-binding protein that functions as a translational suppressor. Ultimately, the result is an overexpression of mRNAs, leading to the clinical features of FXS.<sup>166</sup> The incidence of FXS is approximately 1 in 4,000 males and 1 in 4,000–8,000 females.<sup>59,60</sup> Although affected females are protected to some extent from the full impact of the mutation, due to the phenomenon of X-inactivation, approximately 70% have a borderline or lower IQ or other functional deficits.<sup>167,168,169</sup>

In the setting of premutation, the trinucleotide repeat sequence is not methylated, the FMR1 gene is functional, and FMRP is produced. However, the condition is quite different from the usual unaffected carrier state in two important ways: (1) premutation carriers are at risk for developing disorders that are distinct from FXS, and (2) the affected alleles are unstable and at risk for expansion from the premutation to the full mutation. FXTAS is a progressive neurodegenerative disorder affecting male premutation carriers, generally after age 50, causing intention tremor, ataxia, autonomic dysfunction, cognitive deficits, behavioral abnormalities, and peripheral neuropathy.<sup>170</sup> Female premutation carriers may develop the disorder, but do so infrequently; unfavorable X chromosome inactivation may increase the risk of FXTAS in women.<sup>171</sup> However, women with a FMR1 premutation frequently develop POF. The prevalence of premutations is approximately 15% among women with familial POF and lower, but still significant (1–7%), in those having no family history of POF.<sup>59</sup> The variation in prevalence may be explained by the relationship between the probability of POF and the size of the CGG repeat sequence; risk for POF increases with the number of repeats, between 59 and 99, but rises no further and even decreases for those with more than 100 repeats.<sup>172,173</sup> Women with a modestly expanded repeat sequence (41–58 repeats) also may be at increased risk for POF.<sup>174,175</sup>

Women who carry the FMR1 premutation often exhibit signs of early reproductive aging. The lengths of their menstrual cycles and the follicular phase of the cycles are shorter, FSH levels across all phases of the cycle are higher, and inhibin levels are lower, compared to those in normal women,<sup>176</sup> and an inverse correlation was

demonstrated between length of CGG repeats and AMH levels.<sup>177</sup> Premutation carriers also enter menopause approximately 5 years earlier than average.<sup>172</sup> Exactly why or how the FMR1 premutation predisposes to POF is not entirely clear but may involve gain-of-function toxicity, due to overexpression of mRNAs, resulting in accelerated follicular atresia.

The inheritance of FMR1 mutations and premutations follows the basic pattern of an X-linked disorder; the carrier females transmit the abnormality to 50% of their offspring (sons and daughters), whereas the male carriers transmit the affected allele to 100% of their daughters, while the sons get spared. The pattern of inheritance is complicated by the meiotic instability of the trinucleotide repeat sequence, which tends to expand when passed from the mother to her progeny, thereby increasing the risk for FXS with each successive generation, a phenomenon known as “anticipation.” The risk for expansion depends on the size of premutation; a repeat sequence numbering between 59 and 79 expands to the full mutation range less than half the time, but trinucleotide repeat counts greater than 90 do so more than 90% of the time.<sup>178</sup> In contrast, the size of the premutation remains relatively stable when transmitted from fathers to their daughters and rarely expands to the full mutation,<sup>179</sup> possibly because large repeat sequences are highly unstable in the developing sperm and only smaller premutations can be transmitted. Intermediate or “gray zone” repeat sequences numbering between 45 and 54 may expand to premutation size across generations. **Due to the complexity of the inheritance of FMR1 premutations, all carriers should receive formal genetic counseling.** Issues that must be addressed include the risk for infertility and of early menopause, the risk for and implications of transmitting the premutation to the next generations, and the possibility that other family members may be affected, in a variety of ways, raising still other and obvious ethical concerns.

**All women with POF should be offered screening for the FMR1 premutation.** In sum, guidelines issued by the American College of Medical Genetics, the American College of Obstetricians and Gynecologists, and the American Society for Reproductive Medicine all recommend FMR1 testing for women with unexplained POF.<sup>59,180</sup> **There is consensus that testing should be offered to those having a family history of POF, FXS, or FXTAS or having relatives with unexplained mental retardation or autism. Additionally, screening merits consideration in women demonstrating evidence of diminished ovarian reserve.**<sup>181</sup> Arguments against more liberal or widespread population screening center on the limited resources available to provide the complicated counseling required and the uncertainties surrounding the risks associated with alleles in the intermediate range, which are common.

