---

# CONCLUSION

---

The menopause is a physiologic event that brings clinicians and patients together, providing the opportunity to enroll patients in health maintenance. The failure to respond appropriately (by either clinician or patient) easily leads to a loss of the patient from a practice, but equally, if not more, importantly, is the probability that the loss of a patient from a practice means that another woman has lost her involvement in a preventive health care program. Menopause must not be perceived as a signal of impending decline, but, rather, is a new chapter in life that is to be welcomed and better planned to ensure good health and optimal well-being in the years ahead.

# Transgender Endocrinology

Individuals whose perception of their own gender identity, or those whose preferred gender self, differs from their natal (assigned at birth) sex are classified as transgender (TG). The existence of TG individuals has been recorded from the earliest civilizations, dating back to 1503 B.C. when Queen Hatchepsut dressed as a male and donned a fake beard during her Egyptian rule, preferring the title of King.<sup>1</sup> The 20th century, with broadening management options (medical and surgical) and an increasing interest in the underpinnings as well as sequelae of gender incongruence, can be recognized as a turning point for TG individuals. Magnus Hirschfield and Harry Benjamin, both considered as pioneers in the field, described transgenderism; they advocated for patients who sought relief from their distress by choosing to live according to their perceived gender.<sup>2,3</sup> With the addition of testosterone and diethylstilbestrol in the therapeutic armamentarium in the 1930s, hormonal treatment became a realistic option for TG individuals.<sup>4,5,6</sup> Gender-affirming surgery was similarly being explored and experimentally attempted in Europe as early as the 1930s; however, it was not until the late 1960s that gender reassignment surgery was successfully attempted in the United States.<sup>3,7</sup>

In 2010, one in five TG adults reported being denied medical treatment, harassed, or disrespected by a health care provider.<sup>8</sup> Although more health insurance programs are now offering medical coverage for TG services, this group continues to be underserved and discriminated against in the medical community.<sup>9</sup> In recent years, reputable professional societies such as The Endocrine Society and the World Professional Association for Transgender Health (WPATH) have taken the lead in establishing and promoting standard clinical guidelines for the management and treatment of TG populations.<sup>3,10</sup>

# NOMENCLATURE

---

Historically, the term “transsexual” was used to describe individuals whose gender identity did not align with their birth sex and their preference to utilize assistance to achieve transition from natal to their desired sex. However, it must be noted that not all TG persons wish to “transition.” Additional terms that, although often used interchangeably, are distinguishable include gender dysphoria, gender nonconforming, or gender incongruent. The clear difference between gender dysphoria and gender incongruent or gender nonconforming is that persons with “dysphoria” have clear discomfort or distress due to the inability to express their true gender identity. Since the terminology is rapidly evolving, a table of the common terms is presented to familiarize readers with the common nomenclature (Table 18.1). **The spectrum of nomenclature holds an important concept—that a person’s gender identity is not necessarily binary (male or female).** There are individuals that at any stage of life may relate to different points on the spectrum or may never associate with any particular gender.

## TABLE 18.1 Commonly Used Terminology

Terminology	Definition
Cisgender	Term used for people who identify with their sex designated at birth
Disorders of Sex Development (DSD)	Congenital conditions in which development of the chromosomal, gonadal, or anatomic sex is atypical
Gender	Personal perception of how he/she sees himself/herself
Gender Dysphoria	Discomfort or distress that is caused by a discrepancy between a person's gender identity and that person's sex assigned at birth
Gender Expression	External manifestation of gender, expressed through one's name, pronouns, clothing, haircut, behaviors, and vice and body characteristics
Gender Identity	A person's intrinsic sense of being male, female, or an alternative gender (i.e., eunuch, genderqueer, pangender, gender fluid, or a gender)
Gender Identity Disorder	Term used for gender dysphoria/gender incongruence in previous versions of the <i>Diagnostic Statistical Manual of Mental Disorders</i> , 4th ed., Text Rev (DSM IV-TR) <sup>16</sup>
Gender Incongruence	Categorical term used when the gender identity and/or gender expression differs from what is typically associated with the designated gender
Gender Nonconformity	Extent to which a person's gender identity or expression differs from the cultural norms for the particular gender
Sex	Biologic phenotype present at birth (male, female)
Transgender	Umbrella term for people whose gender identity and/or gender expression differs from what is associated with their sex designated at birth
Transgender Female (Transwoman, Male to Female, MTF, Transgender Woman)	Used to describe an individual assigned male at birth but who identifies and lives as a female
Transgender Male (Transman, Female to Male, FTM, Transgender Man)	Used to describe an individual assigned female at birth but who identifies and lives as a male
Transsexual	Historic term used to refer to individuals who have permanently transitioned through medical interventions or have a desire to do so

Data from **Hembree WC, Cohen-Kettenis PT, Gooren L, Hannema SE, Meyer WJ, Murad MH, Rosenthal SM, Safer JD, Tangpricha V, T'Sjoen GG**, Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society Clinical Practice guideline, *J Clin Endocrinol Metab* 102(11):1–35, 2017; **World Professional Association for Transgender Health**, Standards of care for the health of transsexual, transgender, and gender nonconforming people. # PREVALENCE

---

Estimates on the population prevalence of TG individuals have been fraught with error, given the likely underreporting based on social and cultural stigma. In 2016, it was estimated that 0.6% of adults in the United States, or 1.4 million individuals, were identified as TG.<sup>12</sup> Western European studies suggest a 3 to 1 ratio of transgender females (TGF, or natal male with preferred female sex) to transgender males (TGM, or natal female with preferred male sex). This ratio however cannot be generalized beyond Western Europe given that different cultures have varying levels of tolerance for TG individuals, with resulting barriers for TGs to fully express themselves.<sup>13,14</sup> The number of TG individuals has been steadily increasing; however, it is likely that the incidence has not changed, but rather, social acceptance has contributed to a willingness to identify as TG.<sup>15</sup> Differences by age also exist, with younger adults being more likely to identify as TG compared to older adults. In the United States, an estimated 0.7% of adults between ages 18 and 24 years, 0.6% of adults of ages between 25 and 64, and 0.5% of adults 65 years and older identify as TG.<sup>12</sup>

# **BIOLOGIC DETERMINANTS OF GENDER IDENTITY**

---

# Hormones

Gender identity and gender expression likely involves a complex relationship of biologic, environmental, and cultural factors. In an effort to comprehend gender identity, studies on patients with disorders of sexual development (DSD) have been used as a model to further understand the relevance of both phenotype and the hormonal milieu on gender identity.

Gender ambiguity or feminization of external genitalia in genetic males from androgen synthesis disorders such as 5 $\alpha$ -reductase-2 (5 $\alpha$ -RD-2) and 17 $\beta$ -hydroxysteroid dehydrogenase-3 (17 $\beta$ -HSD-3) deficiencies is well described, and these individuals are commonly raised as females.<sup>17</sup> In the case of 5 $\alpha$ -RD-2 deficiency, depending on the severity of the enzymatic deficiency, the degree of testosterone conversion to the more potent androgen dihydrotestosterone may be compromised, which can result in varying levels of inadequacies in masculinization of the external genitalia. The spectrum of DSD seen in 5 $\alpha$ -RD-2-deficient patients ranges from complete feminization to varying degrees of ambiguity of genitalia in a genetic male. In these cases, testosterone-mediated neurocognitive modulation of the brain is unaffected as testosterone levels, and signals to nonsexual organs are intact. In contrast to 5 $\alpha$ -RD-2 deficiency, those with 17 $\beta$ -HSD-3 deficiency are exposed to in utero testosterone deficiency.<sup>17</sup> If prenatal androgen exposure is critical for gender identity, then genetic males with 5 $\alpha$ -RD-2 deficiency who are exposed to normal testosterone levels in utero should identify as male regardless of the anatomy of their external genitalia. However, gender role changes from female to male were seen in only 56–63% of individuals with 5 $\alpha$ -RD-2 deficiency and in 39–64% of 17 $\beta$ -HSD-3-deficient individuals.<sup>17</sup> These findings raise doubts regarding the potential role of prenatal brain exposure to androgens as the only major contributor to gender identity development.

In genetic females (46, XX) with gender ambiguity, such as those with congenital adrenal hyperplasia (CAH), there is typically an excess of prenatal androgen exposure (discussed in detail in [Chapter 13](#)). Interestingly, although studies have shown that this exposure to excess androgens during fetal development may predispose to masculinization of human behavior, data are inconclusive regarding whether 46, XX patients with CAH have a higher propensity to suffer from gender dysphoria.<sup>18,19</sup> A review of 263 genetic females with CAH examined the prevalence of gender dysphoria in this population; while the large majority, 94.8% (n = 250), did not manifest any gender identity issues, 5.2% (n = 13) of these genetic females manifested evidence of gender dysphoria; this prevalence is higher than seen in the general population.<sup>20</sup> In a cross-sectional study of twenty-two 46, XX CAH patients with ambiguous genitalia, 3 were reared as males and 19 as females. Among the 19 female patients, 17 (89.5%) were found to have no evidence of gender dysphoria using the Gender Identity/Gender

Dysphoria Questionnaire, and 2 of the 3 males also did not show any dysphoria.<sup>21</sup> These studies clearly indicate that more factors are involved in gender expression than simply prenatal hormone exposure.

In contrast to the DSD cases previously mentioned, Reiner and Gearhart studied 16 genetic males (46, XY) with cloacal exstrophy, a complex pelvic defect occurring during embryogenesis which presents with structural anomalies to the lower abdominal wall and includes phallic absence or inadequacy (no hormonal aberrations).<sup>22</sup> Fourteen of the 16 subjects with cloacal exstrophy were assigned female sex at birth due primarily to the appearance of their external genitalia.<sup>3,22</sup> The 16 genetic male subjects, who ranged in age from 5 to 16 years of age, were assessed on their sexual role and sexual identity via questionnaires. Interestingly, 8 of the 14 patients (57.1%) assigned female identity identified as male, whereas the two cases assigned male at birth maintained a male identity.<sup>14,22</sup> Since these individuals have intact androgen exposure and only manifest structural defects, one would expect that all individuals would identify as male. These findings again underscore the concept that there is a complex relationship involved in gender identity that encompasses more than simply hormonal predisposition.

Lastly, physiologic differences among trans- and cisgender persons have been examined without any supportive evidence to this end. Circulating levels of sex hormones are comparable between untreated TG and cisgender individuals.<sup>3,23</sup>

# Structural Determinants

The brain is known to have several regions that differ in organization between men and women.<sup>24,25,26</sup> In particular, postmortem studies evaluating the brain structures of TG individuals have found changes in the central subdivision of the bed nucleus of the stria terminalis (BSTc). BSTc is a limbic structure that plays an important role in controlling autonomic, neuroendocrine, and behavioral responses. This region is of particular interest since it is sexually dimorphic and its size and cell number have been related to gender identity.<sup>24</sup> Chung et al. studied the BSTc of 50 brains from individuals who ranged in age from prenatal to adult life.<sup>24</sup> The divergence of BSTc was not shown to occur prenatally or neonatally.<sup>24</sup> Interestingly, the region's volume appears to become sexually dimorphic after puberty with significant changes seen continuing into adulthood.<sup>24</sup> Although these findings may help explain the phenomenon of new onset gender dysphoria manifesting in adolescents at puberty, there are others who acknowledge a strong sense of gender incongruence since childhood. In a separate study, the brains of six TG females were evaluated and found that the size and staining of the BSTc were within female range, whereas the one TG male had a BSTc within male range.<sup>27,28</sup> In contrast, the cisgender males and females all had BSTc characteristics consistent with their respective gender.<sup>27,28</sup> The differences in BSTc staining seen among TG patients were independent of sex hormone utilization or sexual orientation. Given the few studies and small sample sizes, more research is clearly needed to clarify our understanding if regional brain anatomy holds a causative relevance for gender identity.

# Genetics

To date, there have not been any specific genes associated with TG individuals. However, twin studies have suggested a possible genetic link.<sup>3,29,30</sup> In a case series by Heylens et al., the investigators found a 39.1% concordance rate for gender disorders in 23 monozygotic male and female twin pairs, but no concordance was detected among the 21 same-sex dizygotic or seven opposite-sex twin pairs.<sup>30</sup> Gómez-Gil et al. studied nontwin siblings of 995 TG individuals to evaluate the co-occurrence of gender identity disorder.<sup>31</sup> Of the 2,527 siblings, 12 (1:211) were also TG, suggesting that while the likelihood is slim, biologic siblings of persons with gender identity disorder have a higher risk than the reported prevalence in the general population.<sup>31</sup>

# Environment

Theories regarding the role of the environment and child-rearing in forming one's gender identity have been suggested, although there is little evidence to support this conjecture.<sup>32</sup> Environmental endocrine-disrupting hormones may have a role, but this theory has not been adequately investigated.

In summary, an individual's gender identity likely involves multiple interrelating factors of which there currently are many unknowns. More studies are clearly needed to better grasp the possible and plausible mechanisms that can explain the spectrum of prevalent gender identities.

# TRANSGENDER HEALTH AND WELLNESS

A multidisciplinary team approach has been the cornerstone to the medical management and treatment of TG persons. In the past, such individuals were often underserved due to limited medical resources, social stigma, and provider inexperience. Due to the complexity of medical issues that TG patients often endure, each provider on the team serves a critical role during the transition process. The managing team composition can vary depending on the needs and goals of the TG individual (Table 18.2). An integral role of reproductive endocrinologists on the team is increasingly recognized given the breadth and depth of their expertise; reproductive endocrinologists can assist with gender-affirming hormonal therapy, offer timely counseling on issues of fertility, offer fertility preservation options, as well as provide general gynecologic care.

**TABLE 18.2 Multidisciplinary Team Approach to Transgender Care**

Mental Health Provider	Diagnose gender dysphoria/gender incongruence, and provide support and guidance throughout transition particularly with social and interpersonal interactions.
Primary Care Provider	Coordinate and treat any underlying medical concerns and ensures routine health screening for all remaining birth sex organs, assist with hormone management.
Endocrinologist	Provide hormone management regimens for the preferred gender, while suppressing natal hormones.
Gynecologist	Provide medical and surgical support for all gynecologic needs.
Urologist	Provide medical and surgical support for all urologic needs.
Reproductive Endocrinologist	Counsel on reproductive cryopreservation options, treat with assisted reproductive techniques if needed, assist with hormone management.
Plastic Surgeon	Perform gender-affirming and cosmetic surgeries in accordance with patients' preferred gender.
Speech Therapist	Assist with voice training in congruence with preferred gender.
Dermatology/Aesthetician	Perform electrolysis or laser hair removal on unwanted facial/body hair for transgender females.

# Mental Health

The TG community has a unique set of mental health issues as these persons often endure victimization, discrimination, and physical violence due to their perceived differences. A higher likelihood of concomitant psychological conditions (e.g., anxiety, depression) is well described in TG individuals.<sup>33,34</sup> In the United States alone, nearly 41% of adult TG individuals have attempted suicide in their lifetime, an occurrence that is strikingly higher than the 4.6% attempted suicide rate that is reported for the overall U.S. population.<sup>35</sup>

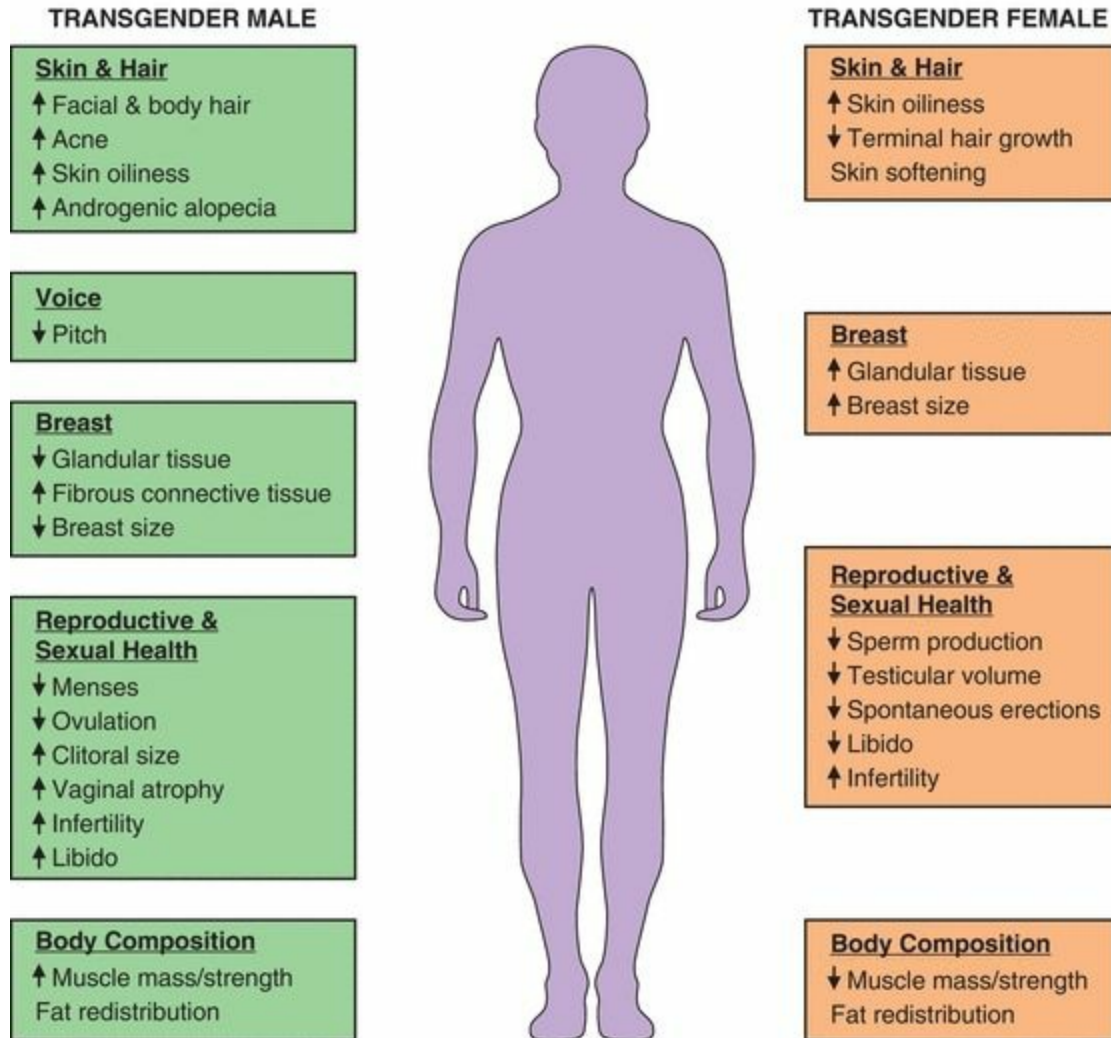

Participation of a trained mental health provider (MHP) is critical to any team approach to TG health care. The MHP participating in TG care must (1) be trained in diagnosing gender dysphoria and/or gender incongruence, (2) be familiar with using the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) or the World Health Organization International Statistical Classification of Disease and Related Health Problems (ICD) for diagnostic purposes, and (3) be able to distinguish gender dysphoria and gender incongruence from other psychiatric conditions that may have similar features (e.g., body dysmorphic disorder).<sup>36,37</sup> The MHP should also be able to educate and provide guidance for a patient wishing to transition into his/her desired gender. Lastly, the MHP should be qualified to assess the person's psychosocial needs and be able to refer the person for further treatment (hormone therapy, surgery) when deemed appropriate. The need for participation of a MHP is evident at the earliest stage of evaluation and should be prioritized to remain available through the life journey of a TG individual.<sup>35</sup>

# GENDER-AFFIRMING HORMONE THERAPY IN MANAGEMENT OF ADULT TRANSGENDER PATIENT

---

One of the key components of the gender transition process involves the initiation of gender-affirming hormone treatment. For many TG individuals, consideration of hormone therapy is the first step toward aligning their physical appearance with their true gender identity (**Figure 18.1**). Several studies have shown that individuals who use gender-affirming hormones have improvement in gender dysphoria, perceived stress, anxiety, and social distress.<sup>38,39,40</sup> In a meta-analysis of 28 studies, which evaluated 1,833 TG patients who initiated gender-affirming hormone therapy, those who received hormone therapy reported an 80% (95% CI = 72–88%) improvement in their gender dysphoria, while 78% (95% CI = 61–81%) described improvement in their overall psychological symptoms.<sup>41</sup> The decision to initiate hormone treatment and choice of hormone regimens must be individualized in order to safely and effectively achieve the desired goal of the patient. Timely intervention with hormone therapy can make an enormous impact not only on the individual goals for their physical appearance but equally important on their overall mental health and stability.

## EFFECTS OF GENDER AFFIRMING HORMONE THERAPY

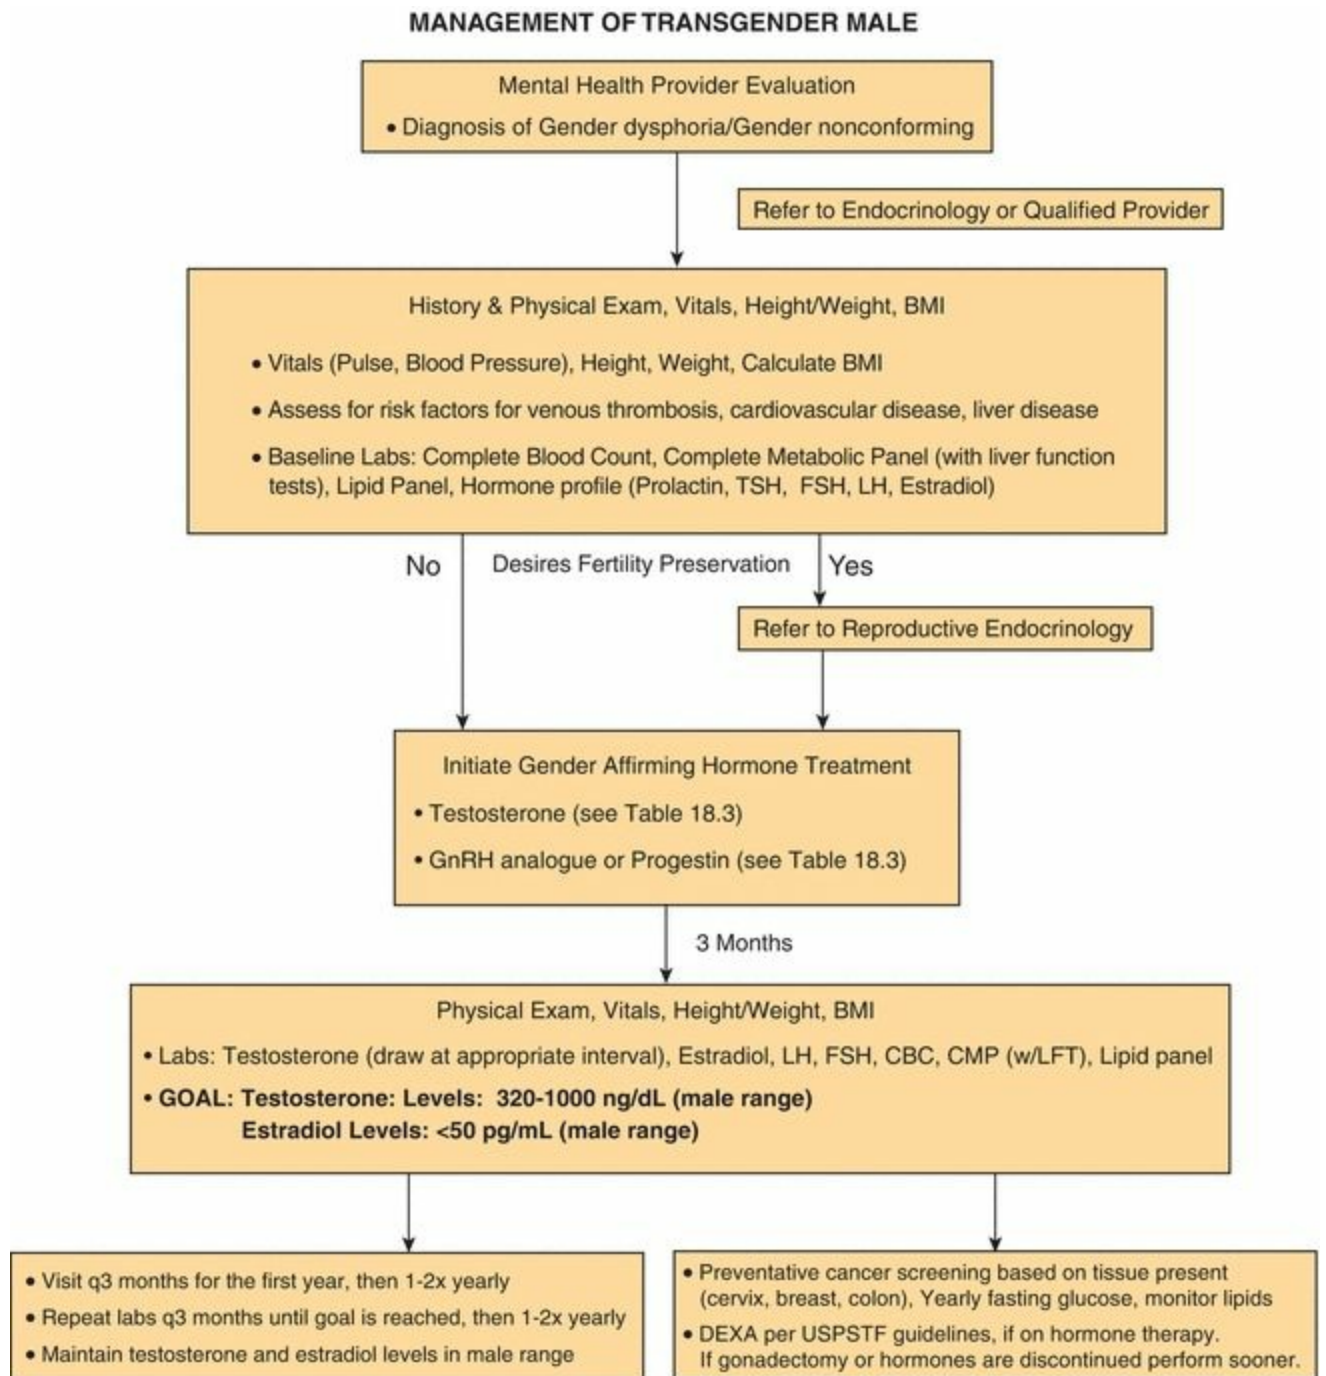

Modified with permission from **Irwig M**, Testosterone therapy for transgender men, *Lancet Diabetes Endocrinol* 5(4):301, 2017.<sup>42</sup>

# Masculinizing Hormone Therapy in Management of Transgender Male

Masculinizing hormone therapy is utilized in managing TG males (or female to male TG). The goal is to achieve a male phenotype through the use of a combination of hormones that stimulate the development of male secondary sex characteristics (deepening of voice, excessive facial and body hair, gain in muscle mass) while suppressing female secondary sex characteristics (regression in breast size, loss of female pattern distribution of body fat). These goals are achieved by administering potent androgens (such as testosterone). Added benefit may be achieved through concomitant suppression of endogenous ovarian estrogen production. The use of gonadotropin-releasing hormone agonists (GnRHa) to suppress ovarian estradiol production is typically only needed until male testosterone levels are reached, at which point the persistently high circulating testosterone levels can serve to suppress the hypothalamic-pituitary-ovarian axis, and at this point, GnRHa can be discontinued.

The algorithm for the evaluation and treatment of TGMs can provide guidance when treating these individuals ([Figure 18.2](#)). A number of testosterone regimens are currently available and outlined in [Table 18.3](#).<sup>3,43</sup> In the United States, testosterone cypionate and enanthate are the most commonly utilized formulations; choice of androgen and regimen should take into consideration safety, availability, cost, as well as patient preference for route and ease of administration. The goal of masculinizing hormone therapy is to attain circulating levels of testosterone and estradiol in physiologic male range: testosterone 320–1,000 ng/dL and estradiol less than 50 pg/mL.<sup>3,10</sup> The timing of when to draw serum testosterone levels during treatment is determined based on the pharmacokinetics and route of the utilized hormone formulation. For example, if testosterone enanthate intramuscular injections are being utilized, a serum testosterone level should be timed midway between injections and adjustments made based on the levels obtained as well as the clinical response ([Table 18.3](#)).<sup>15</sup>

**FIGURE 18.2**

**TABLE 18.3 Testosterone Formulations for Transgender Males**

	Route	Dose	Measure	Advantage (A)/Disadvantage (D)
Testosterone Enanthate/ Cypionate	IM/SQ	100–200 mg/q2wk (half if weekly dosing)	Midway between injections	A: Inexpensive, highly effective at reaching target levels, readily available D: Injection, erythrocytosis
Testosterone Gels	Topical	1%: 25–100 mg/day 1.6%: 50–100 mg/day	Anytime (After 1 wk of use)	A: Consistent concentration D: Expensive, skin to skin contact
Testosterone Transdermal Patch	Topical	2.5–7.5 mg/day	Anytime (After 1 wk of use)	A: Consistent concentration D: Expensive, skin irritation, falls off with moisture/exercise
Testosterone Pellets	SQ implant	150–450 mg/q3–6mo	Anytime (After 1 wk of use)	A: Consistent concentrations, infrequent dosing D: Invasive, inflexible dosing, infection risk
Testosterone Buccal	Buccal	30 mg twice/day	Anytime (After 1 wk of use)	D: Expensive, gum irritation, taste alterations, requires compliance
Testosterone Undecanoate	Oral	40–80 mg/2–3× day	Anytime (levels can be inconsistent)	D: Variable concentrations, requires compliance, limited availability in the United States
Testosterone Undecanoate	IM	1,000 mg/12 wk	Prior to next dose (trough)	A: Infrequent dosing D: Expensive, injection site pain, limited availability in United States

Routine physical examination and laboratory surveillance for possible adverse reactions (i.e., polycythemia associated with use of androgens) should initially be performed every 3 months for the first year of hormone treatment. Visits can become less frequent once the goal hormone levels are reached or as the provider deems necessary.