Up to 5–10% of women with POI who carry an FMR1 premutation will conceive after diagnosis, without medical intervention, but there is no evidence that any treatment

other than oocyte donation can increase the likelihood of pregnancy.<sup>162</sup>

## Autoimmune Disorders

Autoimmune disease is one of the known causes of POI, accounting for approximately 4% of cases.<sup>62,63,159,160</sup> There is substantial evidence to indicate that autoimmunity is the cause of POF in women who also exhibit signs of adrenal autoimmunity.<sup>62</sup> Autoimmune oophoritis may occur as part of a type I or II autoimmune polyglandular syndrome (APS) associated with autoantibodies to multiple endocrine and other organs. Type I APS (also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) presents in childhood, typically as hypoparathyroidism (89%) or mucocutaneous candidiasis (75%), and often is accompanied by adrenal insufficiency (60–80%) and POF (60%); the cause is a mutation in the AIRE (autoimmune regulator) gene, located on chromosome 21. Type II APS has an adult onset and is characterized by adrenal insufficiency (100%) and thyroid autoimmunity (70%) or type I diabetes (50%); 25% of women with the disorder have amenorrhea and 10% have POF.<sup>62</sup> POI also has been described in women with systemic lupus erythematosus and myasthenia gravis.

The mechanism that stimulates or causes ovarian autoimmunity is unknown, but might involve a virus or other cause of damage to ovarian tissue that renders it antigenic, or a basic failure in immune regulation resulting in a loss of tolerance to some component of ovarian tissue. The hallmark of autoimmune oophoritis is a lymphocytic infiltrate surrounding secondary and antral follicles but not primordial follicles,<sup>182,183</sup> strongly suggesting that steroid hormone-producing cells in the theca contain the inciting antigen. Observations of normal inhibin B production in otherwise hypogonadal women with autoimmune oophoritis further suggest that the theca is selectively targeted and that granulosa cells are spared.<sup>184</sup> Almost all women with documented autoimmune oophoritis have circulating antibodies directed against steroidogenic enzymes such as 21-hydroxylase, 17 $\alpha$ -hydroxylase, and side-chain cleavage.<sup>63,182</sup> The diagnosis of autoimmune ovarian failure therefore hinges on the demonstration of autoantibodies against steroidogenic cells. **A positive test for adrenal or 21-hydroxylase antibodies is sufficient to establish a diagnosis of autoimmune ovarian failure.** A commercially available serum antiovarian antibody test had a poor predictive value and an unacceptably high false-positive rate.<sup>185</sup> **Ovarian biopsy solely for diagnosis of autoimmune ovarian failure is unnecessary and is not recommended.** Whereas antibodies against membrane-bound receptors may cause diseases such as myasthenia gravis, the failure to detect antibodies against the FSH receptor in women with POF suggests they rarely, if ever, are the cause.<sup>186</sup> Women with autoimmune ovarian failure may develop large luteinized follicular cysts, possibly due to increased gonadotropin stimulation in response to impaired follicle development and function.<sup>184</sup>

**The strong association between autoimmune adrenal and ovarian failure justifies screening for antiadrenal antibodies in all women with POF, at the time of diagnosis.** The most sensitive and useful methods for their detection are indirect immunofluorescence assays using adrenal tissue as substrate and immunoprecipitation assays for antibodies against the 21-hydroxylase enzyme (CYP21). **Patients with positive antiadrenal antibodies should be further evaluated to exclude asymptomatic adrenal insufficiency, by measuring the morning (6:00–9:00 A.M.) serum cortisol level.** A value greater than 18 mg/dL effectively excludes clinical adrenal insufficiency; those with lower values require further evaluation with an ACTH stimulation test to determine whether ACTH reserve is sufficient to meet demand during times of stress. The test is performed by measuring the serum cortisol concentration before and 60 minutes after administering cosyntropin (synthetic ACTH 1–24; 0.25 mg) intramuscularly or intravenously; a stimulated cortisol concentration  $\geq 18$  mg/dL is a normal response. **Those with negative tests for adrenal antibodies should be followed and monitored with repeat testing at intervals, because POF may precede onset of adrenal insufficiency by up to several years and its autoimmune cause may not, at first, be recognized.**<sup>63</sup>

Other autoimmune disorders that may be identified in women with POI, such as autoimmune thyroiditis, rarely are associated with autoimmune oophoritis and therefore cannot be considered proof of autoimmune ovarian failure. **However, because the prevalence of thyroiditis is relatively high among women with POI (14–27%) and the presence of thyroid autoantibodies identifies patients at risk for developing autoimmune thyroid disease, screening for thyroid peroxidase and thyroglobulin antibodies is indicated when POI is suspected.** For patients screening positive for antithyroid antibodies, TSH levels should be monitored annually; for those testing negative, TSH surveillance can be less often (e.g., 5-year intervals). In the past, screening for other autoimmune endocrine disorders was recommended (serum calcium, phosphorus, fasting glucose, vitamin B<sub>12</sub>), but such screening has a very low yield in asymptomatic patients and can be safely reserved for those with clinical indications.<sup>64</sup>

## **Radiation Therapy**

The adverse effects of radiation on the ovary depend on the age of the patient, the dose of radiation, and the radiation field.<sup>187</sup> In young women, radiation therapy may result only in transient amenorrhea that ends after a period of 6–18 months, probably reflecting the interval required to reestablish the mechanisms that govern the initiation of follicular growth and the size of their follicular reserve. Transient suspension of normal ovarian cycling also has been observed in women who received radioactive iodine for the treatment of thyroid cancer.<sup>188</sup> However, some will suffer immediate and irreversible

ovarian failure, and even those who recover may later exhibit early ovarian aging and an early menopause. The ovaries of older women are more sensitive to the effects of radiation. Whereas doses greater than 6 Gy (gray units, 1 Gy = 100 rad) almost uniformly cause ovarian failure in women over age 40,<sup>189</sup> younger women have achieved successful pregnancies after having received far higher doses.

The radiosensitivity of human oocytes has been estimated at approximately 2 Gy, implying that approximately 50% of remaining oocytes will survive after such exposure.<sup>190</sup> Using the best available model for the rate of natural follicular depletion,<sup>191</sup> estimates for the mean and effective sterilizing doses of radiation (resulting in immediate and permanent ovarian failure in 50% and 97.5% of individuals, respectively) can be calculated. The mean age of subsequent ovarian failure also can be estimated for any given age and dose of radiation. Representative values derived from such calculations are shown in [Tables 10.2](#) and [10.3](#).<sup>192</sup>

## **TABLE 10.2 Patient Age and Radiation Dose are Both Relevant to the Magnitude of Gonadotoxic Insult Following Radiation Exposure**

Age at Treatment (y)	Sterilizing Dose (Gy)	
	Mean (50%)	Effective (97.5%)
0	18.8	20.3
10	17.0	18.4
20	15.0	16.5
30	12.0	14.3
40	8.0	11.3

**TABLE 10.3 Radiation Induced Ovarian Failure**

Age at Treatment (y)	Mean Predicted Age of Ovarian Failure (y)			
	3 Gy	6 Gy	9 Gy	12 Gy
0	35.1	22.6	13.7	7.9
10	36.7	26.5	19.7	15.3
20	39.0	31.4	26.4	22.8
30	42.2	37.0	33.2	30.1

When the radiation field excludes the pelvis, there is no significant risk for permanent ovarian failure.<sup>193,194</sup> Consequently, direct irradiation to the ovaries should be avoided whenever possible. Elective ovarian transposition (moving the ovaries out of the radiation field) can help to preserve gonadal function in patients receiving pelvic radiation without chemotherapy. It may be performed electively before radiation therapy begins or at the time of surgical staging or the primary cytoreductive surgery.<sup>187,195</sup> However, the success of ovarian transposition for preserving fertility after radiation therapy has varied widely, from 16% to 90%, due to differences in treatment regimens, exposure to scatter radiation, shielding, and adjuvant chemotherapy. The procedure also has potential complications, including chronic ovarian pain and cysts, which may require additional surgery. Subsequently, pregnancy also may be difficult to achieve spontaneously or even with IVF, unless the ovaries are moved back into the pelvis.<sup>196</sup> Other fertility preservation strategies that might be considered before radiation therapy include urgent IVF and embryo cryopreservation, oocyte cryopreservation, and ovarian tissue cryopreservation, as discussed in detail in [Chapter 29](#).

There is no evidence for an increased risk of birth defects in the offspring of women treated with radiation therapy, chemotherapy, or both.<sup>197</sup> However, the risk for pregnancy complications such as miscarriage, preterm labor, and low birth weight may be increased due to impaired uterine growth and blood flow.<sup>198,199,200</sup>

## **Chemotherapy**

Most chemotherapeutic drugs target actively dividing cells and therefore might not be expected to have significant adverse effects on oocytes; nonetheless, many do. In fact, the fixed supply of oocytes is extremely sensitive to cytotoxic drugs. **Chemotherapy causes depletion of the primordial follicular pool in a drug- and dose-dependent manner and is a relatively common cause of POI.**

The ovarian toxicity of common chemotherapeutic agents varies significantly.<sup>196,197</sup> Alkylating agents such as cyclophosphamide, which alters base pairs and causes DNA cross-links and breaks, can affect both resting and dividing cells. The risk for ovarian failure after chemotherapy increases with the age of the patient, presumably because the size of the residual follicular pool declines progressively with advancing age and the damage caused by treatment becomes proportionately greater. For example, a dose of cyclophosphamide that uniformly causes amenorrhea in women over age 40 does so in only about half of younger women.<sup>201</sup> However, individual women vary significantly in their sensitivity or susceptibility to gonadal damage from chemotherapeutic agents. The common use of more than a single drug further complicates efforts to predict the likelihood of ovarian failure resulting from treatment (Table 10.4).