Although the external physical changes with testosterone use are clearly evident, TG males may also experience changes in their sexual and emotional health. Many of these changes can be seen within the first 6 months of testosterone treatment to include acne, body fat redistribution, and increased muscle mass. Studies report that in 55–84% of TGMs, menses ceases by 6 months and nearly all by 1 year of androgen therapy.<sup>44, 45, 46</sup> The time to menstrual cessation following initiation of androgen therapy may vary and can be achieved with standard testosterone treatment alone (50–60 mg/wk).<sup>44</sup> If intermittent spotting occurs, or if menses becomes bothersome, progesterone can be added to the hormone regimen.<sup>44</sup> **Figure 18.1** depicts the masculinizing effects of testosterone in TG males.

# Feminizing Hormone Therapy in Management of Transgender Female

Feminizing hormone therapy is utilized in managing TG females (or male to female TG). The goal is to achieve a female phenotype through the use of a combination of hormones that stimulate the development of female secondary sex characteristics (breast development, female pattern body fat distribution) while suppressing male secondary sex characteristics (slowing of facial and bodily hair growth). These goals are achieved by administering estrogen. Added benefit may be achieved through concomitant suppression of endogenous testicular androgen production and/or antagonizing tissue effects of androgens through simultaneous use of antiandrogens. **Figure 18.3** provides an algorithm to guide evaluation and management of TG female.

## FIGURE 18.3

There are many different estrogen formulations (i.e., pill, patch, topical), any of which can be used to achieve the desired effects (Table 18.4). Oral conjugated estrogens 2.5–7.5 mg and oral 17 $\beta$ -estradiol 2–6 mg daily are popular regimens since they are easy to administer and readily available. Although estrogen therapy can suppress androgens, usually a GnRHa or antiandrogen is also necessary for best results. GnRHa suppresses pituitary gonadotropin secretion resulting in a decrease in testicular production of testosterone. Similarly, antiandrogens work primarily by blocking its activity at the level of androgen receptors (i.e., spironolactone and flutamide) or by reducing the conversion of testosterone to the more potent androgen dihydrotestosterone (i.e., finasteride) (Table 18.5); antiandrogens are discussed in detail in Chapter 12. The goal of feminizing hormone treatment is to achieve circulating hormone levels that are within normal female range: estradiol 100–200 pg/mL and testosterone less than 55 ng/dL.<sup>3, 10</sup>

### TABLE 18.4 Estrogen Formulations for Transgender Females

	Route	Dose	Monitor	Advantage (A)/Disadvantage (D)
Conjugated Estrogens	Oral	2.5–7.5 mg/day	Anytime (levels can be inconsistent)	A: Inexpensive, readily available, highly effective D: Requires compliance, difficult to monitor levels, VTE risk
17- $\beta$ Estradiol	Oral	2–6 mg/day	Anytime (levels can be inconsistent)	A: Inexpensive, readily available, highly effective D: Requires compliance, VTE risk
Estradiol Valerate	IM	5–20 mg/q2wk	Midway between injections	A: Infrequent dosing D: Expensive, injections site pain
Estradiol Cypionate	IM	2–10 mg/qwk	2–4 days after injection (peak)	A: Infrequent dosing D: Expensive, injections site pain
Estradiol Transdermal Patch	Topical	0.25–0.2 mg/day 0.1–0.4 mg/2 $\times$ week	Anytime (after 1 wk of use)	A: Consistent concentration, lower VTE risk D: Expensive, skin irritation, falls off with moisture/exercise, difficult to titrate doses

### TABLE 18.5 Antiandrogen Treatment Regimens for Transgender Female

Medication	Dose	Mode of Action
<b>Antiandrogens</b>		
• Spironolactone	100–200 mg/day	Androgen receptor blocker and decreases testosterone synthesis
• Finasteride	1–5 mg/day	5- $\alpha$ reductase inhibitor, blocks conversion of testosterone to DHT
• Dutasteride	0.5 mg/day	5- $\alpha$ reductase inhibitor, blocks conversion of testosterone to DHT
<b>GnRH Agonists</b>		
• Leuprolide Acetate	3.75 mg/mo 11.25 mg/q3mo	Suppresses gonadotropin release and subsequently lowers sex steroids
• Histrelin Acetate Subcutaneous Implant	50 mg/q12mo	
<b>Progestins</b>		
• Medroxyprogesterone Acetate	5–10 mg/day	Progestin with antiandrogenic properties
• Cyproterone Acetate <sup>a</sup>	25–30 mg/day	Progestin with antiandrogenic properties

IM, intramuscular.

<sup>a</sup>Not available in the United States.

Data from **Hembree WC, Cohen-Kettenis PT, Gooren L, Hannema SE, Meyer WJ, Murad MH, Rosenthal SM, Safer JD, Tangpricha V, T’Sjoen GG**, Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society Clinical Practice guideline, *J Clin Endocrinol Metab* 102(11):1, 2017; **World Professional Association for Transgender Health**, Standards of care for the health of transsexual, transgender, and gender nonconforming people. Available at [http://www.wpath.org/site\\_page.cfm?pk\\_association\\_webpage\\_menu=1351&pk\\_association\\_webpage=3926](http://www.wpath.org/site_page.cfm?pk_association_webpage_menu=1351&pk_association_webpage=3926) (Accessed March 14, 2018); and **Chapkin SR, Kim F**, Ten most important things to know about caring for transgender patients, *Am J Med* 130:1238, 2017.

Physical examination and laboratory monitoring should be performed every 3 months for the first year to ensure estradiol levels are not suprathreshold and to monitor for any adverse reactions.<sup>3</sup> It can also be helpful to measure testosterone levels in order to document the degree of suppression of endogenous androgen production. Electrolytes, particularly potassium, should be monitored if spironolactone is utilized and notable changes in lipid parameters should be closely observed.

Transgender females on estrogen therapy will notice an increase in subcutaneous fat distribution, primarily around the hips, breast development, changes to skin texture, thinning of body hair, and feminization of facial features.<sup>3</sup> As female features develop, muscle strength, testicular volume, and libido will decrease.<sup>15</sup> **Figure 18.1** depicts the feminizing effects of testosterone in TGFs.

## Risks of Gender Affirming Hormone Therapy

In general, gender-affirming hormone treatment regimens are well tolerated and safe. The hormonal formulation used, dose, and the route of administration should be considered on an individualized basis in efforts to minimize risks while optimizing outcomes. Serious adverse events can be minimized by screening the patient carefully

for any comorbidity, concerning health habits, and significant family history that would confound treatment.

Polycythemia, weight gain, increased body mass index, acne, androgenic alopecia, and sleep apnea are well described with the use of masculinizing hormone therapy in TG males.<sup>3,10,47</sup> Testosterone therapy has been shown to increase triglycerides and low-density lipoprotein (LDL) while lowering high-density lipoprotein (HDL).<sup>3,48,49</sup> With additional risk factors, such as obesity and a strong family history, there may also be an increased risk of hypertension, type 2 diabetes mellitus, and cardiovascular disease.<sup>47,50</sup> Therefore, routine screening of lipids and fasting glucose levels should be considered prior to initiating hormone therapy and then periodically during maintenance to monitor for adverse metabolic effects such as hyperlipidemia and hyperglycemia. Aromatizable androgens such as testosterone can be aromatized to estrogen by end organs. While osteoporosis is not a concern for TG males on gender-affirming hormone therapy, screening of bone mineral density by dual energy x-ray absorptiometry (DEXA) should be considered for those individuals who are deemed at high risk for skeletal fragility, in those where GnRHa treatment was initiated early in life and continued for prolonged periods, in those contemplating cessation of hormone treatment or if the patient elects for premenopausal gonadectomy.<sup>3,32</sup>

The primary concern with the use of feminizing hormone therapy by TG women is the risk of venous thromboembolic (VTE) development; therefore, modifiable risk factors (i.e., smoking, obesity, hypertension) should be optimized to decrease the underlying hazard.<sup>51</sup> Historically, the previously used and now obsolete drug diethylstilbestrol was seen to cause thrombotic complications in TG females raising the concern about estrogen use within this group.<sup>3,52</sup> VTE risk associated with estrogen use is influenced by dose, route, and regimen. Although VTE risk is increased with the use of all types of systemic estrogen formulations, formulations containing ethinyl estradiol have been associated with a notably higher degree (20-fold increase) than other estrogenic formulations.<sup>50,51,53</sup> Other adverse effects related to estrogen hormone therapy include gallstones, weight gain, hypertriglyceridemia, decreased libido, hyperprolactinemia, and cardiovascular disease.<sup>3,10,50,54</sup> The route of administration may modify the risk factors, for example, transdermal estradiol may have a lower VTE risk by bypassing the first-pass liver metabolism and can be recommended for patients deemed at high risk for oral administration. Similarly, prolactinomas are typically seen with oral estradiol administration; therefore, an alternative route can be considered if this becomes an issue. Furthermore, TG females with risk factors may be predisposed to low bone mass and worsening of glycemic metabolism.<sup>50,54,55</sup> Therefore, a yearly fasting glucose levels should be obtained, and those who discontinue hormone therapy or have known risk factors should get a DEXA scan.

# GENDER DYSPHORIA IN CHILDREN AND ADOLESCENTS

---

There are notable differences between children and adolescents regarding persistence of dysphoria into adulthood. Several studies have shown that the percentage of children whose dysphoria persists into adulthood is only 12–27%, highlighting that gender dysphoria can be transient in this group.<sup>10,56,57</sup> The percentage of those individuals who become TG adults appears to be much higher among adolescents who experience unrelenting gender dysphoria into adulthood.<sup>3,10</sup> It is highly encouraged for gender dysphoric or gender nonconforming individuals to make a social transition or experience living in the new gender role and to determine whether this improves one's quality of life prior to the initiation of any hormone therapy.<sup>3</sup>

As previously highlighted, the Endocrine Society Clinical Practice Guidelines for gender dysphoria/gender noncongruence has provided guidance for medical treatment of TG individuals including adolescents.<sup>3</sup> In adolescent patients, treatment options include those deemed reversible, partially reversible, and those that are irreversible. Reversible treatments include the use of GnRH analogues or GnRH antagonists. Partially reversible treatments include the use of hormone therapy, where some physical changes can lessen upon cessation of treatment; it should be noted that medical or surgical intervention may be required (i.e., mastectomy, laser hair removal). Lastly, irreversible options include genital or gonadal surgery as well as some hormonal changes that once started are permanent.

Once the diagnosis of gender dysphoria or gender nonconforming is made by an MHP, usually with parental involvement if they maintain decision-making authority, the individual can be referred for gender-affirming hormone treatment. Prior to the decision on whether to treat children or adolescents with gender-affirming hormones, a thorough evaluation should be undertaken by a skilled provider who has an understanding of the psychopathology and developmental milestones within this vulnerable age group.

# Puberty Suppressing Hormones and Role in Transgender Care

It is commonplace to first start with treatment that is reversible given the previously highlighted indecision among this group. In efforts to mitigate harm and/or minimize exposure to the nonreversible effects of hormone therapy, it is recommended that patients avoid beginning puberty suppressing medications until the onset of puberty or Tanner stage 2 (girls, Tanner 2 breasts; boys, Tanner 2 genital).<sup>3,10</sup> Physical examination is usually sufficient to determine puberty initiation; however, evidence of gonadotropins elevation in the serum can also be obtained to verify activation of the hypothalamic-pituitary-gonadal (HPG) axis. Laboratory measurements of serum follicle-stimulating hormone (FSH), luteinizing hormone (LH), and the appropriate sex steroid (estradiol, testosterone) can be utilized to corroborate the findings on physical examination. The use of GnRHa is the preferred hormone treatment to achieve puberty suppression (Table 18.6). As previously mentioned, GnRHa suppress pituitary release of gonadotropins by desensitization of the GnRH receptors. In girls who begin GnRHa treatment at the earliest pubertal stage, breast buds may regress, and if begun after onset of menarche, menses will cease with ongoing treatment. Similarly initiation prior to puberty can restrict testicular volume and prevent onset of androgenization, whereas if begun later, ongoing treatment will arrest masculinization.<sup>3</sup> Besides the possibility of reversal of undesired features, the use of GnRHa allows the young adolescent time to determine whether hormone therapy is an intervention they still wish to pursue.

## TABLE 18.6 Puberty Induction and Suppression Strategies for Transgender Adolescents

Medication	Starting Dose	Final Adult Dose	Incremental Change (Dose/Time)
<b>Transgender Female</b>			
17β-Estradiol (Oral)	5 µg/kg/day	2–6 mg/day	Increase by 5 µg/kg/day q6mo
17β-Estradiol (Transdermal)	6.25 µg/24 h (1/4 of 25 µg patch)	50–200 µg/24 h	Increase by 12.5 µg/24 h q6mo
<b>Transgender Male</b>			
Testosterone Enanthate/ Cypionate	25 mg/m <sup>2</sup> /2 wk	100–200 mg/2 wk	Increase by 25 mg/m <sup>2</sup> /2 wk q6mo
<b>GnRH Agonist</b>			
Leuprolide Acetate	3.75 mg/mo		
	11.25 mg/q3mo		
Histrelin Acetate (Subcutaneous Implant)	50 mg/q12mo		

From Hembree WC, Cohen-Kettenis PT, Gooren L, Hannema SE, Meyer WJ, Murad MH, Rosenthal SM, Safer JD, Tangpricha V, T’Sjoen GG, Endocrine treatment of gender-dysphoric/gender-incongruent persons: an Endocrine Society Clinical Practice guideline, *J Clin Endocrinol Metab* 102(11):1, 2017.

Unlike the GnRHa analogues that have been long in use, GnRH antagonists are an expanding class of agents that offer immediate cessation of pituitary gonadotropin release by antagonizing the effects of GnRH at the level of pituitary receptors; however, long-term data on the use of GnRH antagonists in adolescents are lacking.<sup>3</sup>

Progestins, both depot and oral formulations, can be utilized in management of TG males to decelerate pubertal progression; this method was historically used for puberty suppression in girls with precocious puberty.<sup>3,58</sup> Progestins are safe and do suppress gonadotropins, although not to the level seen with GnRHa. Common progestin side effects include acne, fatigue, intermittent uterine bleeding, and headache.

For TG females, antiandrogens that suppress androgen synthesis or action can also be used as a substitute to GnRHa treatment (see Table 18.5). These alternative options could be considered in special circumstances when the cost or availability of GnRHa is limited, or in unique circumstances such as patient preference or in cases of needle phobia where injectable medications can be problematic. Most recently, an oral GnRH antagonist formulation has become available, and can be utilized as an alternative to a GnRHa.<sup>59</sup>

GnRH analogues do have some adverse side effects, which are typically reversible, and however should be kept in mind particularly in adolescents who use GnRHa for a prolonged period of time. Compromised bone mineralization is of utmost concern during this critical period of growth and should be monitored with extended GnRHa usage.

For adolescents and young TG individuals considering initiation of puberty suppression followed by gender-affirmative hormone therapy, a discussion about fertility preservation should be considered and offered (further discussion follows under heading of special considerations).

# GENDER-AFFIRMING HORMONE THERAPY IN MANAGEMENT OF ADOLESCENT TRANSGENDER PATIENT

---

It is recommended to start hormone therapy once the adolescent reaches a level of competence to consent for treatment, which for many countries is the age of 16.<sup>3,60,61,62</sup> Defining a specific age is laden with challenges since for some individuals with severe dysphoria, the risk of withholding treatment until an older age outweighs the benefit, and similarly, there are others for whom treatment should be withheld until competency is reached. Prior to initiating treatment, the patient should be fully informed on the risks of the treatment and the expected outcomes.

Gender-affirming sex hormone induction is performed in a similar fashion as the treatment of hypogonadal patients. TG males will gradually initiate a testosterone regimen, while TG females will begin estrogen treatment in a gradually escalating dose schedule. There are many regimens that can be utilized to achieve the same goal of masculinizing a genetic female and feminizing a genetic male (Table 18.6). In general, hormone regimens should be started at a low dose and increased incrementally. This allows a provider to ensure there are no issues with tolerance or adverse side effects. The slow initiation of hormones also allows the individual to gradually adapt to the physical changes they will experience and provide time for social integration. Gonadal suppression with GnRHa is continued in order to suppress endogenous hormone production to ensure maximal benefit of gender-affirming regimens at the lowest dose. For TG females, the use of a GnRH analogue or an antiandrogen will need to be maintained until gonadectomy. For TG males, GnRHa can be discontinued once male testosterone levels are reached and suppression of the HPO axis has occurred.

Physical examination and laboratory monitoring is similar to the surveillance of the adult TG patients discussed earlier. As deemed medically necessary, visits may be more frequent or for greater duration given the slower titration and prolonged time to achieve stable adult dose on the hormones. Additionally, in the adolescent assessment of Tanner stage, height/weight should be done at every visit, while bone age and bone mineral density evaluation should be considered as indicated.<sup>3</sup>

# **SPECIAL CONSIDERATIONS**

---

# Fertility Preservation

For many individuals who have anticipated the initiation of hormone therapy to feel their authentic self, the thought of postponing treatment, even briefly, may not be acceptable. However, a discussion on fertility potential and fertility preservation is most optimal when undertaken before initiating any definitive intervention (medical or surgical). Studies have shown that 40–50% of TG individuals wish to have children.<sup>63,64,65</sup> Thus, it is imperative that prior to initiation of any gender-affirming hormone treatment, all individuals should be counseled on implications of exogenous hormone therapy on their fertility potential, and reproductive endocrinologists are uniquely positioned to play a critical role in optimizing care of TG patients. Information on the spectrum of available options and recommendations individualized to patient needs and preferences must be provided. The field of assisted reproductive technologies (ART) has expanded the options for TG men and women to have genetic offspring. Providers should be able to discuss the various methods available to achieve a family in the future including gamete (egg or sperm) and embryo cryopreservation, tissue (testicular or ovarian) cryopreservation, donor gamete options, gestational surrogacy, and adoption. If the primary medical provider does not feel competent to counsel an individual regarding fertility preservation options, the patient should be referred to reproductive endocrinologists for further guidance.

The ideal time to preserve gametes is prior to any hormone treatment. In TG males, testosterone treatment suppresses the HPO axis, whereby it inhibits ovulation and results in amenorrhea. Upon cessation of testosterone use, most TG males have a return of menses within 6 months.<sup>66</sup> It should be noted that although most will resume menstruation, in some cases the amenorrhea is irreversible. Numerous pregnancies have resulted in TG males who have stopped gender-affirming hormone treatment and either conceived spontaneously with a partner, used donor sperm insemination, or relied on assisted reproductive technology to successfully conceive. If oocyte or embryo cryopreservation is desired, the TG male will undergo controlled ovarian hyperstimulation with subsequent oocyte retrieval. The mature oocytes retrieved can be cryopreserved until further use or can be fertilized to create embryos when a partner or donor sperm source is available. For those who have already initiated testosterone treatment, it will need to be discontinued; ART can then be offered once hormone parameters have returned to normal female levels. Long-term testosterone exposure on oocyte quality is uncertain; however, normal pregnancies have been reported.<sup>67</sup>

It is not uncommon for TG individuals to have an aversion to their misaligned reproductive organs. Fertility preservation-related consideration must be discussed when definitive surgery (hysterectomy or oophorectomy by TG male and orchiectomy by TG female) is desired. Cryopreservation of the ovarian cortex or of testicular

extracted sperm can be planned at the time of definitive surgery; individuals seeking ovarian tissue cryopreservation to retain fertility potential must be advised that the procedure is still considered experimental. Similarly, if a hysterectomy is desired, a need for gestational surrogate to achieve future pregnancy with biologic gametes must be clarified.

If reproductive organs are preserved, TG males can become pregnant and successfully deliver.<sup>66</sup> For some TG males, pregnancy is not only a means to have a family but is also a highly desired experience. Once pregnancy is attained, regular prenatal care should be ensured with particular attention to the challenges that may arise given the psychological and physical changes in TG males.

For TG females, estrogen and antiandrogen hormones suppress gonadotropin levels resulting in impaired testosterone production. Testosterone is necessary for normal spermatogenesis; therefore, spermatozoa count and motility are significantly affected.<sup>67,68</sup> If hormones are discontinued, spermatogenesis will likely resume when hormones return to normal male levels (this can take a few months and not always reversible). Many TG females are hesitant to discontinue gender-affirming hormones for the duration of time needed to reestablish normal testosterone levels and for spermatogenesis to resume. Elective sperm cryopreservation should be considered prior to hormone treatment or gonadectomy. Depending on the quality and quantity of spermatozoa cryopreserved, it may be best to recommend in vitro fertilization with intracytoplasmic sperm injection (ICSI) instead of an intrauterine insemination.<sup>69</sup> For those who have azoospermia or significantly impaired sperm parameters following hormone cessation, surgical sperm extraction (testicular sperm extraction) may warrant consideration.

For those TG individuals who do not wish to discontinue hormone treatment or whose infertility is irreversible given medical or surgical alterations, the use of donor gametes may be an option to attain parenthood. For others, adoption may be the preferred choice to complete their family.

# Contraception

Gender-affirming hormone therapy alone is not a reliable form of contraception. Furthermore, testosterone during pregnancy, particularly during early embryogenesis, is a teratogen, as are antiandrogens. Contraception is a topic that providers must address with TG individuals. A candid discussion on sexual practices and exogenous hormone exposure should be an integral component of TG care.

Sexual orientation, sexual practices, and individual preference all are relevant when identifying a contraceptive method best suited for an individual. Reproductive age TG males and females, who are not on gender-affirming hormones and in a heterosexual sexual relationship, should use contraception if pregnancy is not desired. For TG males not on gender-affirming hormones, any of the various established methods of contraception to include combined hormonal pills, patches or ring, progestin-only pills, intradermal progestin implants, or hormonal or nonhormonal intrauterine devices can be recommended. The use of levonorgestrel intrauterine device (IUD) may be an attractive option given that it serves the purpose of contraception and often results in a cessation of menses, without the concern of taking an estrogen-based medication. Alternatively, TG males, who are on gender-affirming hormones and in a relationship with a cisgender male, may desire nonhormonal contraceptive options. For these individuals the copper IUD or barrier contraceptive methods may be preferred.<sup>70</sup>

A sexually active TG female in a sexual relationship with a cisgender female partner should use barrier contraceptive measures if pregnancy is not desired. It should be noted that although spermatogenesis is likely compromised with estrogen therapy, TG females may not achieve complete azoospermia. Alternatively, the cisgender partner can use a reliable hormonal or nonhormonal contraceptive method that is currently available. Both TG males and females, particularly those engaging in high-risk sexual behaviors, should be counseled on concomitant use of barrier contraceptive measures for prevention of sexually transmitted infections.

**HEALTH** **SCREENING**  
**RECOMMENDATIONS FOR TRANSGENDER**  
**HEALTH AND WELLNESS**

---

# Breast Screening

It is not uncommon for TG individuals to avoid or minimize care for their natal sex organs. Primary care providers should ensure to follow established screening guidelines while the TG person still has the natal organ or tissue. Transgender males, who have not undergone bilateral mastectomy, should have a screening mammogram performed per current guidelines.<sup>71,72</sup> It should be noted that TG males have a lower rate of breast cancer when compared to cisgender individuals. The reduction is likely attributable to the high rate of mastectomies in these patients, as well as the changes in breast tissue seen with testosterone treatment. Testosterone decreases the glandular breast tissue and increases the amount of fibrous connective tissue.<sup>42,73</sup> No reliable recommendation exists on how to screen TG males who have undergone bilateral mastectomy. Most breast tissue is removed during the procedure; however, residual tissue can always remain. One option is to perform annual chest wall physical examinations, although no data exists to support this approach.<sup>43</sup> If a mass is palpated by the patient or provider, imaging with an ultrasound or magnetic resonance imaging (MRI) should be ordered to further evaluate the concerning area.

There are no current guidelines on how to screen TG females for breast cancer. The use of estrogen hormones increases the breast tissue density of TG females, although typically these individuals have less years of estrogen exposure when compared to cisgender females.<sup>43,74</sup> In a retrospective study of 2,307 TG females treated at a single Dutch center, the incidence of breast cancer was 4.1/100,000 person-years, in comparison to 150/100,000 person-years in the cisgender group.<sup>75</sup> Additionally, supporting the notion that estrogen alone does not increase breast cancer risk, the Women's Health Initiative study reported no increased risk of breast cancer in the group using conjugated equine estrogen alone when compared to placebo.<sup>76</sup>

Although there are no clear guidelines on when, or if, TG females should have breast cancer screening, it is reasonable to individualize recommendations based on the duration of estrogen use. The University of California San Francisco Center of Excellence for Transgender Health recommends starting screening mammograms once the age of 50 and 5–10 years of feminizing hormone use has been reached.<sup>43</sup>

# Cervical Screening

Transgender males who have not had gender-affirming surgery should have a Papanicolaou (Pap) smear with or without human papilloma virus testing beginning at age 21 as per American Society for Colposcopy and Cervical Pathology (ASCCP) guidelines.<sup>77</sup> Since there are limited data on cervical cancer rates within this population, the standard ASCCP guidelines that apply for cisgender females should be followed.<sup>78</sup> Every attempt should be made to have the Pap smear done in a gender-neutral clinic to limit the distress of going to the gynecologist or women's health clinic. If a hysterectomy is performed and all previous Pap smears have been normal, no further cervical screening is indicated.<sup>77</sup> It should be noted that TG women who have a neovagina do not need routine Pap smears. Examination of the neovagina should be performed to ensure normal integrity and to assess for any pathology, such as HPV condyloma formation.<sup>32</sup>

# Prostate Screening

Transgender females, even individuals who have undergone gender-affirming surgery, should continue to be screened for prostate cancer since cases have been reported even after gonadectomy.<sup>79</sup> Although TG females have lower circulating testosterone levels when estrogen and antiandrogens are utilized, there still remains the possibility of developing prostate cancer. As per American Cancer Society guidelines, men at average risk for prostate cancer should be offered screening at age 50.<sup>80</sup> Screening consists of a digital rectal examination and serum prostate-specific antigen (PSA). Transgender females who have had gender-affirming surgery may have prostates in different anatomic positions. For example, the prostate in TG females is typically located along the anterior vaginal wall.<sup>81</sup> A digital exam may need to be performed through the neovagina or rectum in order to palpate the prostate, and the examination should be performed by a provider who understands the anatomic changes following surgery.<sup>81</sup> Although PSA levels less than 2.5 ng/mL are desired in cisgender males, it is suggested that in the setting of prolonged estrogen exposure, PSA can be falsely low. Therefore, it is suggested that the PSA level in TG females should be lowered to less than 1.0 ng/mL or not used since it can be inaccurate.<sup>82</sup>

# GENDER REASSIGNING SURGERY

---

Many TG individuals never elect to pursue gender-affirming surgery, while for others surgery is deemed a medical necessity to complete their gender identity or alleviate their dysphoria. The different surgical options are often referred to as “top surgery” referring to augmentation mammoplasty or mastectomy, or “bottom surgery,” in reference to genital reassignment surgery.

Although not an explicit criterion, some organizations such as World Professional Association for Transgender Health (WPATH) recommend a second-independent assessment from a qualified health care provider prior to genital surgery.<sup>10</sup> Furthermore, prior to genital surgery, it is highly recommended that for at least 1 year, the individual has been on gender-affirming hormone treatment and living in their desired gender.<sup>10</sup> Due to the permanent nature of genital surgery and the high morbidity associated with these procedures, the patient should be extensively counseled and be of legal age.

It is not uncommon for TG males to start the surgical transition with bilateral mastectomies given the relatively low morbidity associated with this procedure. Unlike TG females, TG males can have the mastectomy done at any point, regardless of whether or not they are on hormone therapy.

Genital surgery consists of a total hysterectomy and bilateral oophorectomy. Although TG males do not appear to be at increased risk of uterine, ovarian, or cervical pathologies, by undergoing a hysterectomy with bilateral oophorectomy, issues with uterine bleeding will be resolved, and concerns regarding carcinoma in those tissues will lessen. Procedures such as metoidioplasty, phalloplasty, scrotoplasty, and vaginectomy with implantation of testicular prosthesis allow attainment of male anatomic structures. In approximately 5% of TG males, the clitoral enlargement following testosterone treatment is adequate to serve as a phallus.<sup>83</sup> Metoidioplasty and phalloplasty are alternative methods to create a phallus. Metoidioplasty, which is more commonly done, is a surgical procedure in which the clitoris is elongated to create a shaft, the urethra is lengthened so one can void from the shaft, and a scrotum is created from the existing genital tissue.<sup>15,32</sup> Phalloplasty is the creation of a phallus, typically using graft tissue from a donor site that is sensate, and has a directable urine stream for standing micturition. Penile prosthetics are often utilized for cosmesis and for the ability to have penetrative intercourse.<sup>15,84</sup> Unfortunately, many of the gender-affirming genital surgeries are fraught with a long postoperative hospital course, significant morbidity, and high complications rates and are exceptionally expensive. Phalloplasty with resultant aesthetic phallus is often performed in a multi-step fashion which may require several revisions and up to 1 year to accomplish.<sup>83,84</sup> Urethral complications are the most common and have been reported to be as high as 80%, whereas other

complications include skin necrosis/erosion, infection, hematoma formation, and wound dehiscence.<sup>85</sup>

Transgender females may elect to have augmentation mammoplasty in order to increase their breast size.<sup>86</sup> The use of estrogen therapy will increase breast tissue development in TG females. It is recommended that augmentation surgery not be performed until a minimum of 12 months of estrogen use.<sup>10</sup> This length of estrogen exposure allows for maximum breast tissue development and optimizes cosmetic outcome.<sup>10</sup> Over 50% of TG females find their breast size adequate after 2 years of estrogen use and do not seek further enhancement. Therefore it may warrant waiting until full breast tissue development prior to pursuing augmentation surgery.<sup>31,82</sup>

Genital surgery for TG females include penectomy, orchiectomy, vaginoplasty, clitoroplasty, and vulvoplasty. The simplest option is orchiectomy, which will eliminate endogenous testosterone production. This allows the patient to discontinue the use of any antiandrogen and may allow for lower estradiol doses.<sup>15</sup> Genital surgery involves surgical removal of the penis and testicles, with creation of a neovagina and reconstruction of the urethral meatus and sensate clitoris.<sup>32</sup> The neovagina can be lined using penile and sometimes scrotal skin, nongenital skin flaps, or colonic grafts. While skin grafts and penile inversion procedures are the most commonly used, colonic flaps have been taken from the cecum and rectosigmoid to create a neovagina that has natural lubrication.<sup>32,83,86,87</sup> Regular use of a vaginal dilator or vaginal intercourse is needed in order to maintain the neovagina functional. Vaginal stenosis tends to be the most common complication (12%) seen with neovagina formation; however, other complications such as skin necrosis/erosion, infection, rectovaginal fistula formation, and genital pain can be seen.<sup>88</sup>

In addition to the definitive surgical approaches discussed above, a number of aesthetic interventions can help create more feminine (i.e., facial feminization surgery, permanent hair removal, thyroid cartilage reduction) or masculine features (i.e., pectoral implants) per the individual's desire and discretion and provider's judgment and expertise.<sup>10</sup>

# SUMMARY

---

Due to improving societal understanding, increasing social acceptability, and better health care access, the number of TG individuals seeking medical care has been steadily increasing. It is imperative that health care providers become familiar with the special medical needs of this group to ensure that safe and appropriate treatment is provided. In efforts to achieve this goal, a multidisciplinary team is critical to assure that all aspects of care are addressed by those most skilled in the discipline. Appropriately designed prospective studies in TG health are clearly needed to better understand the mechanisms underlying gender dysphoria and the long-term effects of gender-affirming hormone therapy as well as to optimize surgical techniques to minimize the surgical morbidity of currently utilized interventions. The field must continue to evolve with the goal that TG individuals have access to options that will allow them to achieve their maximal potential as healthy members of their community.

# Obesity

Because approximately 40% of American adults are obese, the unrewarding fight against obesity is all too common, not only with our patients but also with ourselves. An astonishing 66.2% of U.S. women were overweight or obese (28.1% overweight and 38.1% obese) in 2014.<sup>1,2,3,4,5,6</sup> Unfortunately, for over 100 years, the incidence of obesity has been increasing in the United States and Europe, a reflection of an affluent society with an increasingly sedentary life combined with high caloric foods, but most of the increase has been recent, beginning in 1980.<sup>7,8,9,10</sup> About 75% of American adults do zero vigorous physical activity in their leisure time.<sup>11</sup> This change in lifestyle has produced a high prevalence of obesity with a similar trajectory in adults and children; almost 17% of school-aged children and adolescents in 2008 were obese and 32% overweight.<sup>11,12</sup>

The lack of success in treating obesity is not due to an unawareness of the implications of obesity; there is a clear-cut, well-recognized relationship between mortality and weight.<sup>1</sup> The death rate from diabetes mellitus, for example, is approximately 4 times higher among obese diabetics than among those who control their weight. The death rate from appendicitis is double, presumably from anesthetic and surgical complications. The increase in mortality is not limited to obesity; all overweight individuals have an increase in the risk of death.<sup>13</sup> The Nurses' Health Study estimated that 23% of all deaths in nonsmoking middle-aged women are attributable to being overweight.<sup>14</sup>

The incidence of hypertension, heart disease, type 2 diabetes mellitus, metabolic syndrome, gout, gallbladder disease, obstructive sleep apnea, osteoarthritis, and all the most prevalent cancers, including colorectal cancer, endometrial cancer, and postmenopausal breast cancer, is elevated in overweight people.<sup>1,15,16,17</sup> Being overweight in adolescence is even a more powerful predictor of cardiovascular adverse health effects than being overweight as an adult.<sup>18</sup>

The increasing prevalence of obesity and its consequences now threaten to replace smoking as the primary cause of preventive mortality. A 40-year-old woman who is a nonsmoker can expect to lose 3.3 years of life if she is overweight (not obese, just overweight)!<sup>19</sup> If obese, the loss is 7.1 years, and if smoking is added, the loss is 13.3 years. Unless there is a major change, it is estimated that the rise in U.S. life expectancy

experienced over the last several decades will substantially slow down, offsetting the impact of declining smoking.<sup>20</sup>

When the personal and social problems encountered by obese people are also considered, it is no wonder that a clinician without a weight problem cannot comprehend why fat individuals remain overweight. The frequency with which a practitioner encounters the obese patient whose weight does not decrease despite a sworn adherence to a limited-calorie diet makes one question if there is something physiologically different about this patient. Is the problem due to lack of discipline and cheating on a diet, or does it also involve a pathophysiologic factor? Is the physiology of obese people unusual, or are they simply gluttons? **Modern studies of obesity strongly indicate that this is a multifactorial problem and that lack of willpower and laziness is not the simple answer.**

# DEFINITION OF OBESITY

---

Obesity is an excess storage of triglycerides in adipose cells; an excess of body fat. There is a difference between obese and overweight.<sup>21</sup> Overweight is a body weight, including muscle, bone, fat, and body water, in excess of some standard or ideal weight. The ideal weight for any adult is believed to correspond to his or her ideal weight from age 20 to 30. The following formulas give ideal weights in pounds:

- **Women:**  $100 + (4 \times \{\text{height in inches minus } 60\})$
- **Men:**  $120 + (4 \times \{\text{height in inches minus } 60\})$

At a weight close to ideal weight, individuals may be overweight, without having excess fat. This is especially true of individuals engaged in regular exercise. An estimate of body fat, therefore, is more meaningful than a measurement of height and weight.

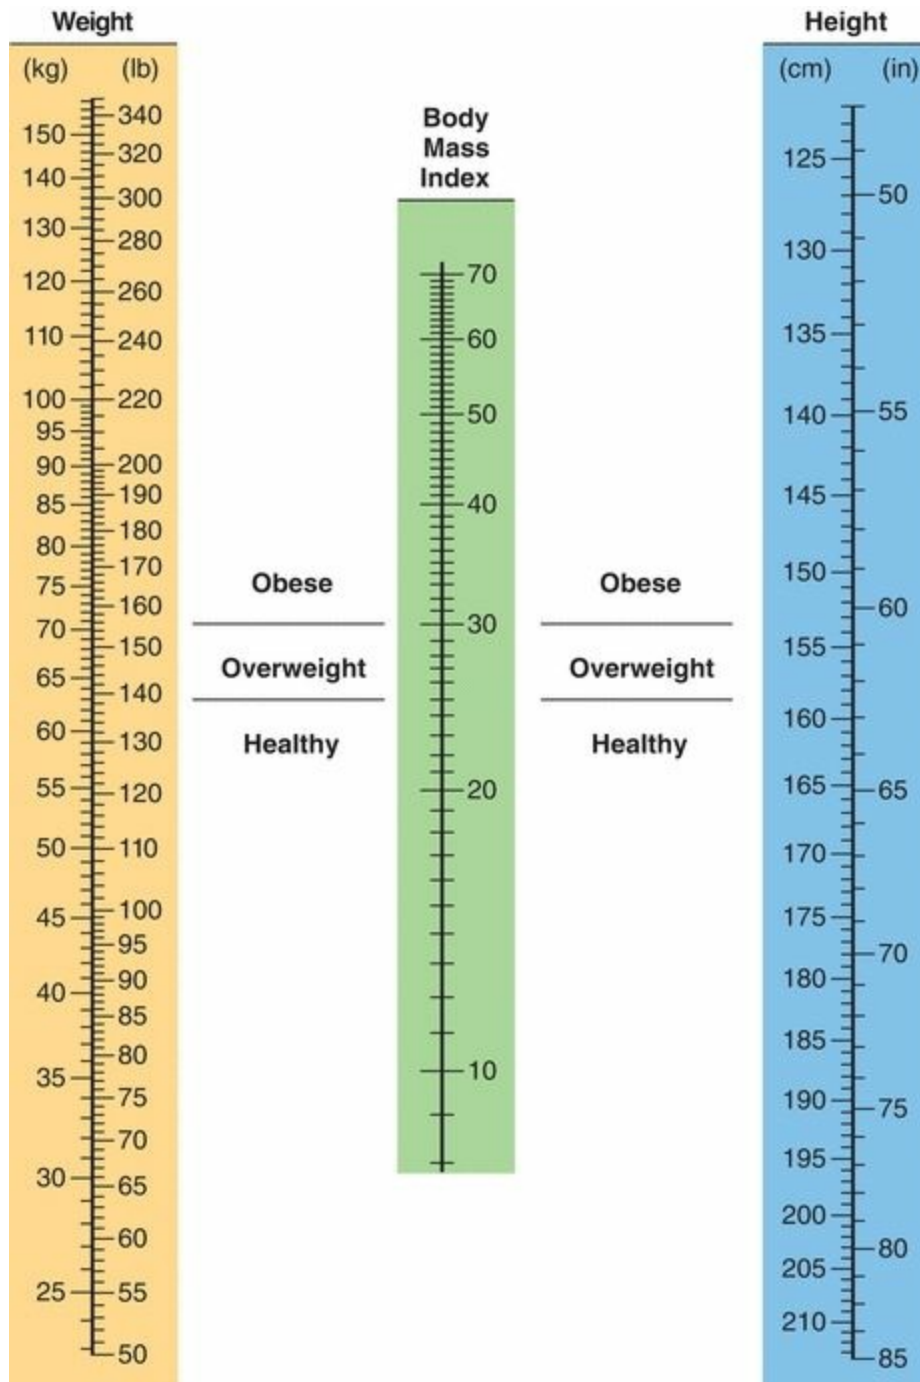

The most accurate method of determining body fat is to determine the density of the body by underwater measurement (hydrodensitometry). It certainly is not practical to measure density by submerging individuals in water in our offices; therefore, skinfold measurements with calipers have become popular as an index of body fat, or expensive imaging techniques can be utilized. These latter methods are not necessary for clinical practice. It is far simpler to utilize the body mass index (BMI) nomogram, a method that corresponds closely to densitometry measurements.<sup>22</sup>

**The body mass index (the Quetelet index) is the ratio of weight divided by the height squared (in metric units):**

$$\text{BMI} = \text{kilograms/meters}^2$$

To use the nomogram for BMI, read the central scale by aligning a straight edge between height and body weight. Overweight is defined as a BMI of 25 or more (66.2% of American women in 2014). Obesity is defined as a BMI of 30 or more (38.1% of American women in 2014). A “good” BMI for most middle-aged people is in the range of 20–24.<sup>23</sup> Mortality is lowest in middle-aged women with a BMI below 19.<sup>14,24</sup> A BMI in the overweight or obese range predicts an increased risk for earlier death, no matter the age of the patient.

- **Overweight:** BMI = 25–29.9
- **Obesity:** BMI = 30 and higher (Figure 19.1)

**FIGURE 19.1**

A person is obese when the amount of adipose tissue is sufficiently high (20% or more over ideal weight) to detrimentally alter biochemical and physiologic functions and to shorten life expectancy. Obesity is associated with four major risk factors for atherosclerosis: hypertension, diabetes, hypercholesterolemia, and hypertriglyceridemia. Overweight individuals have a higher prevalence of hypertension at every age, and the risk of developing hypertension is related to the amount of weight gain after age 25. The two in combination (hypertension and obesity) increase the risk

of heart disease, cerebrovascular disease, and death. The Nurses' Health Study documented a continuing correlation between the BMI and cardiovascular disease, diabetes, and cancer.<sup>14,25,26</sup> In other words, even a modest gain in adult weight, even in a range not considered to be overweight, increases the risk of cardiovascular and metabolic diseases. However, at any given BMI level, the presence of an increase in abdominal fat, metabolic risk factors, or a strong family history of diabetes, hypertension, and heart disease increases the risk to good health.

It is well documented that women have a greater prevalence of obesity compared with men. One reason may be the fact that women have a lower metabolic rate than men, even when adjusted for differences in body composition and level of activity.<sup>27</sup> Another reason that more women gain weight with age is the postmenopausal loss of the increase in metabolic rate that is associated with the luteal phase of the menstrual cycle. The difference between men and women is even greater in older age.

Unfortunately, the basal metabolic rate decreases with age.<sup>28,29</sup> After age 18, the resting metabolic rate declines about 2% per decade. The age-related decline in basal metabolic rate is not observed in women who continue to be involved in a regular endurance exercise program.<sup>30</sup> A 30-year-old individual will inevitably gain weight if there is no change in caloric intake or exercise level over the years. The middle-age spread is both a biologic and a psychosociologic phenomenon. It is, therefore, important for both our patients and ourselves to understand adipose tissue and the problem of obesity.

# PHYSIOLOGY OF ADIPOSE TISSUE

Adipose tissue serves three general functions:

1. Adipose tissue is a storehouse of energy.
2. Fat serves as a cushion from trauma.
3. Adipose tissue plays a role in the regulation of body heat ([Figure 19.2](#)).

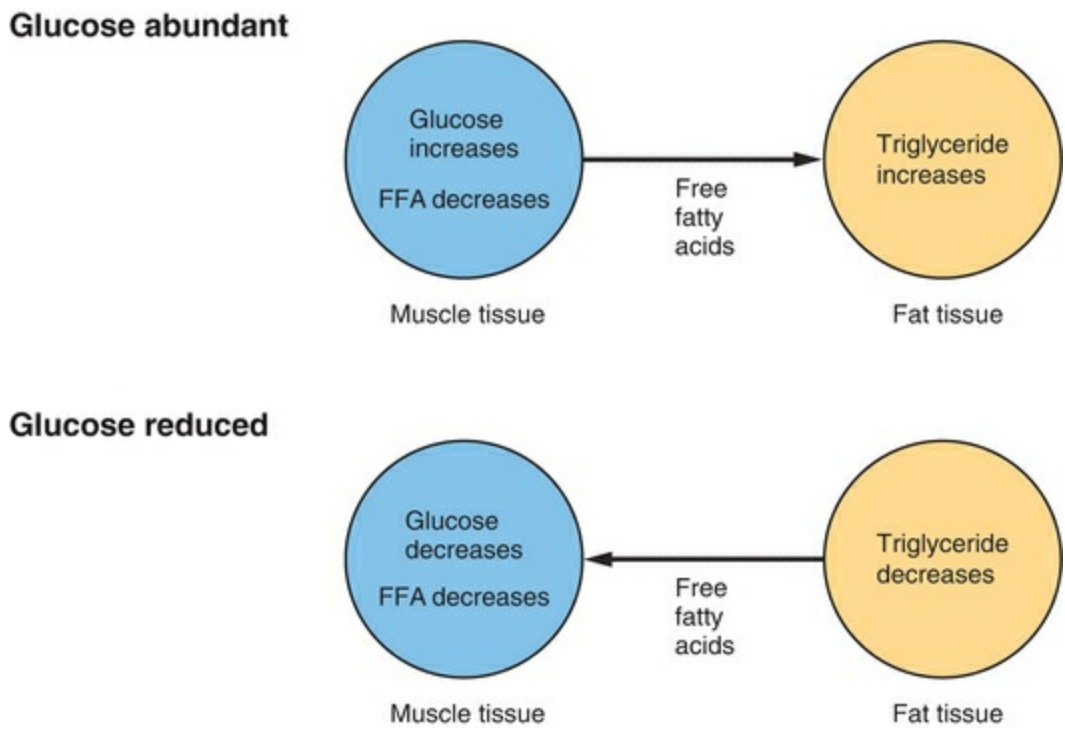

FIGURE 19.2

Each cell of adipose tissue can be regarded as a package of triglyceride, the most concentrated form of stored energy. There are 8 calories/g of triglyceride compared to 1 calorie/g of glycogen. The total store of tissue and fluid carbohydrate in adults (about 300 calories) is inadequate to meet between-meal demands. The storage of energy in fat tissue allows us to do other things besides eating. Our energy balance, therefore, is essentially equivalent to our fat balance. Thus, obesity is a consequence of the fat imbalance inherent in high-calorie diets.

The mechanism for mobilizing energy from fat involves various enzymes and neurohormonal agents. Following ingestion of fat and its breakdown by gastric and pancreatic lipases, absorption of long-chain triglycerides, and free fatty acids takes place in the small bowel. Chylomicrons (microscopic particles of fat) transferred through lymph channels into the systemic venous circulation are normally removed by hepatic parenchymal cells where a new lipoprotein is released into the circulation. When this lipoprotein is exposed to adipose tissue, lipolysis takes place through the action of lipoprotein lipase, an enzyme derived from the fat cells themselves. The fatty acids that are released then enter the fat cells where they are reesterified with glycerophosphate (glycerol-3-phosphate) into triglycerides. A triglyceride is an ester derivative derived from glycerol and three fatty acids; triglycerides are the main constituents of body fat in human and animals as well as vegetable fat. Because alcohol diverts fat from oxidation to storage, body weight is directly correlated with the level of alcohol consumption.<sup>31</sup>

**Glucose serves three important functions (Figure 19.3):**

## FIGURE 19.3

1. Glucose supplies carbon atoms in the form of acetyl coenzyme A (acetyl CoA).
2. Glucose provides hydrogen for reductive steps.
3. Glucose is the main source of glycerophosphate.

The production and availability of glycerophosphate (required for reesterification of fatty acids and their storage as triglycerides) are considered rate limiting in lipogenesis, and this process depends on the presence of glucose.

After esterification, subsequent lipolysis results in the release of fatty acids and glycerol. In the cycle of lipolysis and reesterification, energy is freed as heat. A low variable level of lipolysis takes place continuously; its basic function is to provide body heat.

The chief metabolic products produced from fat are the circulating free fatty acids. Their availability is controlled by adipose tissue cells. When carbohydrate is in short supply, a flood of free fatty acids can be released. The free fatty acids in the peripheral circulation are almost wholly derived from endogenous triglycerides that undergo rapid hydrolysis to yield free fatty acid and glycerol. The glycerol is returned to the liver for resynthesis of glycogen.

Free fatty acid release from adipose tissue is stimulated by physical exercise, fasting, exposure to cold, nervous tension, and anxiety. The release of fatty acids by lipolysis varies from one anatomic site to another. Omental, mesenteric, and subcutaneous fat is more labile and easily mobilized than fat from other sources. Areas from which energy is not easily mobilized are retrobulbar and perirenal fat where the tissue serves a structural function. Adipose tissue lipase is sensitive to stimulation by both epinephrine and norepinephrine. Other hormones that activate lipase are adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), growth hormone, thyroxine (T<sub>4</sub>), 3,5,3'-triiodothyronine (T<sub>3</sub>), cortisol, glucagon, as well as vasopressin and human placental lactogen (hPL).

Lipase enzyme activity is inhibited by insulin, which appears to be alone as the major physiologic antagonist to the array of stimulating agents. When both glucose and insulin are abundant, transport of glucose into fat cells is high, and glycerophosphate production increases to esterify fatty acids.

The carbohydrate and fat composition of the fuel supply is constantly changing, depending on stresses and demands. Because the central nervous system (CNS) and some other tissues can utilize only glucose for energy, a homeostatic mechanism for conserving carbohydrate is essential. When glucose is abundant and easily available, it

is utilized in adipose tissue for producing glycerophosphate to immobilize fatty acids as triglycerides. The circulating level of free fatty acids in muscle, therefore, is low, and glucose is used by all of the tissues.

When carbohydrate is scarce, the amount of glucose reaching the fat cells declines, and glycerophosphate production is reduced. The fat cell releases fatty acids, and their circulating levels rise to a point where glycolysis is inhibited. Thus, carbohydrate is spared in those tissues capable of using lipid substrates. If the rise of fatty acids is great enough, the liver is flooded with acetyl CoA. This is converted into ketone bodies, and clinical ketosis results.

In the simplest terms, when a person eats, glucose is available, insulin is secreted, and fat is stored. In starvation, the glucose level falls, insulin secretion decreases, and fat is mobilized.

If only single large meals are consumed, the body learns to convert carbohydrate to fat very quickly. Epidemiologic studies with schoolchildren demonstrated a positive correlation between fewer meals and a greater tendency toward obesity.<sup>32</sup> The person who does not eat all day and then stocks up at night is promoting an increase in fat.

# CLINICAL OBESITY

---

# Leptin and the Ob Gene (the LEP Gene in Humans)

The hypothalamic location of the appetite center was established in 1940 by the demonstration that bilateral lesions of the ventromedial nucleus produce experimental obesity in rats. Such lesions lead to hyperphagia and decreased physical activity. Interestingly, this pattern is similar to that seen in human beings—the pressure to eat is reinforced by the desire to be physically inactive. The ventromedial nucleus was thought to represent an integrating center for appetite and hunger information. Destruction of the ventromedial nucleus was believed to result in a loss of satiety signals, leading to hyperphagia. Overeating and obesity, however, are not due to ventromedial nucleus damage but rather to destruction of the nearby regions.<sup>33</sup> Indeed, lesions of the ventromedial nucleus produced by radiofrequency current fail to cause obesity. More recent studies established the arcuate nucleus in the hypothalamus as the central location for the regulation of feeding behavior. A sudden onset of hyperphagia can be due to a hypothalamic lesion. Possible causes include tumors, trauma, inflammatory processes, and aneurysms.

Signals arriving at these CNS centers originate in peripheral tissues. Opiates, substance P, and cholecystokinin play a role in mediating taste, the gatekeeper for feeding, while peptides released from the stomach and intestine act as satiety signals.<sup>34</sup> In addition, the CNS centers are regulated by locally released neuropeptides. Neuropeptides that inhibit appetite include corticotropin-releasing hormone (CRH), neurotensin, oxytocin, and cyclo(HisPro), a peptide derived by proteolysis of thyrotropin-releasing hormone.<sup>35,36</sup> The control of food intake and energy expenditure is very complex, and no agent or system functions in isolation.

The word leptin is derived from the Greek word, “leptos,” which means thin. **Leptin is a 167-amino acid peptide secreted primarily by the adipose tissue that circulates in the blood bound to a family of proteins and acts on the central nervous system neurons that regulate eating behavior and energy balance.** Rat studies in the 1950s suggested the existence of a hormone in adipose tissue that regulated body weight through an interaction with the hypothalamus.<sup>37,38</sup> But it was not until 1994 that the Ob gene was identified, the gene responsible for preventing obesity in the mouse.<sup>39,40</sup> In the human, this gene is known as the LEP gene (Table 19.1, Figure 19.4).

## TABLE 19.1 Genetic Rodent Models of Obesity

	Single Gene Mutations	Gene Product	Rodent Chromosome	Human Chromosome
Mice:	ob/ob	Leptin	6	7
	db/db	Leptin receptor	4	1
	fat/fat	Carboxypeptidase E	8	11
	tub/tub	Phosphodiesterase	7	4
	Ay/Ay	Agouti protein	2	20
Rats:	fa/fa	Leptin receptor	5	1

**FIGURE 19.4**

There are at least four recessive gene mutations known in mice and one dominant mutation (Ay/Ay) that result in obesity syndromes.<sup>41</sup>

Ob/ob and db/db mice were described many years ago. The ob/ob mutation arose spontaneously in the Jackson Laboratory mouse colony in 1949. The ob/ob mouse is homozygous for a mutation of the Ob gene on chromosome 6, and the db/db mouse, discovered in 1966, is homozygous for a mutation of the Db gene on chromosome 4.<sup>41,42</sup> These mice have been the subject of thousands of publications. The product of the Ob gene is leptin, and in the human, the LEP gene is located on chromosome 7q31.3. Db is the diabetes gene, and this is the locus of the mouse leptin receptor gene. Thus, the ob/ob mouse is obese because it does not produce leptin, and the db mouse is obese because it cannot respond to leptin; its leptin levels are very high (the mutation alters the leptin receptor).

Fat/fat mice are obese and remain insulin sensitive; the mutation decreases carboxypeptidase E, an enzyme that is involved in the conversion of prohormones to hormones; for example, proinsulin to insulin. The biology of tub is yet unknown. Both homozygous Fat and Tub mutations cause slowly developing but ultimately severe obesity conditions. Although hyperinsulinemia, hyperactivity of the  $\beta$  cell of the islets of Langerhans, and  $\beta$ -cell degranulation are consistent features, these obesity syndromes do not progress to severe diabetes.

The Ay/Ay rodent becomes fat late in life. The Agouti gene encodes a protein produced by hair follicles. This protein binds to a melanocortin receptor in melanocytes

in the skin, thus preventing melanocyte-stimulating hormone (MSH) action. Agouti rats have high levels of this protein and have yellow instead of black fur. The melanocortins are a group of peptide hormones, which include ACTH and the different forms of MSH, all of which are derived from proopiomelanocortin (POMC). POMC is produced by POMC neurons located in the hypothalamus, within the arcuate nucleus. Melanocortin binding to its brain receptor decreases appetite.<sup>43,44</sup> Ay/Ay rodents make an excess of Agouti protein, blocking melanocortin action, leading to obesity. The importance of this pathway is evident in the report of mutations within the POMC gene characterized by deficiencies in both MSH and ACTH, yielding individuals with obesity, adrenal insufficiency, and red hair pigmentation.<sup>45</sup> These findings have culminated in the recognition that mutations in the melanocortin receptor gene account for the most common cause of familial human obesity that can be attributed to a single gene.<sup>46</sup>

**Energy expenditure is composed of the basal metabolic rate, diet- and temperature-induced heat production, and the energy necessary for physical activity. Leptin induces weight loss in mice due to decreased appetite and food consumption and an increase in heat production and activity.<sup>47</sup>**

## The Leptin Receptor

The leptin receptor belongs to the cytokine receptor family.<sup>42</sup> There are multiple isoforms with at least three major forms, a short form and a long form, OB-R<sub>S</sub> and OB-R<sub>L</sub>, plus a circulating protein that consists of the extracellular domain. The extracellular domain is very large with 816 amino acids. The intracellular domain of the short form contains 34 amino acids, and in the long form, about 303 amino acids. The short form has many variations, whereas the long form is the common signaling receptor. The only place that the long form is expressed in greater amounts than the short forms is in the hypothalamus, in the arcuate, ventromedial, paraventricular, and dorsomedial nuclei.<sup>48,49</sup> High levels of the short-form leptin receptors in the choroid plexus indicate a transport role for the short form from blood into the cerebrospinal fluid to diffuse into the brain.<sup>50</sup>

The class I cytokine receptor family (to which the long form belongs) acts by proteins that phosphorylate the receptor after binding and STAT proteins that are activated after phosphorylation and then translocate to the nucleus and stimulate gene transcription. The long-form receptor works through STAT proteins, but gene knockouts specific for STAT proteins are not obese, indicating the presence of other signaling pathways activated by leptin.