### **TABLE 10.4 Chemotherapeutic Drugs Vary in Potential for Gonadotoxicity**

High Gonadal Toxicity	Moderate Gonadal Toxicity	Low Gonadal Toxicity
Cyclophosphamide	Cisplatin	Bleomycin
Chlorambucil	Adriamycin	Actinomycin D
Melphalan		Vincristine
Busulfan		Methotrexate
Nitrogen mustard		5-Fluorouracil
Procarbazine		Taxanes

It is important to note that a large majority of studies examining the effects of chemotherapeutic agents on ovarian function have used the incidence of amenorrhea, from as little as 6 months to as long as 5 years after completion of treatment, as the measure of impact. In recent years, gonadotoxic effects of chemotherapy and radiation therapy have utilized surrogate markers of “ovarian reserve” including serum levels of FSH, inhibin B, and AMH and ovarian antral follicle counts.<sup>202,203</sup> It is known that most women in the advanced stages of follicular depletion, due to aging or other causes, still menstruate even though the number and quality of their remaining oocytes and their fecundity are quite low.<sup>204</sup> Consequently, it seems certain that the amenorrhea rate associated with any given chemotherapeutic drug or combination grossly underestimates its true adverse impact on ovarian function and fertility. Indeed, observations derived from a few studies that have examined the effect of chemotherapy on markers of ovarian reserve (AMH in particular) suggest that chemotherapy induces accelerated ovarian aging and thereby increases the likelihood of POI well beyond the risk estimates based on observations of amenorrhea after the end of treatment.<sup>205,206,207</sup>

Long-acting GnRH agonists (GnRHa, e.g., leuprolide acetate) have been used widely to induce a hypogonadal state before chemotherapy in hopes to reduce or prevent the adverse effects of cytotoxic drugs on ovarian function and future fertility.

Protective effects of GnRHa-induced ovarian suppression against chemotherapy-induced gonadal damage were initially evident in experimental studies in animal models including nonhuman primates.<sup>208</sup> Subsequent studies including randomized controlled trials in women have corroborated that GnRH agonist pretreatment may offer some protection against chemotherapy-induced ovarian follicular depletion.<sup>209,210,211</sup> Overall, less than 10% of patients treated with a GnRH agonist before chemotherapy have developed irreversible POI, compared to 40–70% of those receiving similar treatment but no GnRH agonist. Some have suggested that, at the least, GnRH agonist pretreatment may widen or extend the “fertility window” by 7 years or more for patients who receive chemotherapy.<sup>209</sup> Several mechanisms have been proposed to explain the potential protective actions of GnRH agonists: (1) a decreased number of primordial follicles entering development (due to suppression of FSH), when they become more vulnerable to damage; (2) decreased ovarian perfusion induced by hypoestrogenism, resulting in lower exposure to chemotherapeutic agents; and (3) a direct effect on the ovary, independent of gonadotropins, such as up-regulation of an intraovarian antiapoptotic factor or protection of germline stem cells.<sup>209</sup> Moreover, advocates of GnRH agonist pretreatment have emphasized that it can decrease the risk of menorrhagia resulting from chemotherapy-induced thrombocytopenia and, at least in patients with hormone-sensitive breast cancers, also may improve survival rates.<sup>212</sup>

Questions concerning the value and even the safety of GnRH agonist chemoprophylaxis have stimulated an active and ongoing debate. Despite the accruing evidence supportive of clinical benefit, many have challenged the biologic plausibility of the proposed protective mechanisms and raised concerns that the initial “flare” in gonadotropin secretion that follows GnRH agonist treatment may have effects opposite from those intended. Those who oppose GnRH agonist pretreatment argue that the return of menses after chemotherapy is an insensitive and unreliable measure of protection from drug-induced ovarian injury,<sup>213</sup> that the sustained decrease in serum AMH levels that follows chemotherapy indicates a loss of primordial and preantral follicles (the primary source of AMH),<sup>207</sup> and that GnRH agonist treatment cannot protect against damage from cytotoxic drugs because primordial and preantral follicles are not sensitive to gonadotropin stimulation.<sup>214</sup> Lacking benefit of prechemotherapy, ovarian suppression with GnRHa on ovarian function has also been evident in other studies, raising concerns regarding potential for unequivocal benefit.<sup>215</sup> The safety of GnRH agonists has also been questioned because many tumors of the breast and reproductive tract express GnRH receptors mediating actions that might reduce the efficacy of chemotherapy or promote an even greater loss of follicles.<sup>216,217,218,219</sup> Finally, treatment with a GnRH agonist can be expected to induce acute symptoms of estrogen deficiency, in addition to those that invariably result from chemotherapy, thereby adding to the

overall burden of treatment. Ultimately, more confident conclusions regarding the relative risks and benefits of GnRH agonist pretreatment must await the results of a number of ongoing clinical trials being conducted by the Southwest Oncology Group in the United States and by others in Germany, Italy, Spain, and the United Kingdom.