The Db gene encodes the leptin receptor. The Db mutation converts the long form to the inactive short form, resulting in leptin resistance and obesity. The db/db mouse has a

single G for T nucleotide substitution within the C terminal untranslated end of the short intracellular domain of the ob receptor. This results in a new splice site that creates an abnormal exon inserted into the messenger RNA (mRNA) that encodes the long intracellular domain of the ob receptor. As a result, the long-form mRNA in db/db mice encodes a protein with most of the intracellular domain truncated to be similar to the short form of the ob receptor. The fa/fa mutation is a glutamine for proline substitution in the extracellular domain, and in contrast to the db/db mouse, the fa/fa rat will respond to leptin, but only if it is delivered into the brain.<sup>51</sup>

## Ghrelin

Ghrelin is a complex hormone, named for its ability to stimulate the release of growth hormone. Ghrelin not only participates in the regulation of food intake and energy metabolism but also affects sleep and behavior, and inhibits gonadotropin secretion.<sup>52,53,54</sup> It influences a wide spectrum of activities, including gastric motility and acid secretion, activity of the pancreas, and the secretion of growth hormone, prolactin, and ACTH.<sup>55</sup>

Ghrelin is a 28-amino acid peptide discovered in 1999 that is secreted mainly in the upper portion of the stomach, but in other tissues as well, including the intestine, pituitary, hypothalamus, kidney, ovary, testis, and placenta.<sup>56</sup> The ghrelin circulating in the blood is predominantly from the stomach and intestine, and its target is the energy-regulating centers in the hypothalamus. Given to rodents, ghrelin acutely increases food intake and causes obesity. These actions of ghrelin are independent of its activity in stimulating growth hormone, prolactin, and ACTH secretion, an action that is probably mediated by different ghrelin receptors.<sup>57</sup> The targeted neurons are in the same network influenced by leptin (principally the NPY/AgRP and POMC), with ghrelin and leptin having opposing actions. Another stomach hormone, PYY, acts in a similar fashion as leptin, reducing food intake by modifying the NPY/AgRP system; this leaves ghrelin as the only hormone known that stimulates food intake.<sup>58</sup>

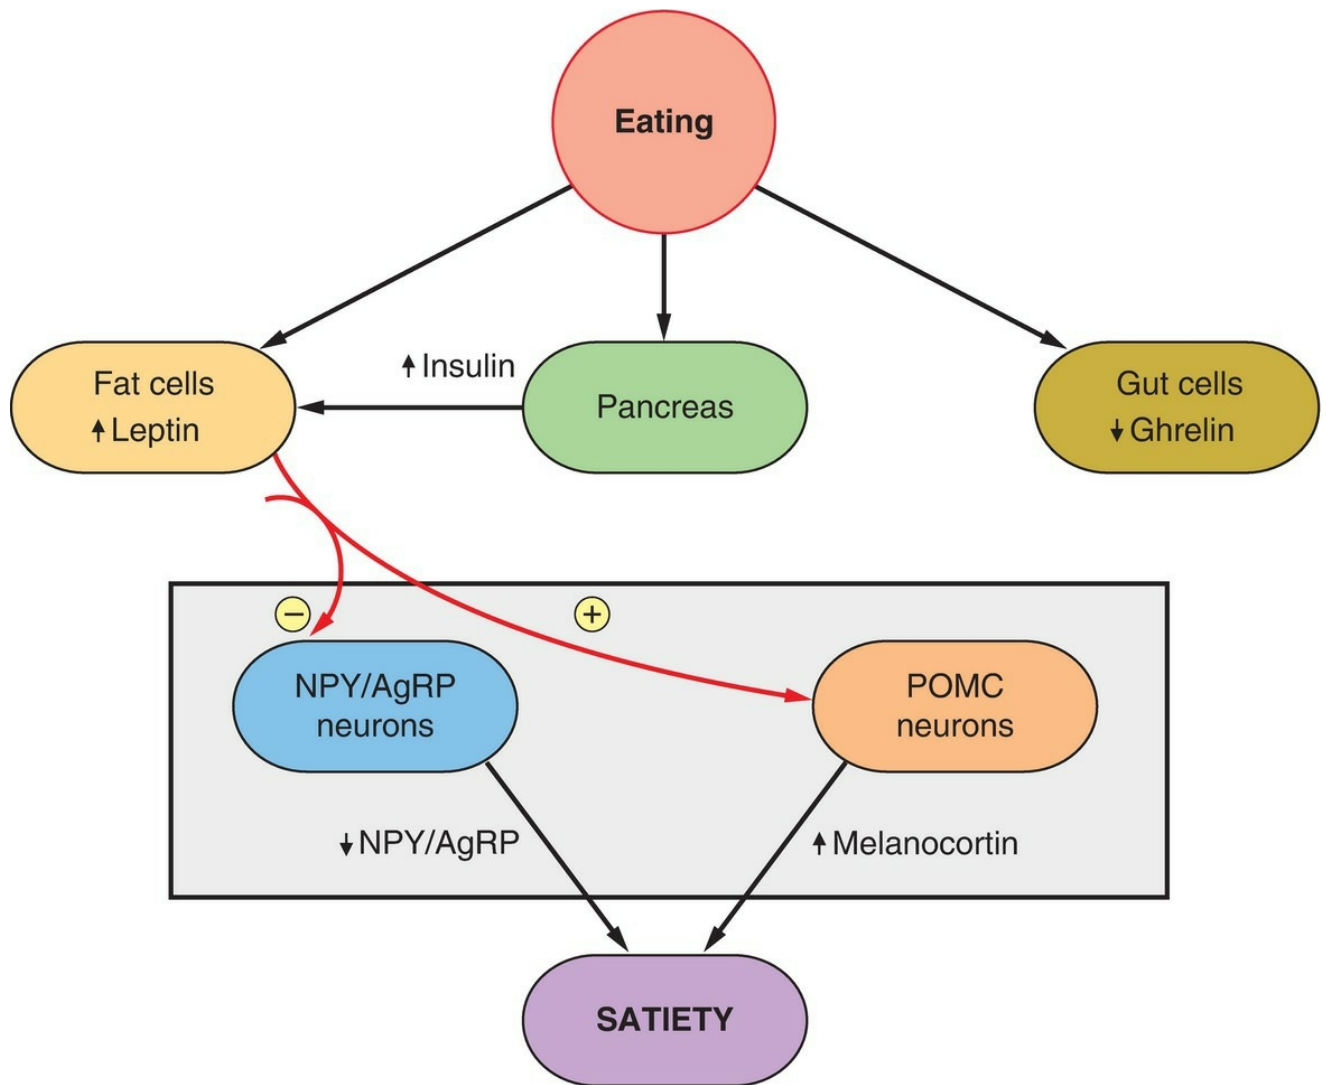

The circulating level of ghrelin is lower in obese individuals, reduced with food intake and increased with fasting. Thus, ghrelin levels are higher in individuals with anorexia, bulimia, or cachexia, and, in contrast to its appetite-stimulating action in healthy individuals and in patients with cancer cachexia, administration of ghrelin intravenously to young women with anorexia nervosa does not increase appetite.<sup>59,60,61</sup> These changes are opposite to those of leptin. Ghrelin is a signal to conserve energy by increasing appetite; leptin (and insulin) is a signal to expend energy.<sup>59</sup> The key regulator in these responses is the circulating glucose level, but in the case of ghrelin, the system is influenced by meals, whereas leptin is modulated by fat mass. **The connection**

**between reproduction and the body's state of energy metabolism is now well established, and the complex leptin-ghrelin system is the means of communication. Specifically, ghrelin exerts a CNS inhibition to prevent reproduction in the presence of an energy deficit, with leptin and ghrelin operating as reciprocal regulators.<sup>62</sup>**

# The Physiologic Feedback Loop Involving the Arcuate Nucleus

In the hypothalamus, a subset of neurons located in the arcuate nucleus that produce neuropeptide-Y (NPY) and agouti-related peptide (Agrp) play a central role in the promotion of feeding (**Figure 19.5**).<sup>63,64,65,66,67,68,69</sup> NPY is a 36-amino acid polypeptide that is a potent stimulator of eating when injected directly into the rodent brain.<sup>70</sup> NPY has a tyrosine at both ends, hence the use of Y to stand for tyrosine. NPY stimulates food intake, decreases heat production, and increases insulin and cortisol secretion. Agouti-related protein (AgRP), also called Agrp, is a 112-amino acid neuropeptide produced in the brain by the AgRP/NPY neuron. AgRP is expressed primarily in the adrenal gland, subthalamic nucleus, and hypothalamus, with lower levels of expression in the testis, kidneys, and lungs. In the hypothalamus, it is synthesized only in NPY-containing cell bodies located in the ventromedial part of the arcuate nucleus.<sup>71</sup> AgRP was independently identified by two teams in 1997 based on its sequence similarity with agouti signaling peptide (ASIP), a protein synthesized in the skin that controls coat color.<sup>72,73</sup> The NPY/AgRP neurons are activated when the body is lacking sufficient energy, such as during periods of fasting and food deprivation.<sup>74,75,76,77,78</sup> Indeed, when the body has a negative energy balance, glucose levels are lower, and there is increased firing of NPY/AgRP neurons.<sup>79</sup> The appetite-stimulating effects of NPY/AgRP neurons are inhibited by the hormone leptin and activated by the hormone ghrelin.<sup>80,81</sup>

**FIGURE 19.5**

In close proximity to NPY/AgRP neurons, another population of neurons produce pro-opiomelanocortin (POMC) neurons, which has the opposite effect on feeding (**Figure 19.6**).<sup>82,83</sup> POMC neuron activity increases when glucose levels rise, consistent with the role of POMC cells as satiety signaling neurons.<sup>79,84,85,86</sup> Activation of the POMC neurons causes the release of  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) from their axon terminals.  $\alpha$ -MSH activates melanocortin receptor 4 (MC4R) and leading to the suppression of food intake and increased in energy expenditure.<sup>82,87,88</sup> In contrast, activation of NPY/AgRP neurons causes the release of AgRP, which antagonizes the effect of  $\alpha$ -MSH on MC4R.<sup>66,82,87,88,89</sup>

In addition to an antagonistic action on MC4Rs, blocking the effect of anorexigenic melanocortin cells, the NPY/AgRP system also has a direct inhibitory effect on POMC perikarya.<sup>90,91,92</sup> Such inhibition involves NPY and GABA, a small inhibitory amino

acid neurotransmitter.<sup>87,90,91,92,93</sup> This unidirectional interaction between the NPY/AgRP and POMC perikarya is noteworthy as it provides tonic inhibition of the melanocortin cells whenever the NPY/AgRP neurons are active.<sup>91,93,94,95</sup> This anatomical organization might, at least in part, explain why the feeding circuit is more likely to induce feeding rather than satiety. While this bias toward a positive energy balance would be useful from an evolutionary perspective, it is also a likely contributor to the etiology of contemporary metabolic disorders.

Serum glucose and free fatty acid levels that regulate AMP kinase (AMPK) activity and therefore conversion of AMP to ATP impact upon the activities of the orexigenic NPY/AgRP-producing neurons and the anorexigenic POMC/ $\alpha$ -MSH-expressing neurons. In addition to circulating glucose and free fatty acids, the activities of NPY/AgRP and POMC neurons are also regulated by peripheral metabolic regulatory hormones—including leptin, ghrelin, and insulin—that respond to the metabolic state of the organism.

Leptin, which is secreted primarily by the adipose tissue in proportion to adipose tissue mass, and suppresses appetite, enhances POMC neuron activity via both pre- and postsynaptic modes of action, whereas the orexigenic NPY/AgRP neurons' activity is diminished by leptin.<sup>87,96,97</sup> It is noteworthy that leptin, not only acts on existing synapses but also promotes rewiring in the arcuate nucleus, and leptin-mediated plasticity in the hypothalamus may underlie some of the hormone's behavioral effects.<sup>98</sup>

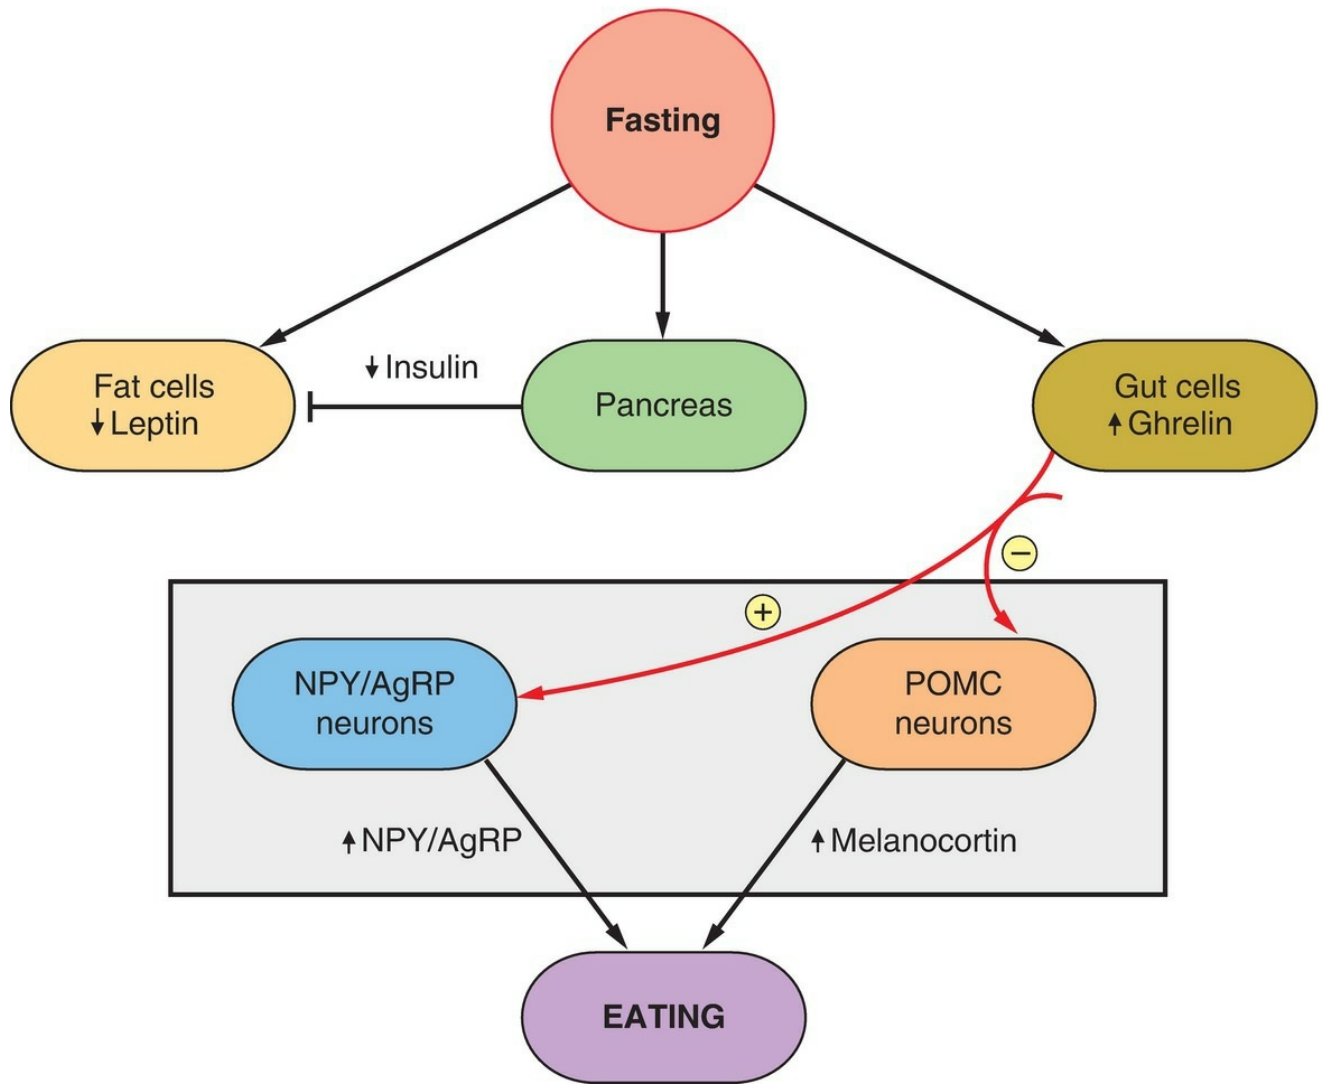

In normal mice, leptin decreases NPY,<sup>99</sup> while in ob/ob mice with no leptin, NPY levels are high in the hypothalamus, and leptin treatment lowers NPY.<sup>48</sup> Fasting and exercise decrease leptin secretion and increase NPY/AgRP expression in the arcuate nucleus. Importantly, fasting decreases leptin more than expected by the decrease in fat content, indicating the presence of other control mechanisms.<sup>100</sup> In most animal models, the NPY content in the hypothalamus is high with obesity, and brain infusions of NPY cause obesity and increased Ob gene expression.<sup>101</sup> In contrast, the gut-derived appetite-stimulating hormone ghrelin is secreted in response to negative energy balance (e.g., fasting) and up-regulates NPY/AgRP neuron activity via a direct mechanism, whereas it decreases the action potential frequency of POMC cells predominantly by a presynaptic mode of action.<sup>102,103</sup> The pancreas-derived hormone insulin was also shown to affect neuronal activity in the arcuate nucleus, possibly acting on ATP-sensitive potassium channels.<sup>104</sup>

A number of studies using mouse knockout models support the conclusion that the activities of metabolic hormones and NPY/AgRP and POMC neurons are required for the regulation of energy metabolism. The deficiency of POMC-derived peptides results in partially penetrant embryonic lethality. These mice also show obesity, in addition to a

defective adrenal development and altered pigmentation.<sup>105</sup> MC4R knockouts exhibit obesity, hyperphagia, insulin resistance, hyperinsulinemia, and hyperglycemia,<sup>40,44,106,107</sup> while MC3R knockouts develop metabolic syndrome with increased adipose mass and decreased energy expenditure.<sup>108</sup> Mice lacking NPY have increased sensitivity to leptin and susceptibility to seizures.<sup>109</sup> While early deletion of AgRP or both AgRP and NPY does not seem to significantly alter energy metabolism, ablation of Agrp neurons in adult mice results in anorexia and death.<sup>110,111,112</sup> As previously discussed, mice homozygous for leptin mutation (Ob/Ob) are obese, have high metabolic efficiency, impaired thermogenesis, short life span, and abnormalities in many organ systems including the cardiovascular, respiratory, nervous, and gastrointestinal systems.<sup>113</sup> Similarly, mice deficient in leptin receptor are also obese, hyperinsulinemic, and hyperglycemic.<sup>114,115</sup> In contrast, when placed on regular diet, ghrelin knockouts do not demonstrate phenotypic abnormalities, while they display increased utilization of fat as an energy substrate on a high fat diet and enhanced glucose-induced insulin release.<sup>116,117</sup>

## Leptin and Insulin

In rodents, insulin increases the expression of the Ob gene, but there is controversy in humans.<sup>47</sup> In humans, there is no acute surge of leptin after meals, and the administration of insulin does not stimulate an acute increase in leptin levels. Indeed, in the human, the LEP gene does not appear to be acutely regulated; feeding increases leptin levels, but slowly, correlating with insulin levels.<sup>118,119,120</sup> An increase in LEP gene expression also occurs in humans with chronic insulin stimulation, a situation that would be similar to overeating.<sup>121</sup> It is likely that insulin is at least one regulator of the LEP gene and its secretion of leptin. It is noteworthy that insulin provides negative feedback to the brain in a manner similar to leptin, including an effect on NPY (**Figure 19.6**).<sup>70</sup> The hyperphagia of diabetes mellitus reflects a deficiency in this insulin action. In fa/fa rats (obese because of a mutation in the leptin receptor), insulin does not affect NPY expression, indicating that the inhibition of NPY exerted by insulin is mediated through the leptin-signaling system.<sup>122</sup>

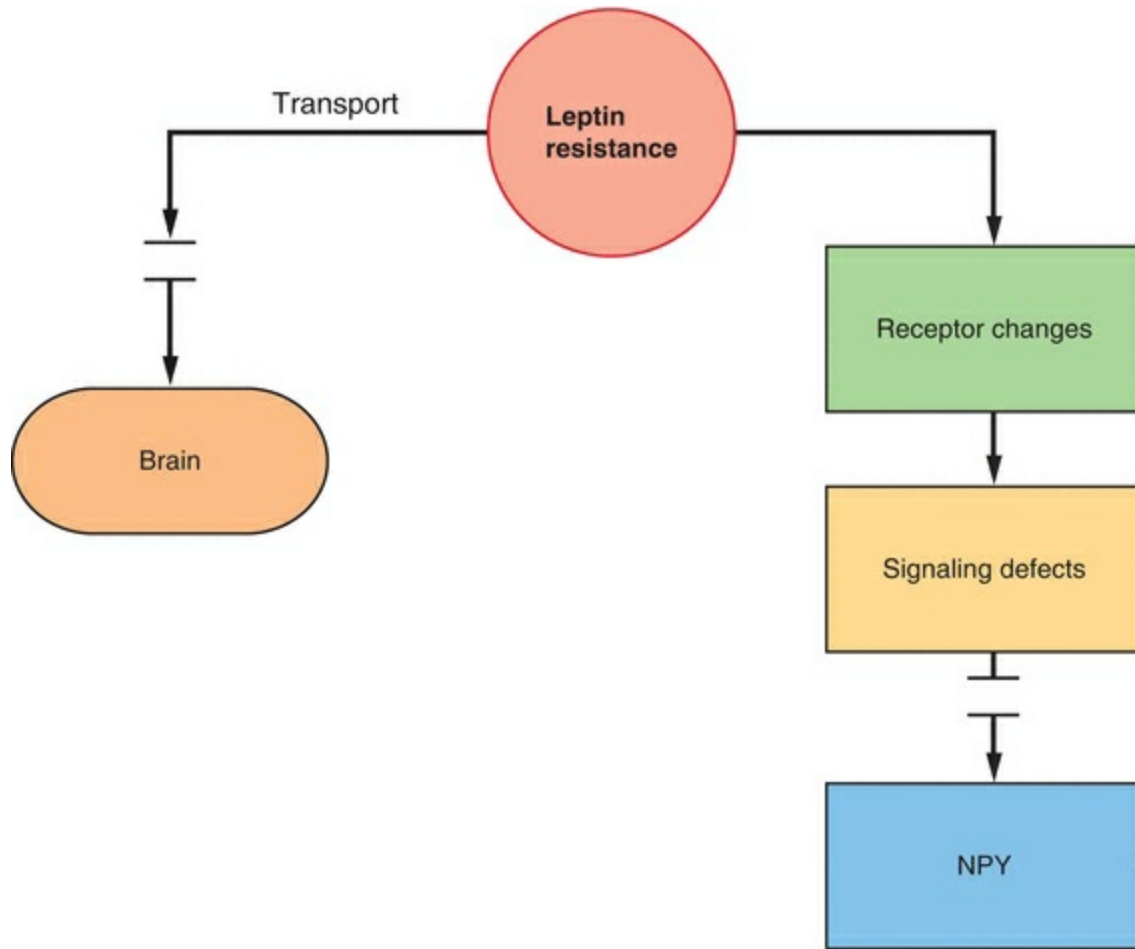

**FIGURE 19.6**

# Leptin in Obese People

Most studies have indicated that nearly all obese individuals have elevated leptin levels, probably due to an increase in LEP gene expression and partly due to greater production because of larger fat cells.<sup>123,124,125</sup> The greater weight of these individuals represents the leptin level at which stability is achieved. In lean individuals, leptin levels are similar in men and women, but in women, as weight increases, leptin increases 3 times more rapidly than in men.<sup>126</sup> Higher levels in women suggest a greater resistance to leptin, correlating with a greater prevalence of obesity.<sup>127</sup>

The incidence of obesity in black and Hispanic women is greater than that of white women.<sup>1</sup> Obese postmenopausal black women have 20% lower leptin levels than white women.<sup>128</sup> These lower leptin levels correlate with a lower resting metabolic rate in the black women. The lower levels may indicate a greater sensitivity to the leptin mechanism in black women.

In obese individuals, fat cells produce leptin normally, and a prevalent genetic failure has not been identified. **Thus, it is hypothesized that obesity is due to resistance to leptin.**<sup>129</sup> This may be due to a transport problem of leptin into the brain, as indicated by the finding that leptin level differences between obese and lean individuals are greater in blood than in cerebrospinal fluid.<sup>130,131</sup> At least in the mouse, this resistance is present only in the periphery in that leptin administered in the brain still works<sup>132</sup> (**Figure 19.7**).

**FIGURE 19.7**

In obese individuals, the majority of leptin is unbound and presumably active, consistent with the resistance hypothesis.<sup>133</sup> In lean individuals, the majority of circulating leptin is bound. Another important subject for research is the regulation of leptin binding to proteins in the circulation.

# Why Is Weight Loss So Hard to Maintain?

The average adult eats nearly 1 million calories per year.<sup>41</sup> When life was tougher, leptin served the purpose of meeting the threat of starvation. During periods of food availability, individuals with leptin defects could consume large amounts and store excess fat. Today, with no shortage of food, the individuals who survived during food shortages in the past now become obese, and succumb to the complications of obesity. But the most vexing problem is that 90–95% of people who lose weight subsequently regain it.<sup>134</sup>

Weight loss in obese and lean people produces the same response, decreased leptin and insulin, and an increase in ghrelin. The obese person tends to regain weight because the lower leptin started from a different set point and is now lower than what the body views as required to be stable in terms of the amount of fat. The ghrelin response also makes it more difficult by stimulating appetite. When energy expenditure, food intake, and body weight are in balance, leptin and ghrelin are at a level consistent with a set point determined by this balance. With weight loss and loss of fat, leptin decreases and ghrelin increases, causing an increase in appetite and a decrease in energy. This is great when you lose weight with an illness, but not good for an overweight person trying to lose weight. Whenever a perturbation occurs, leptin and ghrelin levels change to restore the original status quo, making it difficult for overweight people to maintain weight loss. With both sustained weight loss and persistent weight gain, hormonal mechanisms as well as energy adjustments to maintain lower or higher body weights eventually lead to new set points. However, in the short-term, weight loss can be maintained only by a strict diet or an increase in physical activity to overcome the body's attempt to restore the original set point.

Circulating levels of leptin are correlated with the percent body fat.<sup>123</sup> In other words, increased body fat increases the expression of the LEP gene in fat cells. The amount of leptin in the circulation, therefore, is a measure of the amount of adipose tissue in the body. For this reason, neither baseline levels nor initial changes in leptin predict whether weight loss can be maintained.<sup>135</sup>

A reduction of 10% in body weight is associated with a 53% reduction in serum leptin.<sup>123</sup> This would stimulate an effort to regain the weight. The key question is what happens if an individual can successfully maintain the lower weight. In a longitudinal study of obese people, when weight loss was maintained, leptin levels remained low.<sup>136</sup>

**Whenever a perturbation occurs, leptin and ghrelin levels change to restore the original status quo; these responses work against attempts to lose weight. A change in energy intake causes a change in leptin levels.<sup>122</sup> The body then changes**

**appetite and energy expenditure to conform to the new leptin level. A 10% increase in body weight is associated with a 300% increase in serum leptin.<sup>119</sup> The basic purpose is to conserve energy during periods of fasting and to avoid obesity during periods of excess. When caloric intake is reduced, the basal metabolic rate is reduced in a regulatory compensatory adaptation that makes maintenance of weight loss difficult.**

# Congenital Leptin Deficiency

The LEP gene (Ob gene in mice) has been sequenced from hundreds of obese individuals, and mutations are rare.<sup>129,137</sup>

The first definitive demonstration of a congenital leptin deficiency in humans was reported in two severely obese Pakistani children who were cousins.<sup>138</sup> Despite their mass of fat, their serum leptin levels were very low, and the molecular biology study of a fat biopsy revealed a homozygous deletion of a single guanine in the leptin gene. This mutation results in the introduction of 14 aberrant amino acids into the leptin peptide followed by a premature truncation. All four parents were heterozygotes. These children had normal birth weights, but immediately began gaining excessive weight with marked increases in appetites. In contrast to ob/ob mice, they did not have elevated cortisol levels; however, they were hyperinsulinemic. Three obese members of a Turkish family were reported with an amino acid substitution that impairs intracellular transport of leptin.<sup>139</sup> It is noteworthy that these individuals also displayed suppression of gonadal function. Congenital leptin deficiency is now recognized as a rare recessive inherited disorder, the result of mutations at various sites on the LEP gene and associated with hyperphagia and the onset of obesity at an early age.<sup>140</sup> Polymorphisms have been described in both the leptin gene and the leptin receptor gene, more prevalent in extremely obese patients, but a relatively low overall prevalence in obese individuals.<sup>141</sup>

With the complexity of the system for energy regulation and the large number of hormones and enzymes involved, we can expect to see multiple mutations identified. An obese individual was reported with a mutation in prohormone convertase (an enzyme that participates in the conversion of prohormones into hormones as does the carboxypeptidase E enzyme deficient in the fat/fat mouse).<sup>142</sup> Linkages to obesity have been described to regions near the leptin gene or the leptin receptor gene, perhaps indicating differences in regulatory elements of these genes.<sup>143</sup> Remember that melanocortin peptides, along with NPY, are part of the leptin signaling pathway in the hypothalamus. Mutations in the melanocortin 4 receptor gene<sup>144</sup> are said to be the most frequent monogenetic cause of obesity, yet the 1% or 2% prevalence of this mutation in obese individuals is insufficient to warrant screening.<sup>145</sup> It is noteworthy that obese children with melanocortin 4 receptor gene mutations were able to lose weight with lifestyle interventions, but had greater difficulty in maintaining their weight loss.<sup>146</sup>

**It is expected that only a small percentage (<5%) of obese humans will have mutations in the leptin receptor or the LEP gene, but congenital leptin deficiency of the leptin receptor should be considered in children with hyperphagia and severe**

obesity.

## Leptin and Reproduction

Several observations support a role for leptin in reproductive physiology.

### Key Points

- Leptin administration accelerates the onset of puberty in rodents.<sup>147</sup>
- Leptin levels increase at puberty in boys.<sup>148</sup> Indeed, nocturnal levels of leptin increase in monkeys before the nocturnal increase in pulsatile secretion of LH.<sup>149</sup>
- Low leptin levels are present in athletes and in patients with anorexia and delayed puberty.<sup>150</sup>
- The ob/ob mouse undergoes normal sexual development but remains prepubertal and never ovulates; fertility is restored with leptin administration.<sup>147</sup> A similar presentation and response were reported in a child with congenital leptin deficiency.<sup>151</sup>

Leptin levels are greater in females than in males, and in premenopausal women compared with postmenopausal women.<sup>152</sup> In girls, leptin levels are higher and decrease with increasing Tanner stages of puberty.<sup>153</sup> Thus with puberty, there is increasing sensitivity to leptin. Or in another way to look at this relationship, decreasing leptin during puberty may allow greater food intake for growth by lowering the satiety signal.

The effect of leptin on reproduction can be viewed as an additional role in maintaining responses to stress. Weight loss is known to be associated with an increased adrenal response and a decrease in thyroid function; these endocrine changes, along with suppression of the estrous cycle, occur in fasted mice and are reversed by treatment with leptin.<sup>154</sup>

The puzzle is why CRH is elevated in stress amenorrhea (especially that associated with weight loss) in contrast to the decrease with fasting in normal and obese individuals. One possibility is that the decrease in leptin and increase in NPY associated with stress-related weight loss is the expected response, but it is inadequate to suppress the stress-induced increase in CRH. The blunted patterns in amenorrheic athletes support this. The increase in CRH and resulting hypercortisolism further increase metabolism and weight loss.

Athletes with cyclic menses demonstrate a normal diurnal rhythm in leptin levels. However, amenorrheic athletes do not have a diurnal pattern.<sup>155</sup> Both cycling athletes and amenorrheic athletes have low leptin levels (threefold reduction) that correlate with reduced body fat, but the levels are further lowered by hypoinsulinemia and hypercortisolemia. In addition, amenorrheic athletes have a blunted leptin response to the increase in insulin following meals. In postmenopausal women, leptin levels decrease with endurance training, and hormone therapy has no effect.<sup>156</sup> This indicates that the gender difference (higher levels in women) is due to a difference in fat content, not a hormonal difference.

Because of the tight connection between insulin and leptin levels in mice, and the now well-recognized prevalence of hyperinsulinemia in women with polycystic ovaries, it makes sense to investigate leptin levels in these women. Studies, controlling for weight, detected no differences in leptin levels comparing women with and without polycystic ovaries.<sup>157,158,159,160</sup> In women with polycystic ovaries, the relationship between leptin and body weight is maintained. Thus, in contrast to the rodent model, hyperinsulinemia and insulin resistance do not affect leptin levels in these women. However, a role for leptin in the changes associated with polycystic ovaries should not yet be discounted. There may be subtle differences that have biologic consequences. At least one study demonstrated a correlation between leptin levels and 24-hour insulin levels in women with polycystic ovaries.<sup>157</sup> Furthermore, a drug that lowers insulin resistance, troglitazone, inhibits transcription of the LEP gene.<sup>161</sup>

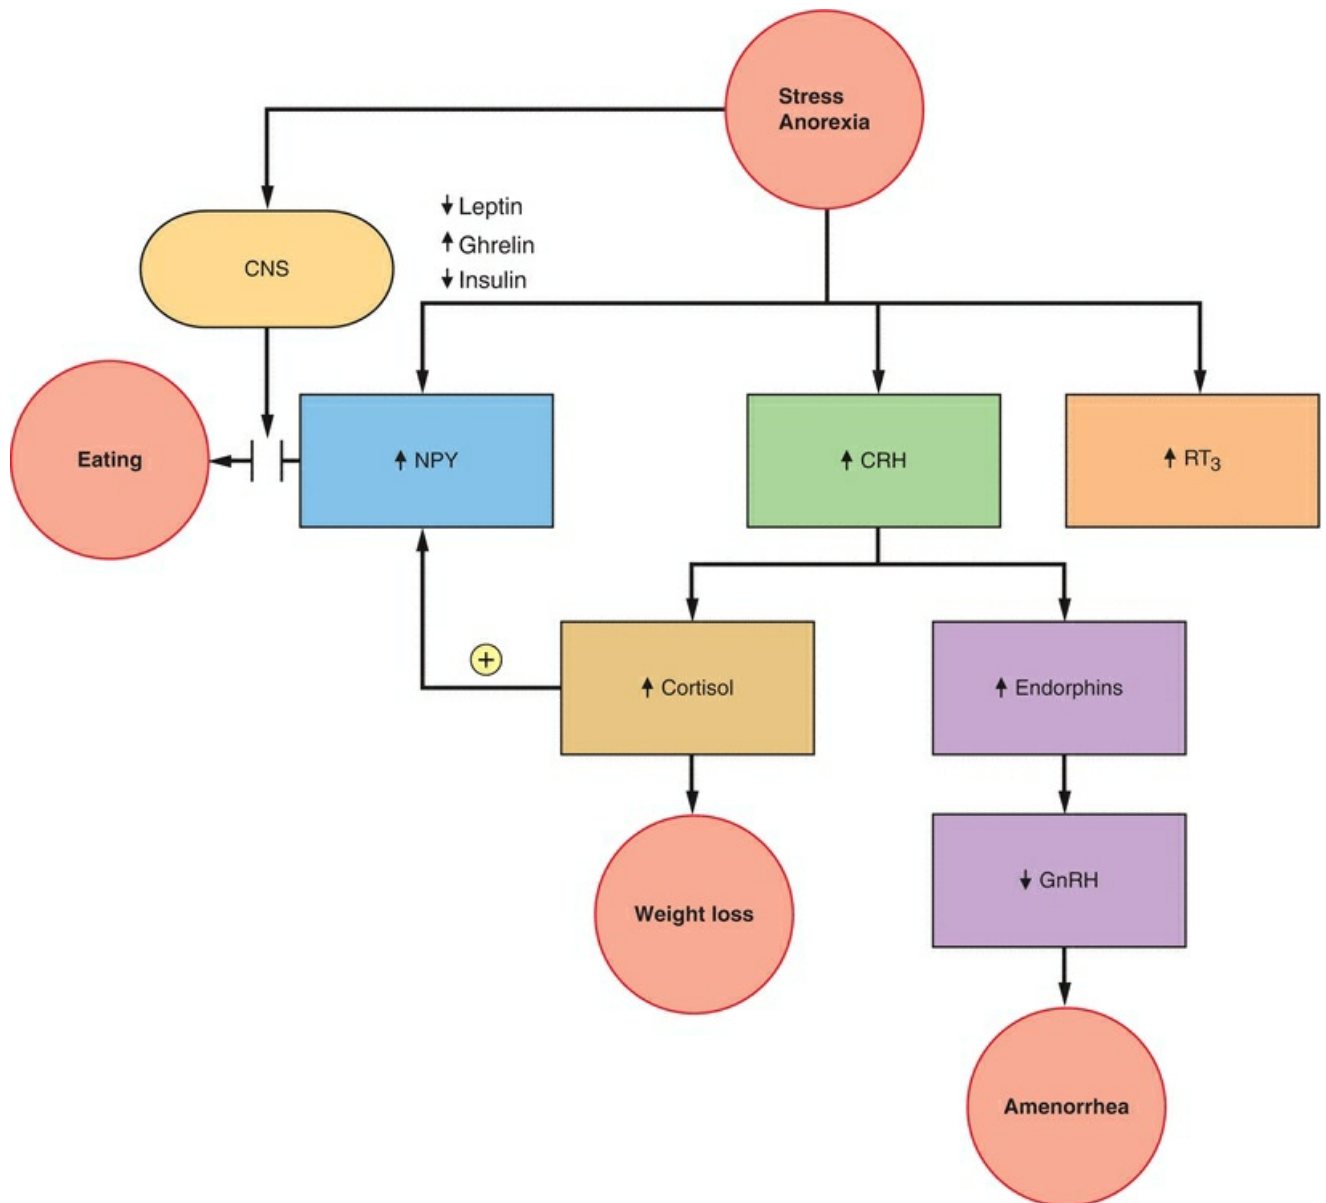

Is it possible that leptin has a target tissue role in reproduction? An isoform of leptin has been identified in the ovary, and leptin exerts specific actions on steroidogenesis as studied *in vitro*.<sup>162,163</sup> Leptin inhibits the synergistic action of insulin-like growth factor-I (IGF-I) on FSH-stimulated estradiol production (but not progesterone) in rat granulosa cells and also inhibits FSH stimulation of IGF-I production. In addition, leptin is expressed in human granulosa and cumulus cells and is present in mature human oocytes and follicular fluid; thus, leptin appears to be secreted by the ovarian follicle.<sup>164</sup> A rise in maternal serum leptin levels after the administration of human chorionic gonadotropin and before ovum retrieval was correlated with a higher pregnancy rate.<sup>164</sup> Leptin, therefore, is involved in a multitude of important metabolic and developmental functions.

The leptin-ghrelin story has restored credibility to the critical weight hypothesis originally proposed by Rose Frisch in the 1970s.<sup>165,166</sup> The critical weight hypothesis states that the onset and regularity of menstrual function necessitate maintaining weight above a critical level, and, therefore, above a critical amount of body fat. It was always a mystery how total body fat could talk with the brain. A mystery no longer! Fat talks to the brain via leptin, and the leptin system affects reproduction. Recombinant human

leptin administration to women with hypothalamic amenorrhea secondary to exercise or weight loss was associated with an increase in the levels of gonadotropins, free thyroxine, and insulin-like growth factor, with a resumption of ovarian activity.<sup>167</sup> In addition, ghrelin secretion by the gastro-intestinal tract is involved in this balancing mechanism. Ghrelin levels are increased in anorectic patients, along with elevations in cortisol.<sup>168</sup>

There is a difference, however, between ordinary weight loss and stress-induced (e.g., exercise or psychologic problems such as anorexia) weight loss. In ordinary weight loss, CRH secretion is reduced. In stress-induced weight loss, CRH secretion is increased.

CRH directly inhibits hypothalamic gonadotropin-releasing hormone (GnRH) secretion, probably by augmenting endogenous opioid secretion. Women with hypothalamic amenorrhea (including exercisers and women with eating disorders) demonstrate hypercortisolism (due to increased CRH and ACTH, perhaps augmented by NPY stimulation of ACTH secretion), suggesting that this is the pathway by which stress interrupts reproductive function.<sup>169</sup> The modulating effect of the leptin-ghrelin system appears to be mediated through CRH.<sup>170</sup> In addition, NPY and AgRP directly inhibit gonadotropin release by suppressing GnRH.<sup>171</sup> In regard to reproduction, the final pathway is suppression of GnRH, a response to multiple inputs indicating the availability of metabolic fuel. The clinical presentation (inadequate luteal phase, anovulation, amenorrhea) depends on the degree of GnRH suppression. Nevertheless, stress and weight loss–induced suppression of reproductive function is associated with low leptin levels, and administration of leptin improves function.<sup>167,172</sup> Unfortunately, the administration of leptin in these patients further suppresses appetite and increases weight loss<sup>167</sup> (**Figure 19.8**).

**FIGURE 19.8**

A unifying hypothesis focuses on energy balance.<sup>173</sup> When available energy is excessively diverted, as in exercise, or when insufficient, as with eating disorders, reproduction is suspended in order to support essential metabolism for survival. Thus, reproduction may not be directly affected by the level of body fat; rather, body fat is a marker of the metabolic energy state, and the extremely low leptin levels in anorexic patients are an appropriate attempt to restore appetite, an attempt that fails to overcome the stress-induced increase in CRH and its consequences. From a teleologic point of view, there is sense to these relationships; the responses that assist the body to withstand stress also inhibit menstrual function because a stressful period is not the ideal time for reproduction.

# Leptin Summary

Because of the high levels of leptin present in overweight people, leptin function may be limited to an effect at low levels. A low circulating level of leptin may serve as a signal that fat stores are not sufficient for growth and reproduction. Thus, low levels would ordinarily stimulate hyperphagia, reduce energy expenditure, and suppress gonadotropin secretion and reproduction. The high levels of leptin and the lack of leptin action associated with excess body weight and fat would then reflect resistance.

Although the leptin-ghrelin mechanism offers the potential for new treatments for obesity, it is not around the corner. Leptin, a polypeptide, cannot be administered orally, and in view of high levels in overweight people, another method must be found to attack the lack of effect, the apparent resistance to leptin. Thus far, it appears that genetic defects in the LEP gene are uncommon; nevertheless, for affected individuals, a leptin agonist is therapeutic. Even if this complex system yields new treatments, it is unlikely that we will be able to ignore eating appropriately and exercising adequately.

# INHERITED ASPECTS OF OBESITY

---

Fat cells develop from connective tissue early in fetal life. An important question is whether new fat cells are produced by metaplasia in the adult, or whether an individual achieves a total complement during a certain period of life. In other words, is excess fat stored by increasing the size of the fat cell, or by increasing the number of cells? The possibility arises that there is an inherited increase in the total number of fat cells, which just wait to be packed full of storage fat. Furthermore, the total number of fat cells may depend on an infant's nutritional state during the neonatal period and perhaps in utero as well.

Studies of fat obtained at surgery indicate that the mean fat cell volume is increased threefold in obese people, but an increase in the number of fat cells is seen only in the grossly obese. When patients diet, the fat cells decrease in size but not in number. Hypercellular obesity may be a more difficult problem to overcome, because an individual may be saddled with a permanent increase in fat cells.

Some researchers think that, at some period in a person's life, a fixed number of fat cells is obtained. Adolescence, infancy, and intrauterine life seem particularly critical.<sup>174,175</sup> This premise is not solidly established, because there is no certain way to identify an empty fat cell, and potential fat cells cannot be recognized. Nevertheless, a hyperplastic type of obesity (more fat cells) may be associated with childhood and have a poor prognosis; a hypertrophic type (enlarged fat cells) that is responsive to dieting may occur in adults.

There certainly appears to be a genetic component. The weights of adopted children in Denmark correlated with the body weights of their biologic parents but not with their adoptive parents.<sup>176</sup> This would suggest that the genetic influence is even more important in childhood than environmental factors. Other work suggests that the familial occurrence of obesity can be attributed in part to a genetically related reduced rate of energy expenditure.<sup>177</sup> In studies of identical and fraternal twins reared apart, approximately 70% of the variance in the BMI could be assigned to genetic influences and the remaining 30% to environmental effects.<sup>178</sup> After the age of 3, obesity in childhood predicts obesity in adulthood, and parental obesity doubles the risk of adult obesity in both obese and nonobese children.<sup>179</sup>

Some argue that each individual has a set point, a level regulated by a signal between the fat cells and the brain (the leptin system). According to this argument, previously obese people who have successfully lost weight have to maintain themselves in a state of starvation (at least as far as their fat cells are concerned).

Genetics and biochemistry are against many obese people. It is best to recognize

that an obese individual who has suffered with the problem lifelong does have a disorder. However, for each individual, the extent to which the genetic predisposition is expressed depends on environmental influences. The prevalence of obesity is inversely related to the level of physical activity and directly related to parity.<sup>180</sup> Obesity prevalence is also associated with income and educational level, although patterns might differ between high-income and low-income countries. Using data from the National Health and Nutrition Examination Survey (NHANES), CDC analyzed obesity prevalence among adults in the United States (aged  $\geq 20$  years) by three levels of household income, based on percentage ( $\leq 130\%$ ,  $>130\%$  to  $\leq 350\%$ , and  $>350\%$ ) of the federal poverty level (FPL) and individual education level (high school graduate or less, some college, and college graduate). During 2011–2014, the age-adjusted prevalence of obesity among adults was lower in the highest income group (31.2%) than the other groups (40.8% [ $>130\%$  to  $\leq 350\%$ ] and 39.0% [ $\leq 130\%$ ]). The age-adjusted prevalence of obesity among college graduates was lower (27.8%) than among those with some college (40.6%) and those who were high school graduates or less (40.0%).<sup>181</sup> Similarly, the prevalence of obesity among U.S. youths (2–19 years old) was lower in the highest income group (10.9%) than in the other groups (19.9% and 18.9%) and also lower in the highest education group (9.6%) than in the other groups (18.3% and 21.6%), grouped based on head of household education.<sup>182</sup> Thus, socioeconomic and behavioral factors are important determinants of body weight, and surely, each individual will reflect varying impacts of genetics and environment.

# ENDOCRINE CHANGES

---

The most important endocrine change in obesity is elevation of the basal blood insulin level. The circulating insulin level is proportional to the volume of body fat. Increases in body fat change the body's secretion and sensitivity to insulin, appropriately so because insulin acts to reduce food intake by inhibiting the expression of NPY/AgRP as well as affecting other agents that influence appetite.<sup>122</sup> The effect on NPY/AgRP is believed to be mediated via the leptin signaling system.

Overweight individuals are characterized by insulin resistance. The key factors that affect insulin resistance are the amount of fat tissue in the body, the caloric intake per day, the amount of carbohydrates in the diet, and the amount of daily exercise. At least one mechanism for the increased resistance to insulin observed with increasing weight is down-regulation of insulin receptors brought about by the increase in insulin secretion. The increase in insulin resistance affects the metabolism of carbohydrate, fat, and protein. Circulating levels of free fatty acids increase as a result of inadequate insulin suppression of the fat cell. Insulin resistance results in decreased catabolism of triglycerides, yielding a decrease in HDL cholesterol and an increase in LDL cholesterol. This, of course, is a major mechanism for the development of atherosclerosis. Hyperinsulinemia is also directly associated with hypertension. The hyperinsulinemia associated with obesity is reversible with weight loss. **A significant improvement is achieved with a modest weight loss, only 5–10% of body weight.**

The metabolic syndrome is a serious complication of excess body weight; 60% of obese men and women have the metabolic syndrome.<sup>15</sup> Individuals with the metabolic syndrome have a very high risk of diabetes and cardiovascular disease. **The diagnosis of the metabolic syndrome in an individual requires that three abnormal findings are present out of the five following clinical characteristics<sup>183</sup>:**

- **Hypertension: 130/85 or higher**
- **Triglyceride level: 150 mg/dL or higher**
- **HDL cholesterol levels: less than 50 mg/dL**
- **Abdominal obesity: greater than 35 inches (40 inches in men) waist circumference**
- **Fasting glucose: 110 mg/dL or higher**

**Because of the variability associated with measurements of insulin, the fasting glucose to fasting insulin ratio is no longer recommended to establish the presence of insulin resistance; a 2-hour oral glucose tolerance test is now the preferred method of assessment, with measurement of 2-hour glucose and insulin levels after**

**a 75-g glucose load.**

**Interpretation of the 2-hour glucose response:**

- **Normal: less than 140 mg/dL**
- **Impaired: 140–199 mg/dL**
- **Non–insulin-dependent diabetes mellitus: 200 mg/dL and higher**

**Interpretation of the 2-hour insulin response:**

- **Insulin resistance very likely: 100–150 U/mL**
- **Insulin resistance: 151–300 U/mL**
- **Severe insulin resistance: greater than 300 U/mL**

It is impossible to predict exactly who eventually will develop diabetes because the tendency is recessive, and it will not develop in every generation in a family. But weight is a good tip-off. As weight increases, the frequency of occurrence of diabetes increases. Both gestational diabetes and insulin-dependent diabetes are more common in overweight pregnant patients.

Contrary to popular misconception, hypothyroidism does not cause obesity. Weight gain due to hypothyroidism is confined to the fluid accumulation of myxedema. There is no place, therefore, for thyroid hormone administration in the treatment of obesity when the patient is euthyroid.

The basic question is whether metabolic changes observed in obesity represent adaptive responses to a markedly enlarged fat organ or whether they are representative of a metabolic or hormonal defect. The former is true. These changes are secondary responses; they are totally reversible with weight loss. Four-year follow-up in a group of patients who did not regain their weight after dieting revealed persistently normal insulin and glucose responses; patients who regained their weight showed further deterioration in these metabolic factors.<sup>184</sup>

# ANATOMIC OBESITY

---

Gynoid obesity (the pear shape) refers to fat distribution in the lower body (femoral and gluteal regions), whereas android obesity (the apple shape) refers to central body distribution. Gynoid fat is more resistant to catecholamines and more sensitive to insulin than abdominal fat; thus, extraction and storage of fatty acids easily occur, and fat is accumulated more readily in the thighs and buttocks. This fat is associated with minimal fatty acid flux, and, therefore, the negative consequences of fatty acid metabolism are less. Gynoid fat is principally stored fat. The clinical meaning of all this is that women with gynoid obesity are less likely than women with android obesity to develop diabetes mellitus and coronary heart disease.<sup>185</sup>

During pregnancy, lipoprotein lipase activity increases in gynoid fat, further promoting fat storage and explaining the tendency for women to gain thigh and hip weight during pregnancy. Also, because this fat is more resistant to mobilization, it is harder to get rid of. This difficulty is related to the adrenergic receptor concentration in the fat cells, the regulation of which remains a mystery.

Android obesity refers to fat located in the abdominal wall and visceral-mesenteric locations. This fat is more sensitive to catecholamines and less sensitive to insulin and, thus, more active metabolically. It more easily delivers triglyceride to other tissues to meet energy requirements. This fat distribution is associated with hyperinsulinemia, impaired glucose tolerance, diabetes mellitus, an increase in androgen production rates, decreased levels of sex hormone-binding globulin, and increased levels of free testosterone and estradiol.<sup>186,187</sup> In addition, women with central obesity have decreased cortisol levels, a finding that would be consistent with increased leptin levels.<sup>188,189</sup> These metabolic changes improve with weight loss.<sup>189</sup>

It is central body obesity that is associated with cardiovascular risk factors, including hypertension and adverse cholesterol-lipoprotein profiles.<sup>190</sup> The waist/hip ratio is a variable strongly and inversely associated with the level of HDL<sub>2</sub>, the fraction of HDL cholesterol most consistently linked with protection from cardiovascular disease.<sup>191</sup> The adverse impact of excess weight in adolescence can be explained by the fact that deposition of fat in adolescence is largely central in location.<sup>18,192</sup> Weight loss in women with lower body obesity is mainly cosmetic, whereas loss of central body weight is more important for general health in that an improvement in cardiovascular risk is associated with loss of central body fat. At any given level of BMI, an increase in central, android fat increases the risk of cardiovascular disease.

# Estimating Central Body Obesity

The waist/hip ratio is a means of estimating the degree of upper to lower body obesity; the ratio accurately predicts the amount of intraabdominal fat (which is greater with android obesity).<sup>193,194</sup> However, studies have demonstrated that the more easily determined circumference of the waist, measured just above the hip bones at end of expiration, is a better predictor of central, android abdominal fat.<sup>195,196</sup> **A waist circumference greater than 102 cm (about 40 inches) in men and 88 cm (about 35 inches) in women is predictive of abnormal endocrinologic and metabolic function and is associated with a major increase in risk of cardiovascular and metabolic diseases.**<sup>195</sup> The risk begins to increase at threshold measurements of 94 cm for men and 80 cm for women.<sup>197,198</sup>

# MANAGEMENT OF OBESITY

---

In addition to not smoking cigarettes, weight reduction is the most important health measure available for reducing the risk of cardiovascular disease. After adjusting for age and smoking, the Nurses' Health Study documented a threefold increase in risk for coronary disease among women with a BMI of 29 or greater.<sup>199</sup> Even women who are mildly or moderately overweight have a substantial increase in coronary risk. In the Nurses' Health Study, 40% of coronary events could be attributed to excessive body weight, and in the heaviest women, 70%. But most importantly, weight loss is followed by a decrease in mortality from all causes, and, especially, a decrease in cardiovascular and cancer mortality.<sup>200</sup>

For most patients, after a routine evaluation to rule out pathology such as diabetes mellitus, the clinician is left with the frustrating task of prescribing a diet. But it is not enough to just prescribe a diet or prescribe an anorexic drug. An effective weight loss program requires commitment from both patient and clinician.

Clinician and patient should agree on the goal of a diet program. Although the clinician may want the patient to reach ideal weight, the patient may be satisfied with less. Motivation is improved when the goals meet both personal and medical objectives. It is realistic to lose 4–5 lb in the 1st month and 20–30 lb in 4–5 months. To achieve a respectable rate of weight loss, intake must be 500–1,000 calories below energy expenditure.<sup>201</sup> But as weight is lost, energy requirements decrease; therefore, unless energy intake decreases, the rate of weight loss will slow. Clinicians and patients need to establish reasonable goals, and only modest changes in diet and activity are necessary.

Despite various fads and diet books, the best diet continues to be a limitation of calories to between 900 and 1,200 calories/day, the actual amount depending on what the individual patient will accept and pursue. When energy intake is less than this, it is very difficult to obtain the recommended levels of vitamins and minerals. A daily vitamin and mineral supplement should be used with very low calorie diets. Randomized, controlled trials concluded that the low-carbohydrate, high-protein, high-fat diet produced a greater weight loss (only a 4-kg difference) in the first 6 months, but after a year, there was no difference compared to a conventional low-calorie, low-fat diet.<sup>202,203</sup> The low-carbohydrate diets produce ketosis, causing significant halitosis.

Ideal diet:

- Carbohydrates—50%
- Protein—15–20%
- Fat—less than 30%

The discouraging aspect is that to lose a pound of fat, the equivalent to a 3,500-calorie intake must be expended. Dieting has to be slow and steady to be effective. Successful programs include behavior modification, frequent visits to the clinician, and involvement of family members. Behavior modification starts with daily recording of activity and behavior related to food intake, followed by the elimination of inappropriate cues (other than hunger) that lead to eating.

Careful studies (performed in hospitalized subjects on metabolic wards) have indicated that the carbohydrate and fat composition of the diet has no effect on the rate of weight loss.<sup>204</sup> Restriction of calories remains the important principle, recognizing that reduction in fat intake is the most effective method of weight loss. The protein-sparing modified fast is a ketogenic regimen providing approximately 800 calories/day. Unsupplemented liquid protein diets have been associated with deaths due to cardiac arrhythmias. The low-calorie diets that use protein and carbohydrate supplemented with minerals and vitamins as the sole source of nutrition are safer but should be used only for severe obesity and under medical supervision.<sup>205</sup> These diets are still potentially dangerous. The other disadvantage to the semistarvation diet is that short-term success does not guarantee long-term weight maintenance. It is reported that at best only one-fourth to one-third of individuals who lose weight by a semistarvation ketogenic regimen plus behavior modification therapy have significant long-term weight reduction.<sup>206</sup> On the other hand, for that one-fourth to one-third, this represents a major accomplishment and is worth doing. Unfortunately, repeated dieting and recidivism have a negative impact. With each episode, the body learns to become more efficient, so that with each diet, weight comes off more slowly and is regained more rapidly.

It is not unusual to encounter patients who claim to be unable to lose weight despite following a diet with less than 1,200 calories/day. In a study of such patients, it was discovered that underreporting of actual food intake and overreporting of physical activity are both common.<sup>207</sup> While it may not be true for all patients, certainly some individuals do eat more than they think and exercise less than they report to their clinicians. This is not a deliberate conscious attempt to deceive the clinician. These patients truly believe that their resistance to weight loss is genetic and not due to their own personal behavior. They are astonished and distressed to learn the results of accurate recording of dietary intake and physical exercise. The help of a dietitian in recording a typical week's worth of eating and exercise is worthwhile. This kind of knowledge proves to be a powerful lever in providing the motivation to make the changes in lifestyle that can yield loss of weight.