## **Galactosemia**

Galactosemia is an autosomal recessive disorder of galactose metabolism caused by a deficiency of the enzyme GALT and is another, albeit very rare, cause of POF.<sup>220</sup> Affected women have fewer primordial follicles, presumably due to the cumulative toxicity of galactose metabolites on germ cell migration and survival.<sup>221,222</sup> Diagnosis usually is made in the first few days of life after feeding with breast or cows' milk-based formulas begins, causing jaundice, vomiting, and failure to thrive.

## **Functional Ovarian Failure Resulting from Disorders of Follicular Development**

Whereas accelerated follicular depletion is the underlying mechanism for the most common causes of POI, a variety of rare genetic disorders causing impaired or abnormal follicular development may result in a functional ovarian failure. Examples include disorders of intraovarian regulation, steroidogenic enzyme defects, and abnormalities in gonadotropins and their receptors. In 1969, Jones and de Moraes-Ruehsen described three patients with amenorrhea and hypergonadotropic hypogonadism who also were resistant to high doses of exogenous gonadotropins, although their ovaries contained numerous follicles. They called the disorder "resistant ovary syndrome" or "Savage syndrome," after the name of their first patient.<sup>223</sup> It now seems likely that the resistant ovary syndrome results from intrinsic defects in follicular development.

Abnormalities in any of the many identified paracrine regulators of ovarian function may interfere with or prevent a normal response to gonadotropin stimulation. For example, mutations in the gene encoding bone morphogenetic protein-15 (BMP15), an oocyte-specific growth factor that stimulates folliculogenesis and granulosa cell proliferation (in the same family that includes activins and inhibins), have been identified in a small number of women with idiopathic POF. In functional assays, the mutant BMP15 was processed abnormally, associated with decreased granulosa cell growth, and antagonized the stimulation of granulosa cell proliferation by wild-type BMP15.<sup>224</sup> In a study of women with POF who underwent genetic screening, 7/166 (4%) having heterozygous mutations in BMP15 were detected, compared to none in control groups containing women who had a natural menopause or women randomly selected from the general population.<sup>225</sup> The blepharophimosis/ptosis/epicanthus

inversus syndrome (BPES) is another example. BPES is a rare autosomal dominant disease characterized by eyelid malformations and POF, caused by a variety of mutations in the gene encoding a forkhead box transcription factor (FOXL2) required for normal granulosa cell function.<sup>226</sup>

Rare steroidogenic enzyme defects that effectively block follicular development may result in hypergonadotropic hypogonadism due to functional ovarian failure. Mutations in the genes encoding the steroidogenic acute regulatory (StAR) enzyme (STAR), the 17 $\alpha$ -hydroxylase enzyme (CYP17A1), and the aromatase enzyme (CYP19A1) are examples. The StAR enzyme transports cholesterol from the outer to the inner mitochondrial membrane where the side-chain cleavage enzyme converts cholesterol to pregnenolone, the first and rate-limiting step in steroid biosynthesis; StAR mutations thus result in impaired synthesis of all adrenal and gonadal steroid hormones. Affected individuals present with congenital lipoid adrenal hyperplasia and exhibit severe adrenal insufficiency soon after birth or in early infancy; those who are recognized and treated early have absent pubertal development.<sup>227</sup> Females with 17 $\alpha$ -hydroxylase deficiency, involving the enzyme complex that converts 21-carbon progestogens to 19-carbon androgens, usually present around the expected time of puberty with primary amenorrhea and sexual infantilism. Elevated levels of progesterone (the hormone immediately proximal to the enzyme block) are alternatively converted to mineralocorticoids (deoxycorticosterone, corticosterone), resulting in hypertension and hypokalemia. Those having a partial or less severe 17 $\alpha$ -hydroxylase deficiency may exhibit varying degrees of sex steroid production and sexual development.<sup>228</sup> Rare females with aromatase deficiency, involving the enzyme that converts androgens to estrogens, classically present with ambiguous genitalia at birth, elevated androgen levels, and absent breast development at puberty. During pregnancy, fetal androgens cannot be aromatized to estrogen in the placenta, resulting in masculinization of both the fetus and mother. Aromatase mutations also can produce variable or nonclassic phenotypes characterized by varying degrees of breast development.<sup>229</sup>