Although most efforts yield short-term success, maintenance of weight loss is uncommon. Commercial organizations are no more successful than physician-directed programs or nonprofit self-help groups.<sup>208,209</sup> However, randomized trials demonstrated

that commercial programs or weight loss medications that include group support and lifestyle changes are more effective, achieving modest but clinically significant improvements.<sup>210,211,212,213,214</sup> Approximately 90–95% of people who lose weight subsequently regain it.<sup>134</sup> Thus, it is obvious why gimmicks abound in this area of patient management. A more reasonable attitude is to emphasize how much can be gained with only a little weight loss. A weight loss of 5–10% of body weight produces beneficial effects on the risks of cardiovascular disease and diabetes mellitus.<sup>200,215</sup> Compliance and caloric intake are more important than the specific dietary composition or reputation. In the U.S. Diabetes Prevention Program randomized clinical trial, intensive lifestyle interventions were more effective than prophylactic metformin treatment in reducing the incidence of diabetes.<sup>216</sup> Ten years after the initiation of the trial, the cumulative incidence of diabetes was reduced by 34% by lifestyle interventions and 18% in the metformin group.<sup>217</sup> These data demonstrate that there are substantial numbers of overweight individuals who can sustain long-term weight reduction when effective support and guidance are provided.

Unfortunately, smoking cessation is associated with an increase in being overweight.<sup>218</sup> And, of course, the link between smoking and weight control is exploited by the tobacco industry in its advertising. This should only increase the importance of our efforts to keep young people from starting smoking and to educate middle aged people regarding the dangers of smoking (Table 19.2).

## **TABLE 19.2 Weight Loss Drugs**

*Sympathomimetic Noradrenergic Agents (Amphetamine-Related Drugs)*

Diethylpropion (Tenuate)	25 mg before meals; 75 mg slow release form in morning
Phendimetrazine (Bontril)	35 mg before meals; 105 mg slow release form daily
Benzphetamine (Didrex)	25–50 mg 1–3 times daily
Phentermine (Adipex-P, Suprenza)	8 mg before meals; 15 or 37.5 mg in morning
Phentermine and Topiramate (Qsymia)	7.5 mg/46 mg once daily PO
<i>Lipase Inhibitor</i>	
Orlistat (Xenical)	120 mg t.i.d.
<i>Glucagon-like peptide-1 (GLP-1) analog</i>	
Liraglutide (Saxenda)	3 mg daily SC injection
<i>Combination of norepinephrine-dopamine reuptake inhibitor and nicotinic acetylcholine receptor antagonist (Bupropion) and opioid receptor antagonist (naltrexone)</i>	
Naltrexone-Bupropion (Contrave)	16 mg/180 mg b.i.d.
<i>Serotonin receptor (5HT-2C) agonist</i>	
Lorcaserin (Belviq)	10 mg b.i.d

Because of CNS and cardiovascular side effects (e.g., insomnia, nervousness, euphoria, hypertension, and tachycardia) and the lack of long-term data, the sympathomimetic noradrenergic agents should be reserved for short-term use (3 months or less) for individuals who wish to lose a small amount of weight. Tolerance and dependence are problems with continued use. Noradrenergic agents should not be used in individuals with cardiovascular disease. More recently, a combination of noradrenergic phentermine and an antiseizure agent topiramate has been approved for FDA for the long-term treatment of obesity. The effect of phentermine on chronic weight management is likely mediated by release of catecholamines in the hypothalamus, resulting in reduced appetite and decreased food consumption, but other metabolic effects may also be involved. The exact mechanism of action is not known. The precise mechanism of action of topiramate on chronic weight management is also not known. Topiramate's effect on chronic weight management may be due to its effects on both appetite suppression and satiety enhancement, induced by a combination of pharmacologic effects including augmenting the activity of the neurotransmitter gamma-aminobutyrate, modulation of voltage-gated ion channels, inhibition of AMPA/kainite excitatory glutamate receptors, or inhibition of carbonic anhydrase.

In addition to phentermine-topiramate, a number of agents have been approved by FDA for long-term use in adults with obesity (BMI  $\geq$  30), or who are overweight (BMI  $\geq$  27) with at least one weight-related medical condition. Among these agents, Orlistat (120 mg t.i.d. with meals) has been in the market the longest and acts only within the

gastrointestinal tract, inhibiting pancreatic lipase and increasing fecal fat loss.<sup>219</sup> Orlistat is associated with annoying gastrointestinal side effects (increased flatulence, cramps, and defecation of oily stools). There is some loss of the fat-soluble vitamins, and a vitamin supplement should be taken at bedtime.

Liraglutide is a glucagon-like peptide-1 (GLP-1) analogue and acts centrally to decrease appetite. It is effective in patients with type II diabetes and as a weight loss agent.<sup>220,221</sup> In addition to gastrointestinal side effect such as nausea, vomiting, and diarrhea that could result in severe dehydration, liraglutide may cause pancreatitis, cholecystitis, and hypoglycemia (especially in those using medications for IDDM). Lorcaserin is a selective 5-HT<sub>2C</sub> receptor agonist. The activation of 5-HT<sub>2C</sub> receptors in the hypothalamus is believed to activate POMC production and promote weight loss through satiety.<sup>222</sup> Despite initial concerns regarding safety (risk of tumors, heart valve issues) and efficacy, in 2012, the FDA officially approved lorcaserin for use in the treatment of obesity. In 2013, the US Drug Enforcement Administration classified lorcaserin as a Schedule IV drug under the Controlled Substances Act, because it has hallucinogenic properties at higher than approved doses and users could develop psychiatric dependencies on the drug. A combination of bupropion, a norepinephrine-dopamine reuptake inhibitor, and naltrexone, an opioid receptor antagonist, has also been approved by the FDA for long-term weight loss treatment.

A number of agents that have been used in the treatment of obesity within the past two decades are no longer available or utilized due to concerns regarding safety and efficacy. The popularity of the serotonergic agents received a setback with reports of increased risks due to high circulating levels of serotonin (even with short-term therapy) of the rare but life-threatening conditions of primary pulmonary hypertension and cardiac valvular disease, and two products, fenfluramine and dexfenfluramine, were withdrawn from the market.<sup>223,224,225</sup> Fluoxetine, a selective serotonin reuptake inhibitor (SSRI) commonly used as an antidepressant, produces only a short-term weight loss.<sup>226</sup> Indeed while acute therapy with fluoxetine is associated with modest weight loss, after remission of depressive symptoms, weight gain or loss for patients taking fluoxetine for longer periods is not different from that for patients taking placebo.<sup>227</sup> Sibutramine (Meridia), which suppresses appetite by blocking the neuronal uptake of both norepinephrine and serotonin, can cause hypertension and has been associated with increased cardiovascular events and strokes; it has been withdrawn from the market in several countries and regions including United States, European Union, and Australia.<sup>228</sup> Rimonabant, a cannabinoid receptor blocker that produces a modest weight loss was first approved in Europe in 2006 but was withdrawn worldwide in 2008 due to serious psychiatric side effects; it was never approved in the United States.<sup>229,230,231</sup>

A recent meta-analysis of 28 randomized clinical trials conducted among overweight and obese adults treated with FDA-approved long-term weight loss agents (orlistat, lorcaserin, naltrexone-bupropion, phentermine-topiramate, or liraglutide) for at least 1 year included 29,018 patients (74% women) with a median age 46 years; median baseline body weight, 100.5 kg; and median baseline BMI, 36.1.<sup>232</sup> A median 23% of placebo-treated participants had at least 5% weight loss compared to 75% taking phentermine-topiramate (OR, 9.22; 95% credible interval [CrI], 6.63–12.85), 63% taking liraglutide (OR, 5.54; 95% CrI, 4.16–7.78), 55% taking naltrexone-bupropion (OR, 3.96; 95% CrI, 3.03–5.11), 49% taking lorcaserin (OR, 3.10; 95% CrI, 2.38–4.05), and 44% taking orlistat (OR, 2.70; 95% CrI, 2.34–3.09).<sup>221</sup> All active agents were associated with significant excess weight loss compared with placebo at 1 year—phentermine-topiramate, 8.8 kg (95% CrI, –10.20 to –7.42 kg); liraglutide, 5.3 kg (95% CrI, –6.06 to –4.52 kg); naltrexone-bupropion, 5.0 kg (95% CrI, –5.94 to –3.96 kg); lorcaserin, 3.2 kg (95% CrI, –3.97 to –2.46 kg); and orlistat, 2.6 kg (95% CrI, –3.04 to –2.16 kg). Compared with placebo, liraglutide (OR, 2.95; 95% CrI, 2.11–4.23) and naltrexone-bupropion (OR, 2.64; 95% CrI, 2.10–3.35) were associated with the highest odds of adverse event–related treatment discontinuation. High attrition rates (30–45% in all trials) were associated with lower confidence in estimates.

Because weight is regained after discontinuing drug treatment, long-term therapy has been championed. However, very little information is available regarding the long-term use of appetite-suppressing drugs. Short-term studies indicate only a modest efficacy with variable responses.<sup>134,233</sup> Most of the weight loss occurs in the first 6 months and is limited to 5–10 kg (11–22 lb). Nevertheless, long-term treatment may enable some individuals to sustain weight loss and to more effectively make beneficial changes in diet and lifestyle. It is recommended that treatment with appetite-suppressing drugs should be limited to individuals who have failed to lose weight with conventional methods and who demonstrate significant comorbidities, such as android obesity, coronary heart disease, insulin resistance, and hypertension.<sup>134</sup> **Attainment of a normal body weight is unlikely with drug treatment; however, a 5–10% weight loss will have an important beneficial impact on risk factors for disease.**<sup>134</sup> Nevertheless, lifestyle changes remain the most important and effective intervention for the treatment of obesity.

Surgical treatment and starvation should be reserved for patients who are morbidly obese. Both methods involve many potential problems and require close monitoring. Although there can be major complications, bariatric surgery, including laparoscopic procedures, produces a weight loss of 50–75% that is sustained for many years and is associated with a reversal of abnormal metabolic conditions in both adults and children with a reduction in mortality rate.<sup>234,235,236,237,238</sup>

Controlled studies have not demonstrated the effectiveness of thyroid preparations or human chorionic gonadotropin.<sup>239</sup> Indeed, adding thyroid hormone increases the loss of lean body mass rather than fat tissue. It is clear that adjunctive drug measures are not successful unless the patient is also motivated either to limit caloric intake or to increase the exercise level in what will be a lifelong battle.

A regular pattern of physical exercise reduces the risk of myocardial infarction in all people.<sup>240</sup> Both weight loss and increased physical activity lower the level of low density lipoprotein (LDL), and increase the level of high density lipoprotein (HDL).<sup>241</sup> A further benefit of strenuous or prolonged exercise is an inhibition of appetite that lasts many hours and that is associated with an increase in the resting metabolic rate for 2–48 hours. The optimal program includes, therefore, a 1-hour, **daily** period of exercise (of moderate intensity, such as brisk walking), but even 2 or 3 times per week can be effective.<sup>242</sup> A combination of diet and exercise is better than either alone, and those who exercise are more successful in maintaining weight loss.<sup>209,243,244</sup> The best time for exercise is before meals or about 2 hours after eating. Lifestyle changes (exercise, no smoking, healthy diet) lower the risk of coronary heart disease even in obese individuals<sup>245</sup> (Table 19.3).

## TABLE 19.3

<b>Activity</b>	<b>Calories/hour</b>
Sleeping	90
Office work	240
Walking	240
Golf	300
Housework	300
Bicycling	360
Swimming	360
Tennis	480
Bowling	510
Running slowly	750 (ca. 120/mile)
Cross country skiing	840
Running fast	960 (ca. 160/mile)

Unfortunately, one cannot burn up significant calories quickly; it takes 18 minutes of running or 2 hours of walking to compensate for the average hamburger.<sup>246</sup>

Most frustrating is the problem of some patients who limit caloric intake yet do not lose weight. In fact, as the weights of certain patients increase, the number of calories required to remain in equilibrium decreases, due to a combination of reduced activity and a change in metabolism, now known to be appropriate consequences of changes in

leptin levels. The Vermont study demonstrated that the normal person with induced obesity requires 2,700 calories to remain in equilibrium; spontaneously obese patients require only about 1,300 calories.<sup>247</sup> Others argue that virtually everyone can lose weight on a diet of 1,000 calories/day in that the maintenance requirement for a sedentary adult is about 1.5 times the resting metabolic rate (about 1,000–1,500 calories/day).<sup>248</sup> Nevertheless, an individual who has been overweight requires about 15% fewer calories to maintain weight than an individual who has never been obese.<sup>249</sup> The clinician must be careful to avoid a condemning or punitive attitude and understand that it is possible to significantly restrict caloric intake and not lose weight.

Patients struggle with frustration and despair unless the clinician can motivate them to increase physical activity. In all individuals, dieting is doomed to failure unless it is combined with physical exercise, but this is especially true in chronically obese patients. In other words, the lifestyle of an obese person must be changed to overcome the desire to be inactive (walk instead of riding). Only by significantly increasing caloric expenditure will the input-output equilibrium be disturbed. Unfortunately, only 25% of American adults are engaged in significant leisure time physical activity.<sup>11</sup>

The obese person feels trapped. Obesity leads to characteristic behavioral manifestations, including passive personality, frequent periods of depression, decreased self-respect, and a sense of being hopelessly overwhelmed by problems. But just as the endocrine and metabolic changes are secondary to obesity, many of the psychosocial attributes surrounding obesity are also secondary.

Maintenance of a newly gained lower weight requires constant preventive attention. Motivation to change and emotional support during the change are important. They can be provided by friends, relatives, clinicians, or self-help organizations. If the vicious circle of failed diets, resignation to fate, guilt, and shame can be broken, a more effective, happier person will emerge.

# Reproduction and the Thyroid

Thomas Wharton, in 1656, gave the thyroid gland its modern name (meaning oblong shield) because he believed that the function of the thyroid was to fill vacant spaces and contribute to the shape and beauty of the neck, especially in women.<sup>1</sup>

For unknown reasons, thyroid disease is more common in women than in men. Because most thyroid disease is autoimmune in nature, an increased susceptibility to autoimmune diseases, perhaps secondary to the female endocrine environment, is a likely contributing factor.

The clinical objective is to detect and treat thyroid disease before the symptoms and signs are significant and intense. Subtle thyroid disease is easily diagnosed by the sensitive laboratory assessments now available. Therefore, the key to early diagnosis is to maintain a high index of suspicion and to readily screen for the presence of abnormal thyroid function. There is growing support to institute routine thyroid screening in three female populations: older women, pregnant women, and women with infertility.

# NORMAL THYROID PHYSIOLOGY

Thyroid hormone synthesis depends in large part on an adequate supply of iodine in the diet. In the small intestine, iodine (I) is absorbed as iodide ( $I^-$ ) that is then transported to the thyroid gland. Plasma iodide enters the thyroid under the influence of thyroid-stimulating hormone (TSH), the anterior pituitary thyrotropin hormone. Within the thyroid gland, iodide is oxidized to elemental iodine, which is then bound to tyrosine. Monoiodotyrosine and diiodotyrosine combine to form thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ). These iodinated compounds are part of the thyroglobulin molecule, the large (660 kDa) protein that is stored in the thyroid follicle and serves as a depot for thyroid hormones. TSH induces a proteolytic process that results in the release of iodothyronines into the bloodstream as thyroid hormone (**Figure 20.1**).

**FIGURE 20.1**

Removal of one iodine from the phenolic ring of  $T_4$  yields  $T_3$ , whereas removal of an iodine from the nonphenolic ring yields reverse  $T_3$  (RT3), which is biologically inactive. In a normal adult, about one-third of the  $T_4$  secreted each day is converted in peripheral tissues to  $T_3$ , and about 40% is converted to the inactive, RT3. About 80% of the  $T_3$  generated is derived outside the thyroid gland, chiefly in the liver and kidney.  $T_3$  is 3–5 times more potent than  $T_4$ , because the nuclear thyroid receptor has a 10-fold greater affinity for  $T_3$  than for  $T_4$ . Consequently, although  $T_4$  is secreted at 20 times the

rate of T3, it is T3 that is responsible for most if not all of the thyroid action in the body, while T4 serves mainly as a prohormone of T3. It is hard to think of a body process or function that does not require thyroid hormone for its normal operation, not only metabolism but also development, steroidogenesis, and most specific tissue activities.

Carbohydrate calories appear to be the primary determinant of T3 levels in adults. A reciprocal relationship exists between T3 and RT3. Low T3 and elevated RT3 are seen in a variety of illnesses such as febrile diseases, burn injuries, malnutrition, and anorexia nervosa. The metabolic rate is determined to a large degree by the relative production of T3 and RT3. During periods of stress, when a decrease in metabolic rate would conserve energy, the body produces more RT3 and less T3, and metabolism slows. On recovery, this process reverses, and metabolic rate increases.

Thyroid hormones are present in the circulation mainly bound to proteins. Approximately 70% of thyroid hormones are bound to thyroxine-binding globulin (TBG), which, therefore, is the major determining factor in the total thyroid hormone concentration in the circulation. The remaining 30% is bound to thyroxine-binding prealbumin and albumin. The binding proteins have a greater affinity for T4 and, thus, allow T3 to have greater entry into cells. TBG is synthesized in the liver, and this synthesis is increased by estrogens. The passage of thyroid hormones into and out of cells is regulated by cell membrane thyroid hormone transporters; mutations in a key transporter are associated with elevated T3 levels and psychomotor retardation.<sup>2</sup>

The nuclear receptor for thyroid hormone is a member of the super family that includes the steroid hormone receptors ([Chapter 1](#)).<sup>3</sup> The thyroid hormone receptor exists in several forms, the products of two genes located on different chromosomes. The  $\alpha$  receptor gene is on chromosome 17, and the  $\beta$  receptor gene is on chromosome 3. The nuclear T3 receptor is truly ubiquitous, indicating the widespread actions of thyroid hormone throughout the body. Mutations in the gene for the thyroid receptor may lead to the synthesis of a receptor that actually antagonizes normal receptors, a syndrome of thyroid resistance characterized by elevated thyroid hormone levels. TSH is elevated as well because of the impairment in thyroid hormone action.

The thyroid axis is stimulated by the hypothalamic factor, thyrotropin-releasing hormone (TRH), and inhibited by somatostatin and dopamine. Thyroid hormones regulate TSH by suppressing TRH secretion, but primarily by affecting the pituitary sensitivity to TRH (by reducing the number of TRH receptors). Pituitary secretion of TSH is very sensitive to changes in the circulating levels of thyroid hormone; a slight change in the circulating level of T4 will produce a many-fold greater response in TSH. TSH-secreting cells are regulated by T4 but only after the T4 is converted to T3 in the pituitary cells. Although modulation of thyroid hormone occurs at the pituitary level, this function is permitted by the hypothalamic releasing hormone, TRH. Indeed, while some

tissues depend mainly on the blood T3 for their intracellular T3, the brain and the pituitary depend on their own intracellular conversion of T4. The measurement of T4 and TSH, therefore, provides the most accurate assessment of thyroid function.

The TSH response to TRH is influenced mainly by the thyroid hormone concentration in the circulation; however, lesser effects are associated with dopamine agonists (inhibition), glucocorticoids (inhibition), and dopamine antagonists (stimulation). Estrogen increases the TRH receptor content of the pituitary; hence, the TSH response to TRH is greater in women than in men and greater in women taking estrogen-progestin contraceptives.

TRH also stimulates prolactin secretion by the pituitary. The smallest doses of TRH that are capable of producing an increase in TSH also increase prolactin levels, indicating a physiologic role for TRH in the control of prolactin secretion. However, except in hypothyroidism, normal physiologic changes as well as abnormal prolactin secretion can be understood in terms of dopaminergic inhibitory control, and TRH need not be considered.

# Functional Changes with Aging

Thyroxine metabolism and clearance decrease in older people, and thyroxine secretion decreases in compensation to maintain normal serum thyroxine concentrations.<sup>4</sup> With aging, conversion of T4 to T3 decreases, and TSH levels increase. The TSH response to TRH is normal in older women. TBG concentrations decrease slightly in postmenopausal women but not enough to alter measurements in serum.

# THYROID FUNCTION TESTS

---

## **Free Thyroxine (FT4)**

Assays that measure free T4 are usually displacement assays using an antibody to T4. The result is not affected by changes in TBG and binding. The free T4 level has a different range of normal values from laboratory to laboratory but is usually 0.8–2.0 ng/dL.

## **Total Thyroxine (TT4)**

The total thyroxine, both the bound portion to TBG and the free unbound portion, is measured by displacement assays, and, in the absence of hormone therapy or other illnesses, it estimates the thyroxine concentration in the blood. However, the free T4 is unaffected by factors that influence TBG and is preferred.

## **Free Thyroxine Index (FTI or T7)**

The free thyroxine index is calculated from the TT4 and the T3 resin uptake measurements. This test has been replaced by the free T4 assay.

## **Total T3 and Reverse T3**

Both of these thyronines can be measured by sensitive immunoassays. However, in most clinical circumstances, they add little to what is learned by the free T4 and TSH measurements. The clinical situations in which measurement will be useful are discussed under the specific diseases and indicated on the algorithm.

# Thyroid-Stimulating Hormone

TSH (also called thyrotropin) is measured by highly sensitive assays using monoclonal antibodies, usually in a technique that uses two antibodies, one directed at the  $\alpha$  subunit and one directed at the  $\beta$  subunit of TSH. The normal levels vary from laboratory to laboratory, but the sensitive TSH assay can detect concentrations as low as 0.01  $\mu\text{U/mL}$ , and the normal range is usually 0.45–4.5  $\mu\text{U/mL}$ . White people and the elderly normally have slightly higher TSH levels (individuals 80 years and older may have an upper limit as high as 7.5  $\mu\text{U/mL}$ ), making the upper limit for the normal range more difficult to interpret.<sup>5,6</sup> TSH is a very sensitive indicator of thyroid hormone action at the tissue level because it is dependent on the pituitary exposure to T<sub>4</sub>. In the absence of hypothalamic or pituitary disease, the sensitive TSH assay will provide the best indication of excess or deficient thyroxine; slight changes in T<sub>4</sub> are reflected in a many-fold greater response in TSH. Nearly all women with elevated TSH levels have hypothyroidism. Transient changes in TSH can be caused by systemic illnesses, major psychiatric disturbances, and pharmacologic treatment with glucocorticoid agents or dopamine.

# TSH Receptor, Thyroid Peroxidase, and Thyroglobulin Autoantibodies

Autoimmune thyroid disease is characterized by the presence of autoantibodies against various thyroid components, namely the TSH receptor, thyroid peroxidase (TPO), and thyroglobulin (Tg), as well as an inflammatory cellular infiltrate of variable severity within the gland.

Autoantibodies that compete with TSH for its receptor are collectively known as TSH receptor autoantibodies (TRAb) and include thyroid-stimulating immunoglobulin (TSI) and thyrotropin-binding inhibitory immunoglobulin (TBII). All forms of autoimmune thyrotoxicosis (Graves disease, Hashitoxicosis, neonatal thyrotoxicosis) are caused by the production of stimulating TRAb.

TRAb test is a binding assay that detects both TSI and TBII; it can be used instead of TSI assay for most applications, as long as the results are interpreted in the clinical context. Most patients with Graves disease will have detectable TRAbs. This is an essential test in patients with hyperthyroidism to differentiate Graves disease from nonautoimmune hyperthyroidism, specifically toxic multinodular goiter, in order to select appropriate therapy. This test (or TSI test) is not needed to monitor treatment.

The role of the TPO and Tg autoantibodies in either autoimmune thyrotoxicosis or autoimmune hypothyroidism is less well established; they may merely represent epiphenomena. Detectable concentrations of anti-TPO antibodies are observed in most patients with autoimmune thyroid disease (e.g., Hashimoto thyroiditis, idiopathic myxedema, and Graves disease).

# Radioactive Iodine Uptake Scan

Because the thyroid gland is the only tissue that utilizes iodine, radioisotopes of iodine can be used as a measure of thyroid gland activity and to localize activity within the gland. The scan is obtained 24 hours after the administration of  $I^{123}$  given orally.

# The Laboratory Evaluation

The algorithm represents a cost-effective and accurate clinical strategy. For screening purposes, or when there is a relatively low clinical suspicion of thyroid disease, the initial step is to measure TSH. A normal TSH essentially excludes hypothyroidism or hyperthyroidism. A high TSH requires the measurement of free T4 to confirm the diagnosis of hypothyroidism.

If the initial TSH is low, especially less than  $0.08 \mu\text{U/mL}$ , then measurement of a high T4 will confirm the diagnosis of hyperthyroidism. If the T4 is normal, the T3 level is measured, because some patients with hyperthyroidism will have predominantly T3 toxicosis. If the T3 is normal, this compensated state is called subclinical hyperthyroidism. Some of these patients will eventually have increased T4 or T3 levels with true hyperthyroidism.

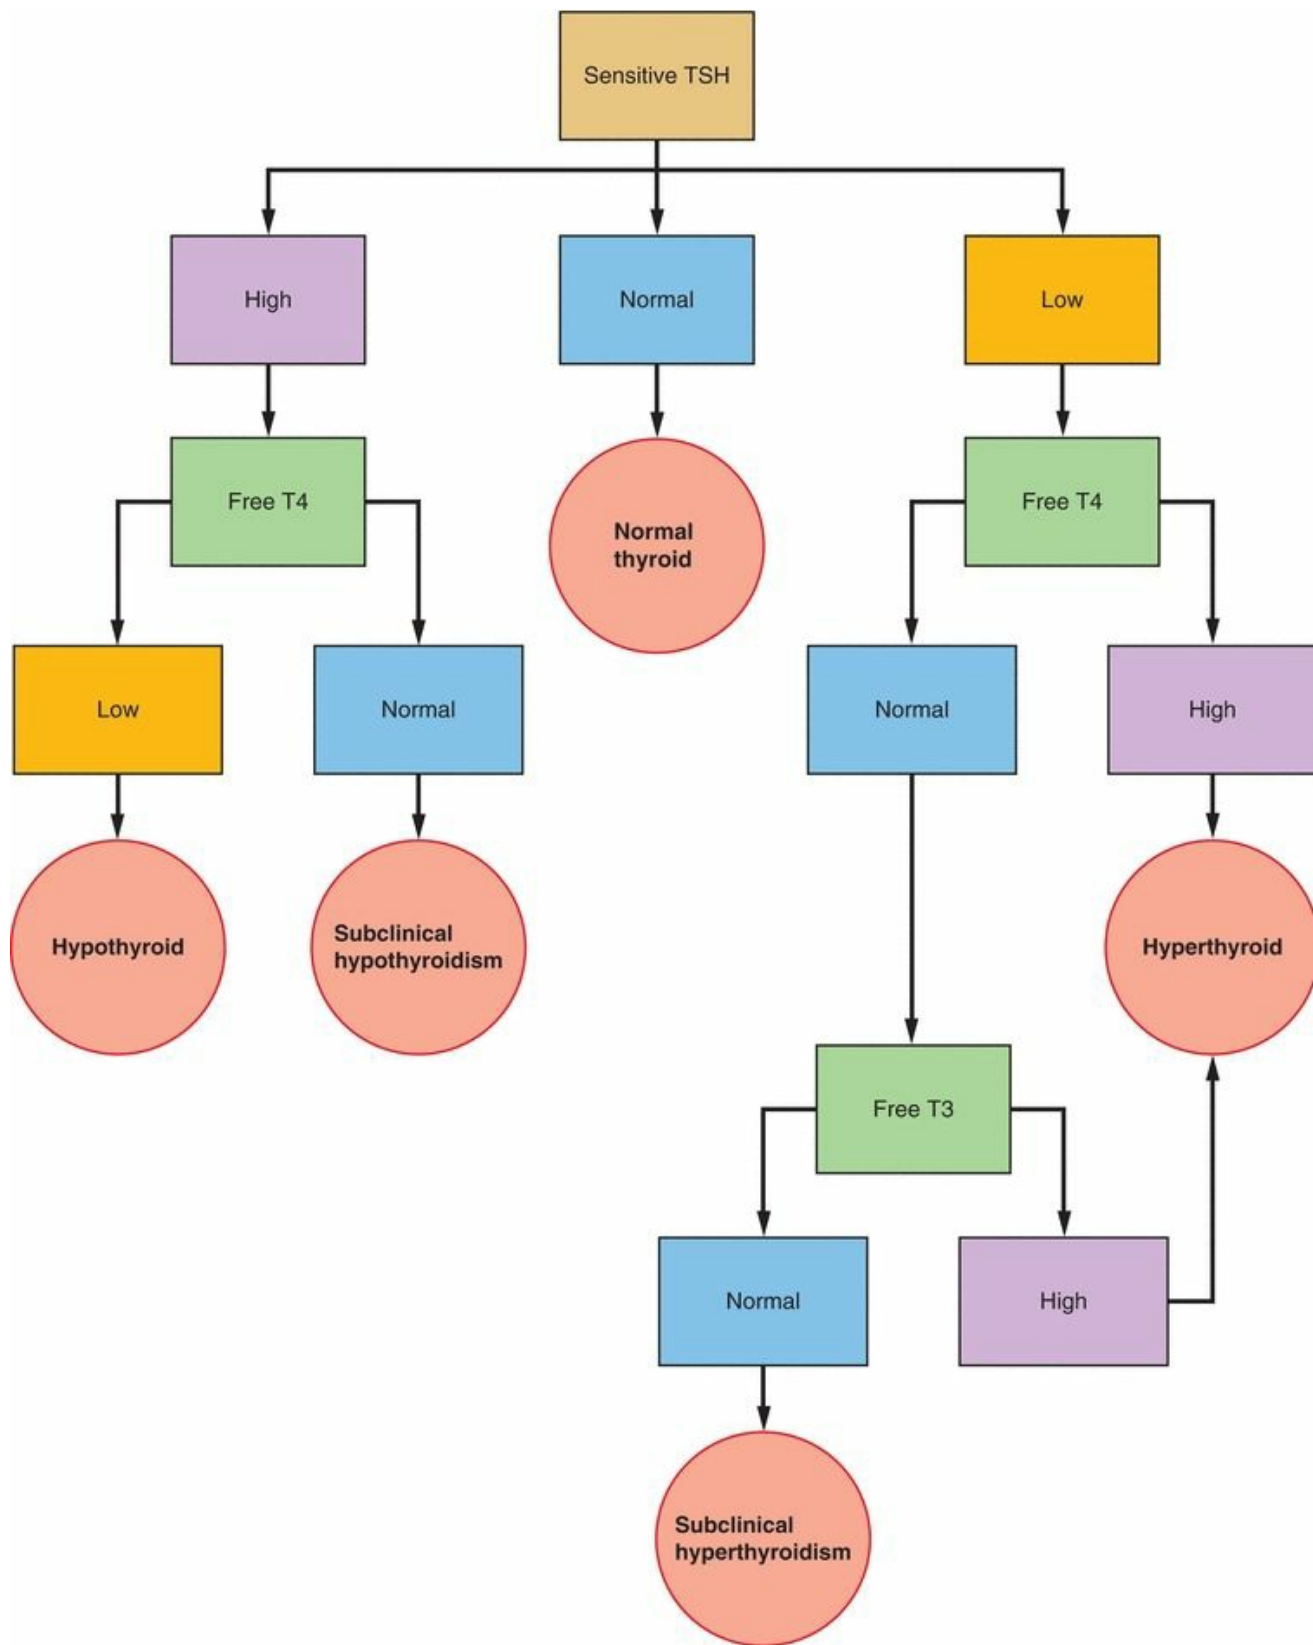

# HYPOTHYROIDISM

---

In most cases of hypothyroidism, a specific cause is not apparent. It is believed that hypothyroidism is usually secondary to an autoimmune reaction, and, when goiter formation is present, it is called Hashimoto thyroiditis.<sup>7</sup> Unless abnormal thyroid function can be documented by specific laboratory assessment, empiric treatment with thyroid hormone is not indicated. Hypothyroidism is also associated with recurrent miscarriages, and an assessment of thyroid function is worthwhile in these patients.