Inactivating mutations in the  $\beta$  (beta)-subunit of LH or FSH can result in abnormal gonadotropin molecules having limited or no immunoreactivity or bioactivity. Affected individuals are hypogonadal and have a high level of one (the normal) gonadotropin, but a basal or undetectable level of the other.<sup>230,231</sup> Inactivating mutations in the FSH or LH receptor may result in a failure of gonadotropin binding or signal transduction and thus again in hypergonadotropic hypogonadism due to a failure of follicular development.<sup>232</sup> One specific point mutation in the FSH receptor has a relatively high gene frequency in the Finnish population (0.96%).<sup>233,234</sup> A search for the same mutation among women with POF in the United States, Brazil, Switzerland, Denmark, Japan, and Singapore

found only a single carrier,<sup>235,236,237,238</sup> but other inactivating mutations have been identified.<sup>239,240</sup> A few women with similar mutations in the LH receptor have been described, presenting with amenorrhea, enlarged cystic ovaries, and a high serum LH but normal FSH concentration.<sup>241,242</sup>

## Management of Premature Ovarian Insufficiency

**It is important to emphasize that effective management of POI requires careful counseling and emotional support, as well as specific evaluation and medical treatment.** Young women with POI understandably are not prepared for the diagnosis, and many are dissatisfied with the manner in which they were informed.<sup>243</sup> Affected women need, and deserve, sufficient time for thorough education and for planning their longer-term management.

Attention should focus first on excluding those causes of POI having important potential health consequences for the patient or other members of her family. Those with chromosomal translocations or deletions or fragile X premutations should receive appropriate genetic counseling, and those with autoimmune disease will require careful monitoring over time to ensure that emerging and potentially serious health problems are promptly recognized and treated.

### Hormone Therapy

The short-term as well as longer-term management of women with POI centers on their hypogonadism and its sequelae. In the absence of exogenous estrogen treatment, women with POI are at a real risk for developing skeletal fragility due to low bone mass.<sup>244,245,246</sup> In the absence of hormone therapy, hypoestrogenism of POI is similarly implicated in predisposing this population to early coronary heart disease.<sup>247,248,249,250,251</sup> Inevitably, they also will develop symptoms of estrogen deficiency such as vasomotor flushes and genitourinary atrophy that can be debilitating. Therefore, unless there is a specific contraindication to its use, timely initiation of exogenous estrogen-based hormone therapy is of pivotal importance in the management of women with POI. Other strategies for protecting bone and heart health also deserve discussion, including regular exercise, diet, adequate calcium and vitamin D intake, stress reduction, and the avoidance of smoking.

Estrogen treatment in women with POI can take several forms. An increasing number of estrogen formulations are available for oral, transdermal (patch, gel, spray), and vaginal (creams, pessaries, tablets, rings) use. Physiologic levels of estrogen and symptom relief can be achieved in the majority using oral (e.g., micronized estradiol 1–2 mg daily or conjugated equine estrogens 0.625–1.25 mg daily) or transdermal

estrogen regimens (0.1 mg/24 hours).<sup>252</sup> Attention to concepts of hormonal formulation, dose, and route and hormonal regimen merits attention given that estrogen requirements to achieve symptom benefit in young women with POI may be higher when compared to older menopausal women.<sup>253,254,255</sup> Because most women with POF have an intact uterus, cyclic or continuous treatment with a progestogen is essential to prevent endometrial hyperplasia and neoplasia that can result from treatment with estrogen alone.<sup>256</sup> Cyclic treatment with a progestogen (e.g., micronized progesterone 200 mg daily or MPA 10 mg daily for 12–14 days each month) is preferable for those still hoping to conceive. Oral contraceptives also may be used to achieve symptomatic relief. However, the menopausal estrogen formulations are suggested to be superior to the synthetic ethinyl estradiol containing contraceptive formulations in conferring skeletal benefit.<sup>257</sup> Contraceptive hormonal regimens may thus be reserved for those who want to prevent even the possibility of random ovulation and pregnancy. **It is important to emphasize to young women with POF that they are distinctly different from older postmenopausal women and that the balance between the risks and benefits of hormone therapy for them also differs from that in postmenopausal women.** Because they are significantly younger, their baseline risks for cardiovascular disease and breast cancer are much lower than those for older postmenopausal women. In women with POI, timely initiation and use of estrogen therapy may actually reduce the risk of coronary heart disease and of all-cause mortality, whereas without estrogen therapy, their risk for later coronary heart disease is increased.<sup>248,249,250,251,255</sup> Estrogen-based hormone therapy should continue up to at least the age of 50, in much the same way as endogenous hormone production does in normal women.

Ovarian androgen levels (testosterone, androstenedione) may be somewhat lower in women with POI than in normal women of comparable age,<sup>258,259,260</sup> although in most they are maintained at least to the same extent as in normal postmenopausal women. Currently, there are no established criteria for diagnosis of androgen deficiency, and there is no approved or validated method for providing physiologic androgen treatment in women.<sup>255,261</sup> Moreover, exogenous androgen treatment may cause acne and hirsutism and, when administered orally, dyslipidemia. The longer-term clinical consequences of reduced androgen levels, if any, have not been studied, and the safety of long-term androgen treatment has not been established. Consequently, androgen treatment cannot be recommended for women with POF.