Hypothyroidism increases with aging and is more common in women.<sup>8</sup> Up to 45% of thyroid glands from women older than age 60 show evidence of thyroiditis.<sup>9</sup> In women admitted to geriatric wards, 2–4% have clinically apparent hypothyroidism. **Therefore, hypothyroidism is frequent enough to warrant consideration in most older women, justifying screening even in asymptomatic older women. We recommend that women be screened with the TSH assay every 5 years beginning at age 35, then every 2 years beginning at age 60, or with the appearance of any symptoms suggesting hypothyroidism (Figure 20.2).**<sup>10,11</sup>

**FIGURE 20.2**

Menstrual irregularities and bleeding problems are common in hypothyroid women.

Amenorrhea can be a consequence of hypothyroidism, either with TRH-induced increases in prolactin or with normal prolactin levels. Other clinical manifestations of hypothyroidism include constipation, cold intolerance, psychomotor retardation, carpal tunnel syndrome, and decreased exercise tolerance. However, patients often are asymptomatic. Close evaluation can reveal mental slowness, decreased energy, fatigue, poor memory, somnolence, slow speech, a low-pitched voice, water retention, periorbital edema, delayed reflexes, or a low body temperature and bradycardia. Hypothyroidism can also cause hypertension, cognitive abnormalities, pericardial effusion, asymmetric septal myocardial hypertrophy, myopathy, neuropathy, ataxia, anemia, elevated cholesterol and LDL-cholesterol, or hyponatremia. Myxedematous infiltration can produce enlarged, cystic ovaries.<sup>12</sup> The increase in cholesterol is due to impaired LDL-cholesterol clearance secondary to a decrease in cell membrane LDL receptors. The mechanism for this LDL effect is attributed to a thyroid response element in the LDL receptor gene.<sup>13</sup>

Serum enzymes may be elevated because of decreased clearance, including creatine phosphokinase (CPK), aspartate aminotransferase (AST, SGOT), alanine aminotransferase (ALT, SGPT), lactic dehydrogenase (LDH), and alkaline phosphatase, triggering a fruitless search for other organ disease. **It is worth screening for hypothyroidism in any women with abnormal menses or with complaints of fatigue and depression. In addition, patients who have elevated levels of cholesterol and LDL-cholesterol should be screened.**

# Diagnosis of Hypothyroidism

With primary thyroid failure, the circulating thyroid hormone levels fall, stimulating the pituitary to increase TSH output. Elevated TSH and low T4 confirm the diagnosis. The prevalence of hypothyroidism is estimated to be 4.5% of among those 12 years or older.<sup>14</sup> The most common cause is autoimmune thyroid disease (elevated titers of antithyroid antibodies) in areas with normal iodine intake. Hypothyroidism can also occur due to pituitary failure in which case the TSH will be inappropriately low for the T4. However, making an etiologic diagnosis in women adds little to the clinical management.

## Subclinical Hypothyroidism

In early hypothyroidism, with undetectable symptoms or signs, a compensated state can be detected by an elevated TSH (greater than the upper limit of the normal range of 0.45–4.5  $\mu\text{U}/\text{mL}$ ) and normal T4 (called subclinical hypothyroidism). Subclinical hypothyroidism is present in 4–8.5% of U.S. adults, is more common in women, and increases with age, affecting up to 20% of women over age 60.<sup>15,16</sup> Of those with subclinical hypothyroidism, about 2–5% **each year** will become clinically hypothyroid with low T4 concentrations.<sup>15,16</sup>

A good reason to treat subclinical hypothyroidism is to avoid the development of a goiter. Furthermore, some patients in retrospect (after treatment) recognize improved physical and mental well-being. Patients with subclinical hypothyroidism have alterations in energy metabolism in skeletal muscle.<sup>17</sup> An improvement in impaired cognitive function and emotional behavior has been documented with thyroxine treatment of subclinical hypothyroidism.<sup>18</sup> In those patients who are asymptomatic, it is worth measuring antithyroid antibodies. A positive test identifies those who are more likely to become clinically hypothyroid, at a rate of approximately 20% per year. With only very slight elevations of TSH ( $<10 \mu\text{U}/\text{mL}$ ), it is reasonable not to treat asymptomatic patients, especially those over age 80, and to check thyroid function every 6 months to detect further deterioration; however, symptomatic patients may benefit from treatment.<sup>15</sup> Patients with an abnormal cholesterol-lipoprotein profile can show a rapid improvement with thyroxine treatment.<sup>19,20,21</sup> Subclinical hypothyroidism is a strong risk factor for coronary heart disease.<sup>22</sup> In addition, iron deficiency anemia is common in patients with subclinical hypothyroidism and responds better when levothyroxine is added to iron treatment.<sup>23</sup>

The risk of pregnancy loss is increased for women with uncorrected overt or even subclinical hypothyroidism. The results of a study of pregnancy outcomes in women

with hypothyroidism challenged the notion that subclinical hypothyroidism has no impact on pregnancy.<sup>24</sup> The incidence of pregnancy loss was very low in treated hypothyroid women having normal thyroid indices but markedly increased in women with elevated TSH levels, including both women with untreated subclinical disease and those with overt disease who received inadequate exogenous thyroid hormone replacement. **These observations indicate that subclinical hypothyroidism may not be entirely benign and further justify recommendations to include TSH screening in the evaluation of women with recurrent pregnancy loss.**

# Treatment of Hypothyroidism

Initial therapy is straightforward with synthetic thyroxine, T4, given daily. Mixtures of T4 and T3, such as desiccated thyroid, provide T3 in excess of normal thyroid secretion. It is better to provide T4 and allow the peripheral conversion process to provide the T3.<sup>25,26</sup> “Natural” thyroid preparations are not better and in fact are potentially detrimental. Patients taking biologic preparations should be switched to synthetic thyroxine. Studies have documented that adding T3 to T4 does not improve treatment outcomes.<sup>27,28,29</sup> Because of a risk of coronary heart disease in older women, the initial dose should be 25–50 µg/day for 4 weeks, at which time the dose is increased by 25 µg daily every 4 weeks according to the clinical and biochemical assessment. Usually the dose required will be close to 1.5 µg/lb body weight, but it may be less in very old women.<sup>30</sup> The average final dose required in the elderly is approximately 70% of that in younger patients. **Patients who have been on thyroid hormone for a long time may have their medication discontinued. Recovery of the hypothalamic-pituitary axis usually requires 8 weeks at which time the TSH and free T4 levels can be measured.**

## Evaluation of Therapy

When the patient appears clinically euthyroid, evaluation of TSH levels will provide the most accurate assessment of the adequacy of thyroid hormone replacement. The goal is to maintain the TSH in the **lower half** of the normal range, between 0.45 and 2.0 µU/mL.<sup>7,31</sup> Thyroid hormone requirements decrease with age. A patient being treated with thyroid hormone should be evaluated once every year with the TSH assay, and each patient should consistently remain on the same levothyroxine product. If the TSH level is low, then the free T4 should be measured to help adjust the thyroxine dose.<sup>32</sup> **The full response of TSH to changes in T4 is relatively slow; a minimum of 8 weeks is necessary between changes in dosage and assessment of TSH.**

# HYPERTHYROIDISM

---

Hyperthyroidism affects 1.3% of adult US population,<sup>14</sup> and its two primary causes are Graves disease (toxic diffuse goiter) and Plummer disease (toxic nodular goiter).<sup>33</sup> Plummer disease is usually encountered in postmenopausal women who have had a long history of goiter. Twenty percent of hyperthyroid patients are older than 60, and 25% of older women with hyperthyroidism present with an apathetic or atypical syndrome.

Graves disease, about 5–10 times more common in women than in men, is characterized by the triad of hyperthyroidism, ophthalmopathy, and pretibial myxedema and is caused by autoantibodies that have TSH properties and, therefore, bind to and activate the TSH receptor. The measurement of TSH receptor antibodies is essential to distinguish Graves disease from toxic nodular goiter. Menstrual changes associated with hyperthyroidism are unpredictable, ranging from amenorrhea to oligomenorrhea to normal cycles (hence, the amenorrhea in a thyrotoxic woman can be due to pregnancy).

The classic symptoms of thyrotoxicosis are nervousness, disturbed sleep, heat intolerance, weight loss, sweating, palpitations, and diarrhea. These symptoms are associated with typical findings on physical examination: proptosis, lid lag, tachycardia, tremor, warm and moist skin, and goiter. Women in the reproductive years usually present with the classic picture. In postmenopausal women, symptoms are often concentrated in a single organ system, especially the cardiovascular or central nervous system. Goiter is absent in 40%. Sinus tachycardia occurs in less than half, but atrial fibrillation occurs in 40% and is resistant to cardioversion or spontaneous reversion to sinus rhythm. In old women, there is often a coexistent disease, such as an infection or coronary heart disease that dominates the clinical picture.

Hyperthyroidism in older women is sometimes described as “apathetic hyperthyroidism” because the clinical manifestations are different. The triad of weight loss, constipation, and loss of appetite, suggesting gastrointestinal malignancy, occurs in about 15% of older patients with hyperthyroidism. Ophthalmopathy is rare in older patients. The clinician should consider the diagnosis in older patients with “failure to thrive”; in patients who are progressively deteriorating for unexplained reasons; and in patients with heart disease, and unexplained weight loss. Mental or psychological changes are not unusual in hyperthyroid women. Women who complain of emotional lability and nervousness should be screened for hyperthyroidism.

# Diagnosis of Hyperthyroidism

The diagnosis of hyperthyroidism requires laboratory testing. A suppressed TSH (below 0.4  $\mu\text{U}/\text{mL}$ ) with a high T4 or a high T3 confirms the diagnosis. Graves disease is associated with the presence of TRAb. The measurement of TRAb in all patients with hyperthyroidism is important in order to confirm a diagnosis of Graves disease.<sup>34</sup> Most patients should have a radioactive iodine uptake scan after laboratory confirmation of the diagnosis. The scan will indicate whether the patient has a diffuse toxic goiter, a solitary hot (functional) nodule, or a hot nodule in a multinodular gland. Toxic multinodular goiters occur more frequently in the elderly. TSH hypersecretion as a cause of hyperthyroidism is extremely rare; the combination of a normal or elevated TSH and elevated thyroid hormone will be the clue to this possibility.

# Subclinical Hyperthyroidism

By definition, patients with subclinical hyperthyroidism have normal T4 and T3 levels but subnormal concentrations of TSH. About 2% of U.S. adults will have subclinical hyperthyroidism, more common in women and blacks.<sup>16</sup>

TSH levels can be suppressed to 0.1–0.5  $\mu\text{U}/\text{mL}$  by general illnesses and drugs such as glucocorticoids, dopamine, and anticonvulsants; however, this suppression does not extend below 0.1  $\mu\text{U}/\text{mL}$ . Values below 0.1  $\mu\text{U}/\text{mL}$  are regarded as nondetectable, and patients with overt hyperthyroidism usually have undetectable TSH. Subclinical hyperthyroidism is half as common in older people as subclinical hypothyroidism (excluding the most common cause, treatment with excessive doses of thyroxine). Keep in mind that the dose of thyroxine required to treat hypothyroidism declines with age (because of the decrease in metabolic clearance with age); all patients being treated with thyroid hormone should have their TSH levels assessed every year. Atrial fibrillation is a common cardiovascular problem associated with subclinical hyperthyroidism, especially in older women when the TSH is less than 0.1  $\mu\text{U}/\text{mL}$ .<sup>16,35</sup> Progression to overt hyperthyroidism is uncommon and essentially limited to patients with a TSH level lower than 0.1  $\mu\text{U}/\text{mL}$ . **Therefore, TSH levels less than 0.1  $\mu\text{U}/\text{mL}$  should be treated to avoid bone loss and atrial fibrillation in older women, or in those at risk for osteoporosis and heart disease. With TSH levels of 0.1–0.4  $\mu\text{U}/\text{mL}$ , treatment is indicated only in older patients while TSH follow-up in younger women is warranted every 6 months.**<sup>16,36,37</sup>

# Treatment of Hyperthyroidism

There are multiple objectives of therapy: control of thyroid hormone effects on peripheral tissues by pharmacologic blockade of beta-adrenergic receptors, inhibition of thyroid gland secretion and release of thyroid hormone, and specific treatment of nonthyroidal systemic illnesses that can exacerbate hyperthyroidism or be adversely affected by hyperthyroidism.<sup>38</sup> Antithyroid drugs are administered first to achieve euthyroidism before definitive therapy is accomplished by radioactive iodine treatment only when symptoms are severe or when radioactive iodine therapy must be delayed. Of course, it is important to ensure that a woman is not pregnant before treatment with radioactive iodine, and pregnancy should be postponed for several months after treatment. Monitoring treatment response requires a full 8-week interval for stabilization of the hypothalamic-pituitary-thyroid system.

## Antithyroid Drugs

The drug of choice in most circumstances (except in pregnant women, as discussed later) is methimazole because it has fewer adverse effects. The drug inhibits organification of iodide and decreases production of T<sub>4</sub> and T<sub>3</sub>. The oral dose is 10–20 mg daily. The onset of effect takes 2–4 weeks. Remember that the half-life of thyroxine is about 1 week, and the gland usually has large stores of T<sub>4</sub>. Maximal effect occurs at 4–8 weeks. Once the disease is controlled, the dose can be titrated down to a maintenance dose of 5–10 mg daily. The major side effects are rash, gastrointestinal symptoms, and agranulocytosis (an idiosyncratic reaction). Propranolol and other beta-blockers are effective in rapidly controlling the effects of thyroid hormone on peripheral tissues. The dose is usually 20–40 mg, every 12 hours orally, and the dose is titrated to maintain a heart rate of about 100 beats/minute. The drug may cause bronchospasm, worsening congestive heart failure, fatigue, and depression. Rarely inorganic iodine is needed to block release of hormone from the gland. Lugol solution, 2 drops in water daily, is sufficient. The onset of effect is 1–2 days, with maximal effect in 3–7 days. There may be an escape from protection in 2–6 weeks, and the drug can cause rash, fever, and parotitis. Iodine precludes radioiodine administration for several months.

Most patients to be treated with radioactive iodine are not pretreated with antithyroid drugs. Some patients with hot nodules in multinodular glands require surgery because of the size of the gland and because the hyperthyroidism tends to recur in new nodules after the ablation of the original hot nodule. This can result in repetitive treatments with substantial doses of radioactive iodine, and surgery may be preferable. All patients definitively treated for hyperthyroidism must be monitored for the onset of hypothyroidism.

# OSTEOPOROSIS AND EXCESSIVE THYROXINE

---

Because postmenopausal women are at increased risk for osteoporosis and frequently develop hyperthyroidism or receive levothyroxine treatment for hypothyroidism, it is important to understand how thyroid hormone affects bones. Thyroid hormone excess alters bone integrity via direct effects on bone and gut absorption of calcium and indirectly through the effects of vitamin D, calcitonin, and parathyroid hormone.<sup>39</sup>

Thyroid hormone increases bone mineral resorption. In addition, total and ionized calcium increase in hyperthyroid women, leading to increases in serum phosphorus, alkaline phosphatase, and bone Gla protein (osteocalcin), a marker of bone turnover. Parathyroid hormone decreases in response to the increased serum calcium, and this results in decreased hydroxylation of vitamin D. Intestinal calcium and phosphate absorption decrease, while urinary hydroxyproline and calcium excretion increase. The net effect of excessive thyroid hormone is increased bone resorption and a subsequent decrease in bone density—osteoporosis.<sup>40</sup>

These effects become more clinically important in prolonged exposure to excessive thyroid hormone.<sup>41</sup> Women who have had hyperthyroidism are at greater risk for fractures and experience postmenopausal fractures earlier than usual.<sup>42,43</sup> Postmenopausal women with subclinical hyperthyroidism have lower bone density measurements and experience a higher rate of fractures.<sup>44,45</sup>

A major concern is that mild chronic excess thyroid hormone replacement, especially in postmenopausal women, might increase the risk of osteoporosis, and indeed this has been documented.<sup>46,47</sup> A meta-analysis of the literature on this subject concluded that premenopausal women treated for long durations did not suffer a clinically significant loss of bone (probably because of the protective presence of estrogen); nevertheless, postmenopausal women lose an excess of bone if thyroid treatment results in TSH levels below the normal range.<sup>48</sup> Case-control and cohort studies, however, have been unable to detect an increase in fractures associated with thyroid hormone administration.<sup>49,50,51</sup>

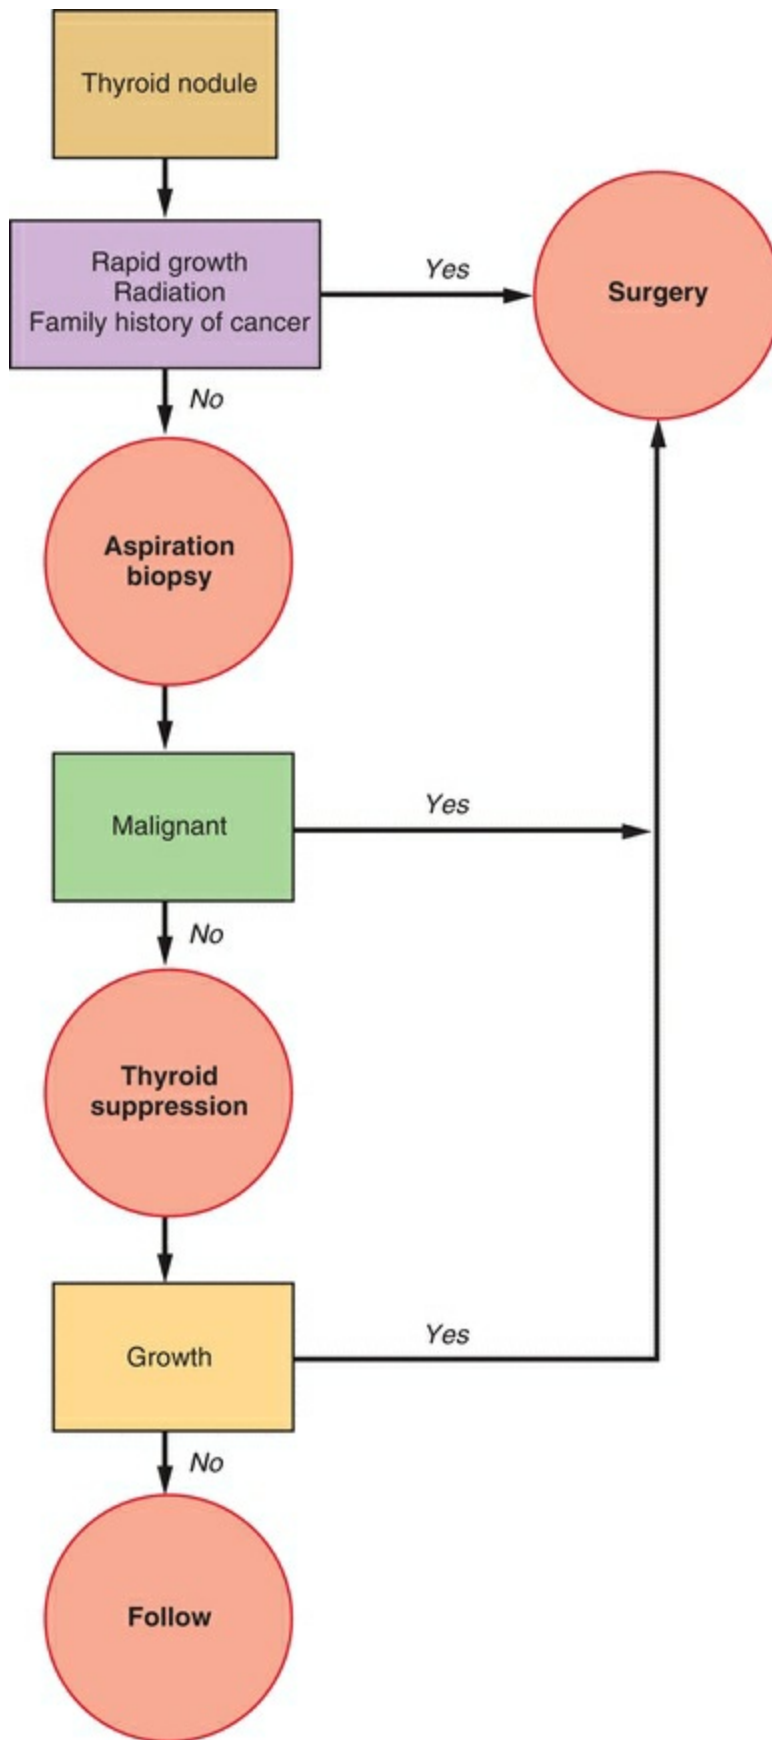

Because this is a problem easily avoided, we believe that exposure to excessive thyroxine must be added to the risk factors for osteoporosis. It makes sense to monitor patients (both premenopausal women and especially postmenopausal women) receiving thyroxine with TSH levels to ensure that levothyroxine doses are “physiologic.” Some patients who require TSH suppressive doses of thyroxine, such as patients with cancer, must be considered at increased risk of osteoporosis. It would be wise to assess bone density in women on long-term thyroid treatment and in women receiving high-dose

thyroxine suppression of TSH. The use of estrogen replacement therapy, exercise programs, and possibly bisphosphonate treatment must be seriously considered for these patients. In a cross-sectional study of elderly women, the bone loss associated with long-term thyroid treatment was avoided in those women also taking estrogen.<sup>52</sup>

# THYROID NODULES

---

The major concern with thyroid nodules is the potential for thyroid cancer.<sup>53</sup> Single nodules are 4 times more common in women, and carcinoma of the thyroid is nearly 3 times more common in women than in men. The incidence rises steadily after the age of 55. Mortality from thyroid cancer occurs predominantly in the middle aged and the elderly. There are four major types of primary thyroid carcinoma: papillary, follicular, anaplastic, and medullary. In solitary nodules that are “cold” (those that do not take up radioactive iodine or pertechnetate on thyroid scan), 12% prove to be malignant. This also means that the majority are benign (**Figure 20.3**). Surgical excision of nodules can result in vocal cord paralysis, hypoparathyroidism, and other complications. Therefore, the goal is to select patients for curative surgery who have the greatest likelihood of having cancer in the nodule.

**FIGURE 20.3**

# Epidemiologic and Clinical Data

The major risk factors for thyroid cancer are family history of this disease or a history of irradiation to head or neck. In those who have received thyroid irradiation, about one-third will have thyroid abnormalities, and about one-third of those with abnormalities will have thyroid cancer (about 10% overall). The carcinogenic risk has been estimated to be 1% per 100 rad in 20 years.

A rapidly growing nodule, a hard nodule, the presence of palpable regional lymph nodes, or vocal cord paralysis greatly increase the probability of thyroid cancer. The risk of thyroid cancer in patients with multiple nodules is not less than in those with single nodules.<sup>54</sup> Therefore, they should be similarly assessed.

Thyroid nodules in multinodular thyroid glands, not previously exposed to thyroid irradiation, have no greater risk of thyroid carcinoma than normal glands. Therefore, predominant thyroid nodules in multinodular glands should be followed, and, if a nodule grows, then biopsy or surgery should be considered.

# Diagnostic Strategy

Detection of a thyroid nodule is followed by clinical characterization of the nodule; examination of the lymph nodes; and inquiry regarding rapid growth, history of thyroid irradiation, and family history. In the presence of any positive findings, surgery is recommended for excision of the nodule. Laboratory assessment of thyroid function is also essential in patients with a thyroid nodule, as abnormal thyroid function is almost always associated with benign etiology. In patients with a thyroid nodule and no personal or family history suggestive of increased risk of thyroid cancer, a fine needle aspiration biopsy is indicated if serum TSH level is normal. In those with low TSH indicating an active nodule, a thyroid scan would be helpful, while high TSH would necessitate testing antithyroid antibodies to diagnose autoimmune inflammation. Ultrasonography of the thyroid is also necessary to identify the presence of nonpalpable nodules and to guide fine needle biopsy. Suppression with levothyroxine treatment is no longer recommended for two reasons: poor efficacy and an inability to differentiate benign lesions from thyroid cancer.

Although accounting for only 5% of thyroid cancers, medullary carcinoma is associated with early spread and poor survival rates. Medullary carcinoma of the thyroid is unique in having serum calcitonin as a very sensitive and specific tumor marker. Measuring serum calcitonin is recommended for older patients with solitary nodules to achieve earlier diagnosis of medullary carcinoma.<sup>55</sup>

Thyroid nodules discovered during pregnancy are not managed differently. Pregnancy does not affect the course of thyroid malignancy, and low-grade tumors can be treated after delivery.<sup>56</sup> Radioactive iodine, of course, must not be administered during pregnancy.

# Fine Needle Aspiration

Fine needle aspiration biopsy has an 83% sensitivity and 92% specificity in diagnosing thyroid malignancy.<sup>57</sup> When “indeterminate” by biopsy, about one-third prove to be malignant at thyroidectomy. If the fine needle aspiration biopsy reveals suspicious cells or is indeterminate, a subtotal thyroidectomy should be performed for diagnosis and treatment. If the aspiration biopsy is benign, some would repeat the biopsy in 1 year to avoid false negatives. Growth indicates the need for biopsy or surgery. In some cases, especially in older women, nodules can be followed with little risk.

# THE THYROID GLAND AND PREGNANCY

---

In response to the metabolic demands of pregnancy, there is an increase in the basal metabolic rate (which is mainly due to fetal metabolism), iodine uptake, and the size of the thyroid gland (caused by hyperplasia and increased vascularity).<sup>58</sup> However, despite this increase in thyroid activity, a pregnant woman is euthyroid with levels of TSH, free T4, and free T3 remaining within the normal range; thyroid nodules and goiter require evaluation. During pregnancy, iodide clearance by the kidney increases. For this reason (plus the iodide losses to the fetus), the prevalence of goiter is increased in areas of iodine deficiency.<sup>59</sup> This is not a problem in the United States, while in many parts of the world where iodine is not sufficiently available in the environment, pregnancy increases the risk of iodine deficiency. The increase in thyroid activity in pregnancy is attributed to the thyrotropic substances secreted by the placenta: the thyrotropic activity in human chorionic gonadotropin (hCG) and a chorionic thyrotropin.<sup>60,61</sup> The thyroid-stimulating activity of hCG is explained by the molecular homology between hCG and TSH, and between their receptors, and it has been calculated that hCG contains approximately 1/4,000th of the thyrotropic activity of human TSH. Especially during early pregnancy, hCG causes a small but important increase in maternal thyroid hormones for the fetus until fetal thyroid function is sufficient to serve fetal needs.<sup>61,62,63</sup> In conditions with very elevated hCG levels (trophoblastic disease, hCG-secreting cancers), the thyrotropic activity can be sufficient to produce hyperthyroidism (gestational hyperthyroidism), and this can even be encountered in normal pregnancy.<sup>64</sup>

The increase in thyroid activity in pregnancy is accompanied by a marked increase in the circulating levels of TBG in response to estrogen; therefore, a new equilibrium is reached with an increase in the bound portion of the thyroid hormone. The mechanism for the estrogen effect on TBG is an increase in hepatic synthesis and an increase in glycosylation of the TBG molecule that leads to decreased clearance.