**Fertility** Although the likelihood of achieving pregnancy after diagnosis is only about 5–10%, some women with POF do conceive and approximately 80% of their pregnancies end in a healthy live birth.<sup>162</sup> **However, there is no evidence that any form of treatment other than donor egg IVF can increase the chance for pregnancy.**

Intermittent or episodic ovulation is by no means rare in women with POI. Serial blood sampling and transvaginal ultrasonography can demonstrate residual and even developing follicles, but disordered patterns of folliculogenesis frequently are observed and premature luteinization, possibly a consequence of elevated LH levels, is common.<sup>262</sup> Evidence indicates that physiologic exogenous estrogen therapy allows, but does not improve, follicular development or ovulation.<sup>263</sup> Although ovulation induction with exogenous gonadotropins often has been attempted, women with established hypergonadotropic hypogonadism are, for obvious reasons, poor candidates. Attempts to improve ovulation rates achieved with gonadotropin therapy by pretreatment with estrogen or a GnRH agonist have met with some limited success,<sup>263,264,265,266</sup> but pregnancy and live birth rates remain extremely low. Recent decades have witnessed increasing utilization of oocyte and embryo donation strategies for family building by a diverse group of populations including women with POI, who are excellent candidates for IVF using donor oocytes.<sup>267</sup> Attempts at harnessing the therapeutic potential of ovarian stem cells and at in vitro activation of residual gametes within POI ovaries are emerging frontiers in the field of reproductive medicine.<sup>268,269,270</sup> It has long been known that unlike naturally menopausal women, residual but arrested ovarian follicles exist in ovaries of women with POI. Recent data offer tantalizing hope for harnessing the procreative potential of these residual oocytes in POI ovaries through a sequence of steps that include surgical collection of ovarian tissue followed by in vitro activation of the AKT pathway that allows activation of the few dormant follicles that are present within the ovarian cortex; the activated ovarian tissue is then retransplanted followed by ovarian stimulation and IVF.<sup>270</sup> Refining of the methodology and establishment of safety are needed before this promising technologic advancement can be adopted in routine clinical care of POI patients.

## **Psychological and Emotional Support**

Profound grief and a sense of loss for the children they hoped for and expected are common in women after diagnosis of POF; validating those emotions can be both therapeutic and reassuring. It also is important to emphasize that the diagnosis of POF does not imply or predict premature aging in any other way, something that many women understandably may fear. Women with POF also are at risk for developing related depression and anxiety disorders.<sup>243,271</sup> Consequently, referral to a support group ([www.pofsupport.org](http://www.pofsupport.org)) and to a therapist having expertise in counseling women and couples with reproductive failure can be very helpful.

# Disorders of the Anterior Pituitary

A variety of disorders involving the anterior pituitary may be a cause of amenorrhea. Pituitary tumors are the most common by far and the majority of these are benign adenomas; in a large transsphenoidal surgical series, 91% of sellar and parasellar masses were pituitary adenomas.<sup>272</sup> Malignant pituitary tumors are almost never encountered. Other tumors that may arise in the sellar region include craniopharyngiomas, meningiomas, gliomas, metastatic tumors, and chordomas. Not all sellar masses are neoplastic<sup>273</sup>; cysts, tuberculosis, sarcoidosis, and fat deposits that compress the pituitary have been reported. Nearby lesions, such as internal carotid artery aneurysms, by compressive effects on the adjoining pituitary gland and the resident endocrine cells, and/or the pituitary stalk, can interfere with the delivery of hypothalamic releasing or inhibiting factors; the net effect is of functional disruption of the pituitary hormonal axis as a mechanism for amenorrhea.

Other pituitary causes of hypogonadotropic hypogonadism include damage from surgery or radiation, ischemia and infarction (e.g., Sheehan syndrome), and infiltrative diseases such as lymphocytic hypophysitis and hemochromatosis.

## Pituitary Adenomas

Pituitary adenomas are true neoplasms that are almost always benign. The large majority are monoclonal, suggesting that somatic cell mutations precede clonal expansion and play an important role in tumorigenesis.<sup>274,275</sup> Specific genetic mutations are known to be involved in the development of some pituitary tumors. Autosomal dominant inactivating mutations in the MEN1 gene (encoding menin, a putative tumor suppressor) predispose to the development of parathyroid, pituitary, and enteropancreatic adenomas (insulinomas, gastrinomas, carcinoid tumors) in patients with one of the multiple endocrine neoplasia (MEN) syndromes (type 1).<sup>276</sup> Activating mutations in the GNAS1 gene (encoding the stimulatory G-protein alpha subunit involved in the signal transduction pathway that links receptor-ligand interactions with activation of adenylyl cyclase) are identified in approximately 40% of GH secreting somatotroph adenomas.<sup>277</sup> The pituitary tumor transforming gene (PTTG1) is overexpressed in most all pituitary adenomas and, to an even greater degree, in those that extend outside of the sella.<sup>278</sup>

Pituitary adenomas are classified by cell type and size and may be functional (hormone-secreting) or nonfunctional. The large majority of pituitary adenomas are either functional prolactin-secreting lactotroph adenomas or nonfunctional adenomas, most of which derive from the gonadotrophs. Functional thyrotroph adenomas (secreting TSH and causing hyperthyroidism), somatotroph adenomas (secreting GH and causing

acromegaly), and corticotroph adenomas (secreting ACTH and causing Cushing disease) are rare, particularly in women presenting with amenorrhea. If large enough, even the nonfunctioning adenomas can have functional consequences, by compressing the pituitary stalk and interfering with the delivery of hypothalamic releasing or inhibiting factors or by compressing the surrounding cells. Tumors less than 10 mm in size are called microadenomas and those 10 mm or larger are called macroadenomas. Pituitary adenomas may be discovered during evaluation for neurologic symptoms or symptoms attributable to hormone imbalance (e.g., prolactinomas are often diagnosed during workup for menstrual irregularities including amenorrhea) or when the head is imaged for other reasons (such as following head trauma). MRI (with gadolinium contrast) is the best radiologic method for imaging the pituitary gland and surrounding region and may reveal tumor extending outside of the sella, into the cavernous sinuses or sphenoid sinus, or causing elevation of the optic chiasm.

The most common neurologic symptom associated with pituitary tumors, in particular macroadenomas, is visual impairment. The classical complaint is of bitemporal hemianopsia (tunnel vision), caused by upward pressure on the optic chiasm at its center (affecting those portions of the optic nerves correlating with the nasal retinas and the temporal visual fields); however, one or both eyes may be affected and to varying degrees. Decreased visual acuity develops with more severe compression of the chiasm, and diplopia (blurred vision) results from lateral extension and compression of the oculomotor nerve. The onset of visual symptoms is so gradual they often go unrecognized for months or years. Other neurologic symptoms include nonspecific headaches (from expansion of the sella), cerebrospinal fluid rhinorrhea (from inferior extension of the tumor), and pituitary apoplexy (caused by sudden hemorrhage into the adenoma).

The endocrine consequences of pituitary adenomas depend on whether they are functional or nonfunctional and on their size. Functional microadenomas and macroadenomas secrete excessive amounts of hormone, according to their specific cell type, and cause symptoms that result from overstimulation of the target organ or tissues, as discussed below. Functional and nonfunctional macroadenomas also may cause pituitary hormone deficiencies, due to their mass effects on the pituitary stalk and surrounding cells. Whereas gonadotropin deficiency results in symptoms of hypogonadism such as amenorrhea and vaginal atrophy, the symptoms of TSH deficiency are those of hypothyroidism and include fatigue, lethargy, cold intolerance, decreased appetite, constipation, dry skin, bradycardia, and anemia. Symptoms of GH deficiency vary based on timing of occurrence; GH deficiency in children causes short stature, whereas in adults, GH deficiency is often subtle, often with tiredness and an overall reduced sense of well-being as the only manifestations. Less manifest features of GH deficiency in adults include decreased muscle mass and increased fat mass,<sup>279,280</sup>

decreased bone mineral density,<sup>281</sup> and an increased risk for cardiovascular disease.<sup>282,283</sup> Prolactin deficiency has no known symptoms other than failure to initiate and establish lactation after delivery. The symptoms of ACTH deficiency are those of cortisol deficiency and include postural hypotension and tachycardia, fatigue, anorexia, weight loss, hypoglycemia, and eosinophilia. Whereas primary adrenal insufficiency (due to abnormalities involving the adrenal glands) also results in salt wasting, volume contraction, and hyperkalemia resulting from aldosterone deficiency and hyperpigmentation due to the compensatory increase in pituitary ACTH secretion, secondary adrenal insufficiency (as occurs due to defective function of the pituitary adrenocorticotrophs with resulting ACTH deficiency) does not. Both primary and secondary adrenal insufficiencies can cause hyponatremia due to inappropriate secretion of antidiuretic hormone (ADH) (vasopressin), which results from cortisol deficiency. **Moderate deficiencies of TSH, GH, and ACTH often cause few or no recognizable symptoms and easily can go unrecognized if not suspected and specifically excluded through targeted testing.**

## **Pituitary Function Tests**