TBG levels reach a peak (twice nonpregnant levels) at about 15 weeks, which is maintained throughout the rest of pregnancy.<sup>62</sup> T4 undergoes a small increase in the first trimester, but T3 increases more markedly. Because of the increase in TBG, free T4 and T3 levels then decrease, although they remain within the normal range.<sup>65</sup> There is an inverse relationship between maternal circulation levels of TSH and hCG.<sup>62</sup> TSH reaches a nadir at the same time that hCG reaches a peak at 10 weeks of pregnancy. TSH levels then increase as hCG levels drop to their stable levels throughout the rest of pregnancy. **Thus, the range of normal for TSH levels change with each trimester.**<sup>66</sup> **The lower limit of TSH in the first, second, and third trimesters are 0.1, 0.2, and 0.3  $\mu$ U/L, respectively. The upper limit of normal in the first trimester is 2.5 and 3.0  $\mu$ U/L in the second and third trimesters.**<sup>67,68</sup> In normal pregnancies, placental transfer

of TSH, T4, and T3 is limited in both directions. Slight, but significant, transfer of T4 and T3 does occur, however, when maternal levels are very high or when fetal levels are substantially lower than the maternal levels. Therefore, in the early weeks of pregnancy, before the fetal thyroid gland becomes active, the fetal brain is dependent on the placental transport of maternal T4.<sup>69</sup> Both overt and subclinical maternal hypothyroidism are associated with increased risks of miscarriage, preeclampsia, low birth weight, premature delivery, and a decrease in intelligence in the children<sup>24,70,71,72,73,74</sup> (Figure 20.4).

**FIGURE 20.4**

The majority of patients with hyperemesis gravidarum have laboratory values consistent with hyperthyroidism, and the severity of the hyperemesis correlates with the degree of hyperthyroidism.<sup>75,76</sup> These patients have higher levels of hCG, and the transient hyperthyroidism and severity of the hyperemesis may be mediated by the thyrotropic and steroidogenic activity of the hCG. These clinical manifestations in normal pregnancies may be linked to a specific subpopulation of hCG molecules with greater thyrotropic bioactivity (because highly purified, standard hCG has only trivial TSH-like activity).<sup>77</sup> Specifically, hCG with reduced sialic acid content is increased in pregnant patients with hyperemesis and hyperthyroidism.<sup>78</sup> Women with hyperemesis gravidarum do not require antithyroid drug treatment unless they exhibit symptoms of hyperthyroidism, supported by appropriate laboratory results.

# Thyroid Physiology in the Fetus and the Neonate

The human fetal thyroid gland develops the capacity to concentrate iodine and synthesize hormone between 8 and 10 weeks of gestation, at the same time that the pituitary begins to synthesize TSH.<sup>79,80</sup> Some thyroid development and hormone synthesis are possible in the absence of the pituitary gland, but optimal function requires TSH. By 12–14 weeks, development of the pituitary-thyroid system is complete. Function is minimal, however, until an abrupt increase in fetal TSH occurs at 20 weeks. As with gonadotropin and other pituitary hormone secretion, this increase in thyroid function correlates with the maturation of the hypothalamus and the development of the pituitary portal vascular system, which makes releasing hormone available to the pituitary gland.

Fetal TSH increases and reaches a plateau at 28 weeks and remains at relatively high levels to term. The free T4 concentration increases progressively. At term, fetal T4 levels exceed maternal levels. Thus, a state of fetal thyroidal hyperactivity exists near term<sup>81</sup> (Figure 20.5).

**FIGURE 20.5**

The major thyroid hormone secreted by the fetus is T4, while total T3 and free T3 levels are low throughout gestation, and levels of RT3 are elevated, paralleling the rise

in T4. Like T3, this compound is derived predominantly from conversion of T4 in peripheral tissues. The increased production of T4 in fetal life is compensated by rapid conversion to the inactive RT3, allowing the fetus to conserve its fuel resources. However, there is some evidence that RT3, as well as T4, through nongenomic actions, regulate fetal brain development.<sup>82</sup> With delivery, the newborn moves from a state of relative T3 deficiency to a state of T3 thyrotoxicosis. Shortly after birth, serum TSH concentrations increase rapidly to a peak at 30 minutes of age. They fall to baseline values by 48–72 hours. In response to this increase in TSH, total T4 and free T4 increase to peak values by 24–48 hours of age. T3 levels increase even more, peaking by 24 hours of age. By 3–4 weeks, the thyroidal hyperactivity has disappeared.

The postnatal surge in TSH is accompanied by a prolactin surge, suggesting that both are increased in response to TRH. The TRH surge is thought to be a response to rapid neonatal cooling. A puzzle is the fact that the early increase in T3 is independent of TSH and is tied in some way to cutting of the umbilical cord. Delaying cord cutting delays the increase in T3, but TSH levels still reach their peak at 30 minutes. Probably by changing liver perfusion, cord cutting augments peripheral (largely liver) conversion of T4 to T3. The later increases in T3 and T4 (after 2 hours) are due to increased thyroid gland activity. These changes in thyroid function after birth probably represent an adaptation mechanism for the sudden entry into the cold world. The high RT3 levels during pregnancy continue during the first 3–5 days of life and then fall gradually to normal levels by 2 weeks.

## Key Points: Fetal and Newborn Thyroid Changes

- TSH and T4 appear in the fetus at 10–13 weeks. Levels are low until an abrupt rise at 20 weeks.
- T4 rises rapidly and exceeds maternal values at term.
- T3 levels rise, but concentrations are relatively low, similar to hypothyroid adults.
- RT3 levels exceed normal adult levels.
- The fetal pattern of low T3 and high RT3 is similar to that seen with calorie malnutrition.
- After delivery, TSH peaks at 30 minutes of age, followed by a T3 peak at 24 hours and a T4 peak at 24–48 hours. The T3 increase is independent of the TSH change.
- High RT3 levels persist for 3–5 days after delivery and then reach normal values by 2 weeks.

# HYPOTHYROIDISM IN PREGNANCY

---

Serious hypothyroidism is rarely encountered during pregnancy. Patients with this degree of illness usually do not get pregnant. Many patients with mild hypothyroidism never have a laboratory assessment for thyroid function during pregnancy and go undetected. Preeclampsia, intrauterine growth retardation, fetal distress, and fetal death are more frequent in women with significant hypothyroidism or with subclinical hypothyroidism.<sup>24,70,71,72,73,74,83,84</sup> There is also reason to believe that patients with hypothyroidism, even subclinical hypothyroidism, have an increased rate of spontaneous miscarriage.<sup>24,83,84,85</sup> The mechanism may be impaired function of important organs such as the endometrium, the corpus luteum, and especially the placenta. The children born to women with hypothyroidism have deficits in intelligence; remember that in the first half of pregnancy, the fetus is dependent on maternal thyroid hormones.<sup>86,87,88,89,90</sup> For all of these reasons, a strong case can be made for detecting and treating hypothyroidism prior to or early in pregnancy. **Preconceptual screening is ideal with establishment of the euthyroid state (a TSH not higher than 2.5  $\mu$ U/L) before pregnancy.**<sup>67,68</sup> **The upper limit of normal in the first trimester is 2.5 and 3.0  $\mu$ U/L in the second and third trimesters.**<sup>67,68</sup> There is no debate in regard to treating pregnant women who are hypothyroid; however, detecting and treating women with elevated TSH and normal T4 levels (subclinical hypothyroidism) is controversial, as is what should be considered elevated TSH.<sup>67,68,91,92</sup>

Universal screening of pregnant women will detect both subclinical hypothyroidism and subclinical hyperthyroidism, each present in a substantial number of asymptomatic women.<sup>73,93,94</sup> Advocacy for universal screening is not an established recommendation. A major prospective U.S. study could not detect adverse outcomes associated with maternal thyroid hypofunction, although only 247 women had low thyroid function out of a population of 10,990 patients.<sup>94</sup> The conservative approach, as expressed by the American College of Obstetricians and Gynecologists, is to await the results of clinical trials.<sup>91</sup> Because there is a consensus to treat subclinical hypothyroid function in nonpregnant women, in our view, it is only logical to apply the same standard to pregnant women. This includes measuring antithyroid antibodies in women with elevated TSH levels because a positive test identifies those who are likely to become clinically hypothyroid. Women with thyroid antibodies have a significant risk of becoming hypothyroid as pregnancy progresses and also an increased risk of postpartum thyroiditis.<sup>95</sup>

Women with positive thyroid antibodies undergoing in vitro fertilization may experience a lower pregnancy rate and an increase in spontaneous miscarriage, which

can potentially be prevented with levothyroxine treatment.<sup>74,96</sup> The experience with assisted reproduction emphasizes the importance of detecting and treating less than normal thyroid function. Pregnant women treated for hypothyroidism have been reported to have an increase in preeclampsia, diabetes, and preterm birth.<sup>97,98</sup> **The obstetrical complications in treated women may reflect a lack of appreciation for the change in thyroid hormone requirement during pregnancy.**

Women being treated for hypothyroidism require an increase (20–50%) in thyroxine during pregnancy, beginning as early as the 5th week of pregnancy.<sup>99,100,101</sup> The reasons for this increase include the estrogen-induced increase in TBG, the dilutional effect of the increase in vascular volume, and the increase in placental transport and metabolism. When previously diagnosed hypothyroid women become pregnant, it is best to empirically increase the levothyroxine dose by about 30% as soon as pregnancy is diagnosed, with further adjustments according to the TSH levels.<sup>101,102</sup> **TSH should be monitored monthly and again in the postpartum period, and dosage should be adjusted to keep the TSH level in the lower half of the normal range, less than 2.5  $\mu\text{U}/\text{mL}$  in the first trimester and less than 3.0  $\mu\text{U}/\text{mL}$  in the rest of pregnancy.** Postpartum, the dose should be immediately decreased to the prepregnancy level. The need for proper monitoring and adequate treatment cannot be overemphasized; surveys of pregnant women with hypothyroidism find a substantial number with either excessive suppression of TSH or elevated TSH levels.<sup>83,103</sup> Women with thyroid autoimmunity (presence of thyroid antibodies) must be monitored with TSH levels for at least 6 months after delivery because of their increased risk for postpartum thyroiditis.

# Newborn Screening for Hypothyroidism

Impaired thyroid function may be limited to the fetus, the mother, or may affect both. Fetal hypothyroidism may be permanent or transient. Transient fetal hypothyroidism is most commonly due to transplacental passage of autoantibodies or drugs, while combined maternal and fetal hypothyroidism is almost always caused by iodine deficiency.

Fetal permanent hypothyroidism is mostly caused by congenital hypothyroidism (incidence is about 1 in 4,000 live births), and newborn screening programs exist in most of the world.<sup>104</sup> Majority of congenital hypothyroidism cases are due to thyroid dysgenesis and are not clinically apparent at birth. Fortunately, infants with congenital hypothyroidism have low T4 and high TSH concentrations easily detected in blood, and early high-dose treatment before 3 months of age is usually associated with normal mental development,<sup>105</sup> while persistent impaired mental performance has been observed in long-term follow-up studies.<sup>106,107</sup> Less than normal development can be a consequence of a delay in treatment or inadequate dosage, but despite early treatment with high doses, extremely low thyroid hormone production in the fetus is associated with deficits later in life.<sup>108</sup> Recently, a failure to develop normally in a small percentage of individuals despite early diagnosis and treatment has been linked to genetic defects in transcription factors (FOXE-1, NKX2.1, PAX8) that are important for both the thyroid gland and the central nervous system.<sup>109,110</sup>

There is a familial tendency for hypothyroidism, and if the diagnosis is made in the antepartum period, intra-amniotic injections of thyroxine can raise fetal levels of thyroid hormone.<sup>111</sup> A early clue to the presence of congenital hypothyroidism is a reduction in baseline variability in fetal heart rate tracings.<sup>112</sup> Ultrasonographic examination of patients with polyhydramnios should include a search for a fetal goiter. In addition, the fetus should be monitored for goiter formation in women treated with antithyroid drugs for hyperthyroidism during pregnancy. Amniotic fluid iodothyronines and TSH reflect fetal plasma levels, and abnormal values may allow prenatal diagnosis of fetal hypothyroidism by amniocentesis.<sup>111,113</sup> However, fetal cord blood sampling is advocated for accurate diagnosis.<sup>114</sup> Treatment of fetal hypothyroidism is important because prenatal hypothyroidism can affect some aspects of development, for example, the full function of physical skills.

The fetus is iodine deficient when a mother's iodine intake is low. Supplying the mother adequate iodine is an important problem in many parts of the world.<sup>115</sup> A fetal goiter is occasionally detected by ultrasonography at a size that could impede normal delivery. The fetus can be treated, with regression of the goiter, by the administration of

levothyroxine into the amniotic fluid.<sup>116</sup> However, the fetus is usually protected by the transplacental transfer of maternal T<sub>4</sub>, and, therefore, fetal treatment of hypothyroidism can usually be postponed until delivery (**Figure 20.6**).

**FIGURE 20.6**

# Postpartum Thyroiditis

Autoimmune thyroid disease is suppressed to some degree by the immunologic changes of pregnancy. Thus, there is a relatively high incidence of postpartum thyroiditis (5–10%), 1–6 months after delivery (most commonly at 3 months), manifested by either hyperthyroidism or hypothyroidism, although usually transient hyperthyroidism (lasting 1–2 months) is followed by hypothyroidism.<sup>117,118</sup> This condition is due to a destructive thyroiditis associated with thyroid microsomal autoantibodies.<sup>119</sup> A possible etiologic mechanism is fetal microchimerism, the presence of fetal cells in the maternal thyroid gland.<sup>120</sup> Women at high risk for postpartum thyroiditis are those with a personal or family history of autoimmune disease, and those with a previous postpartum episode. Women with insulin-requiring diabetes mellitus are at particularly high risk.<sup>121</sup> Postpartum thyroiditis can also be triggered by an early miscarriage.<sup>122</sup> **Women at high risk for postpartum thyroiditis, especially those with thyroid antibodies, should have TSH measurements at 3 and 6 months postpartum.**

Most importantly, the symptoms in these women are often attributed to anxiety or depression, and the obstetrician must have a high index of suspicion for hypothyroidism. The symptoms usually last 1–3 months, and almost all women return to normal thyroid function. Postpartum thyroiditis tends to recur with subsequent pregnancies, and eventually hypothyroidism remains.<sup>123</sup> Because spontaneous remission is common, patients who are treated for hypothyroidism should be reassessed 1 year after gradual withdrawal of thyroxine. **Patients who return to normal should undergo annual laboratory surveillance of their thyroid status; at least 20% and probably more will develop hypothyroidism in the next 5–10 years.**<sup>124</sup>

# Hyperthyroidism in Pregnancy

Untreated thyrotoxicosis in pregnancy is associated with a higher risk of preeclampsia, heart failure, intrauterine growth retardation, preterm birth, and stillbirth.<sup>125,126</sup> Heart failure is a consequence of the demands of pregnancy superimposed on the hyperdynamic cardiovascular state induced by increased thyroid hormones.<sup>127</sup>

The most common cause of thyrotoxicosis in pregnancy is Graves disease. Most patients with Graves disease will have detectable levels of TRAb. The clinician should always keep in mind that trophoblastic disease can cause hyperthyroidism due to the TSH property inherent in hCG. The maternal changes with pregnancy can make diagnosis difficult. Tachycardia on awakening from sleep and a failure to gain weight should make a clinician suspicious. Hyperemesis gravidarum is a common presentation of hyperthyroidism in pregnancy. Laboratory assessment is unaffected by pregnancy and should follow our algorithm. TRAb will be undetectable in gestational hyperthyroidism. **Remember that the range of normal for TSH levels change with each trimester.**<sup>66</sup> **The lower limit of TSH in the first, second, and third trimesters are 0.1, 0.2, and 0.3  $\mu$ U/L, respectively.**<sup>67</sup>

**Subclinical hyperthyroidism need not be treated as it is not associated with adverse obstetrical and neonatal complications.**<sup>128,129</sup> **Women with gestational hyperthyroidism associated with hyperemesis gravidarum seldom have clinical signs of hyperthyroidism and usually experience a rapid, spontaneous recovery within a few weeks. A few women with gestational hyperthyroidism will require antithyroid drug treatment; therefore, screening all women with hyperemesis for thyroid function is strongly recommended.**

Most women can be successfully treated with thioamide drugs propylthiouracil and methimazole, which are equally effective for pregnant women.<sup>125</sup> Although the data are controversial, methimazole has been associated with teratogenesis and therefore is not recommended during the first trimester, making propylthiouracil the drug of choice.<sup>56,93</sup> During the second and third trimester, methimazole is preferred due to hepatotoxicity associated with propylthiouracil.<sup>93</sup>

The aim of treatment should be to use the lowest possible dose to keep T4 at a high normal or slightly above normal level while maintaining mild hyperthyroidism in the mother to avoid thyroid dysfunction in the fetus. Treatment of maternal hyperthyroidism with propylthiouracil, even with moderate doses of 100–200 mg daily, suppresses T4 and increases TSH levels in newborns.<sup>130</sup> The infants are clinically euthyroid, however, and their laboratory measurements are normal by the 4th to 5th day of life. In addition, follow-up assessment has indicated unimpaired intellectual development in children

whose mothers received propylthiouracil during pregnancy.<sup>131</sup> With proper antithyroid drug treatment, very few, if any, deleterious effects are experienced by mother, fetus, or neonate.<sup>132</sup> Although small amounts of antithyroid drugs are transmitted in breast milk, the amount has no impact on neonatal thyroid function, and breast-feeding should be encouraged. Propylthiouracil is the preferred antithyroid drug in breast-feeding patients because it is less concentrated in breast milk.<sup>133</sup> Poor control of maternal hyperthyroidism is associated with increased risks of preeclampsia and low birth weight infants.<sup>126</sup>

Maternal TSH receptor autoantibodies (stimulating TRAb, TSI) can cross the placenta and cause fetal thyrotoxicosis and demise. Some have advocated fetal cord blood sampling in women with Graves disease who are euthyroid but who have positive titers of TRAb to assess the fetal thyroid status.<sup>134</sup> However, the size of the fetal thyroid can be monitored by ultrasonography and be used to monitor treatment of maternal hyperthyroidism.<sup>135,136</sup> Fetal cord blood sampling is rarely needed. An increase in fetal thyroid size on ultrasonography indicates excessive treatment, and, when dosage reductions are ineffective in reducing size, fetal thyrotoxicosis should be suspected because of the transplacental passage of TSH-like antibodies. Close monitoring of the fetus is not necessary if the maternal TRAb measurements are negative.<sup>136</sup> The fetus can be treated by treating the mother. Neonates have to be observed closely until antithyroid drugs are cleared (a few days) and the true thyroid state can be assessed.

# CONTRACEPTION

---

**Chapter 21:** Family Planning, Sterilization, and Abortion

**Chapter 22:** Hormonal Contraception

**Chapter 23:** Long-Acting Methods of Contraception

**Chapter 24:** Barrier Methods of Contraception and Withdrawal

# Family Planning, Sterilization, and Abortion

The era of modern contraception in the United States dates from 1960 when intrauterine devices (IUDs) were reintroduced and oral contraception was first approved by the Food and Drug Administration. It took 12 years after this approval for the social and legal climate in the United States to change enough to allow for widespread access to contraception. In 1961, the Connecticut Planned Parenthood Executive Director Estelle Griswold and the Yale Department of Obstetrics and Gynecology Chair C. Lee Buxton opened a birth control clinic in New Haven, thus publicly challenging a state law prohibiting the prescribing of contraceptives; both were arrested and convicted. Appeals went to the supreme court where contraception rights were established. In 1965, **Griswold versus Connecticut** allowed for married women to have access to contraceptives by arguing that the right to contraception fell under the right to privacy protected by the due process clause in the 14th amendment. This partially overturned the Comstock Laws passed in 1873 that were designed to ban distribution of contraception. A complete overturn of the Comstock Laws in relation to contraception distribution happened in 1972 when **Eisenstadt versus Baird** extended access to nonmarried persons. National family planning services and research began to be funded by the U.S. Congress in 1970.

An estimated 42% of pregnancies in North America and 40% of pregnancies worldwide are unintended.<sup>1</sup> This is indicative of a need for improved family planning initiatives. Additionally, the teen pregnancy rate in the United States is 57 per 1,000 female adolescents, while in other developed countries, the teen pregnancy rate varies from 47 (England and Wales) to 8 (Sweden) pregnancies per 1,000 female adolescents.<sup>2</sup> About 75% of all pregnancies among American teenagers are unintended.<sup>3</sup> Increasing effective contraceptive use among young Americans began to have an impact in 1991 and decreases in teen birth rates in the United States continued through 2015 for a 61% decline overall, most recently dropping 8% from 2014 to 2015.<sup>2,4,5</sup> From 1995 to 2002, 14% of the decline in teen pregnancy was a consequence of decreased sexual activity among US teenagers; however, 86% of the decline was attributed to an increase in the use of effective contraception.<sup>6</sup>

In recent years, fewer teens have received instruction regarding contraception.<sup>7</sup> The

evidence overwhelmingly indicates that abstinence programs have **not** had a positive impact on teen sexual behavior, including the delay of the initiation of sex or the number of sexual partners.<sup>8</sup> In contrast, comprehensive sex education programs that include contraception are effective and do not increase the frequency of sex or hasten the initiation of sexual activity.<sup>9</sup>

Of the unplanned pregnancies in the United States, about 39–42% are aborted.<sup>1,3</sup> American teenagers abort 26–38% of their pregnancies, which is a decrease from the mid-1990s when about 50% of adolescent pregnancies were aborted.<sup>2,3</sup> Unintended pregnancies in American females aged 20–34 have a higher rate of abortion, between 42% and 44%. The unintended pregnancy rate for American females aged 20–30 is 66–81 per 1,000 females.<sup>3</sup> In other developed countries, the unintended pregnancy rate for all age ranges is 44 per 1,000 females.<sup>1</sup> American women older than 35 aborted 46% of unintended pregnancies from 2008 to 2011, the highest rate of any age group.<sup>3</sup> The unintended pregnancy rate for this population is 16 per 1,000 females. Despite Americans having higher rates of unintended pregnancy than other developed countries, this number is decreasing. From 2008 to 2011, unintended pregnancy rates decreased by 18% overall.<sup>3</sup>

This decrease in unintended pregnancy in the United States may be partially attributable to the Affordable Care Act, which in 2010 enacted legislation requiring contraceptive coverage for women. The biggest change in contraception in the United States before and after 2010 is the increased use of long-acting reversible contraceptive (LARC) use. Between 2009 and 2012, LARC use in the United States increased significantly, from 8.5% to 11.6%.<sup>10</sup> Currently, 62% of all reproductive-aged women in the United States use a contraceptive method. Ninety percent of all women at risk of unintended pregnancy (those who are sexually active and not desiring pregnancy) use a contraceptive method.<sup>11</sup> Use of oral contraceptives, female sterilization, male condom, male sterilization, withdrawal, injectables, contraceptive rings or patches, and the rhythm method have all remained fairly consistent before and after 2010.<sup>12</sup>

Compared to other countries, such as the United Kingdom, where 82.3% of all women of reproductive age use contraception, women in the United States are at a higher risk of unintended pregnancy.<sup>13</sup> The gap in contraceptive use by American women as compared to their peers in other developed countries has been posited as an access issue, attributable to the availability of contraception, rather than a difference in sexual activity or experience. In other developed countries, contraceptive services can be obtained from more accessible resources and relatively inexpensively. Additionally, the diversity of the American people in both belief system and wealth distribution makes it difficult to implement sex education and affordable contraceptive service

providers. Time will tell if more affordable access to contraceptives in the United States leads to increased use and a decrease in unintended pregnancies.

# EFFICACY OF CONTRACEPTION

---

A clinician's anecdotal experience with contraceptive methods is truly insufficient to provide the accurate information necessary for patient counseling. The clinician must be aware of the definitions and measurements used in assessing contraceptive efficacy and must draw on the talents of appropriate experts in this area to summarize the accurate and comparative failure rates for the various methods of contraception. The publications by Trussell et al., summarized below, accomplish these purposes and are highly recommended.<sup>14,15,16,17</sup>

# Definition and Measurement

Contraceptive efficacy is generally assessed by measuring the number of unplanned pregnancies that occur during a specified period of exposure and use of a contraceptive method. The two methods that have been used to measure contraceptive efficacy are the Pearl Index and life-table analysis.

## The Pearl Index

The Pearl Index, created by Raymond Pearl in 1933, is defined as the number of failures per 100 woman-years of exposure.<sup>18</sup> The denominator is the total months or cycles of exposure from the onset of a method until completion of the study, an unintended pregnancy, or discontinuation of the method. The quotient is multiplied by 1,200 if the denominator consists of months or by 1,300 if the denominator consists of cycles.

With most methods of contraception, failure rates decline with duration of use. The Pearl Index is usually based on a lengthy exposure (usually 1 year) and, therefore, fails to accurately compare methods at various durations of exposure. This limitation is overcome by using the method of life-table analysis.

## Life-Table Analysis

Life-table analysis calculates a failure rate for each month of use. A cumulative failure rate can then compare methods for any specific length of exposure. Women who leave a study for any reason other than unintended pregnancy are removed from the analysis, contributing their exposure until the time of the exit.

# Contraceptive Failures

Contraceptive failures do occur and for many reasons. Thus, “method effectiveness” and “use effectiveness” have been used to designate efficacy with correct and incorrect use of a method. It is less confusing to simply compare the very best performance (the lowest expected failure rate) with the usual experience (typical failure rate) as noted in the table of failure rates during the 1st year of use. The lowest expected failure rates are determined in clinical trials, in which the combination of highly motivated subjects and frequent support from the study personnel yields the best results. Contraceptive typical failure rates have been estimated using the data from the 1995 and 2002 U.S. National Survey of Family Growth, correcting for the underreporting of induced abortion.<sup>17,20</sup>

These more recent estimates were not significantly different compared with the previous estimates from the 1995 national survey. Women over the age of 30 were less likely to experience failure than young women; teens were more than twice as likely to experience a failure than older women. Hispanic women and Black women experienced higher failure rates. Groups that were less likely to experience contraceptive failure were women who did not intend to have a subsequent birth and women who had no previous births. Married women experienced the lowest failure rates and women cohabiting with a male partner the highest. The most important determinants of contraceptive pill failure were age, intention toward a future birth, parity, and marital status. Interestingly, once these factors were accounted for, duration of use, race, ethnicity, and poverty status no longer affected the risk of pill failure. The same factors influence condom use, but when corrected for these factors, race, ethnicity, and poverty affected the risk of condom failure (Table 21.1, Figure 21.1).

## **TABLE 21.1 Failure Rates During the First Year of Use, United States<sup>15,16,17</sup>**

Method	Percent of Women with Pregnancy	
	Lowest Expected	Typical
No method	85%	85%
Combination pill	0.3%	8.7%
Progestin only	0.5%	3.0%
IUDs		
Levonorgestrel IUD	0.1%	0.1%
Copper T 380A	0.6%	1.0%
Implant	0.05%	1.0%
Injectable		
3 mo	0.3	0.3%
1 mo	0.05	3.0%
Patch	0.3	8.0%
Vaginal ring	0.3	8.0%
Female sterilization	0.5%	0.7%
Male sterilization	0.1%	0.2%
Spermicides	18.0%	29.0%
Periodic abstinence		25.3%
Calendar	9.0%	
Ovulation method	3.0%	
Symptothermal	2.0%	
Postovulation	1.0%	
Withdrawal	4.0%	18.4%
Cervical cap		
Parous women	26.0%	32.0%
Nulliparous women	9.0%	16.0%
Sponge		
Parous women	20.0%	32.0%
Nulliparous women	9.0%	16.0%
Diaphragm and spermicides	6.0%	16.0%
Condom		
Male	2.0%	17.4%
Female	5.0%	27.0%

### Changes in Methods by U.S. Contracepting Women 15–44<sup>12,19,20</sup>

**FIGURE 21.1**

# CONTRACEPTIVE USE IN THE UNITED STATES

---

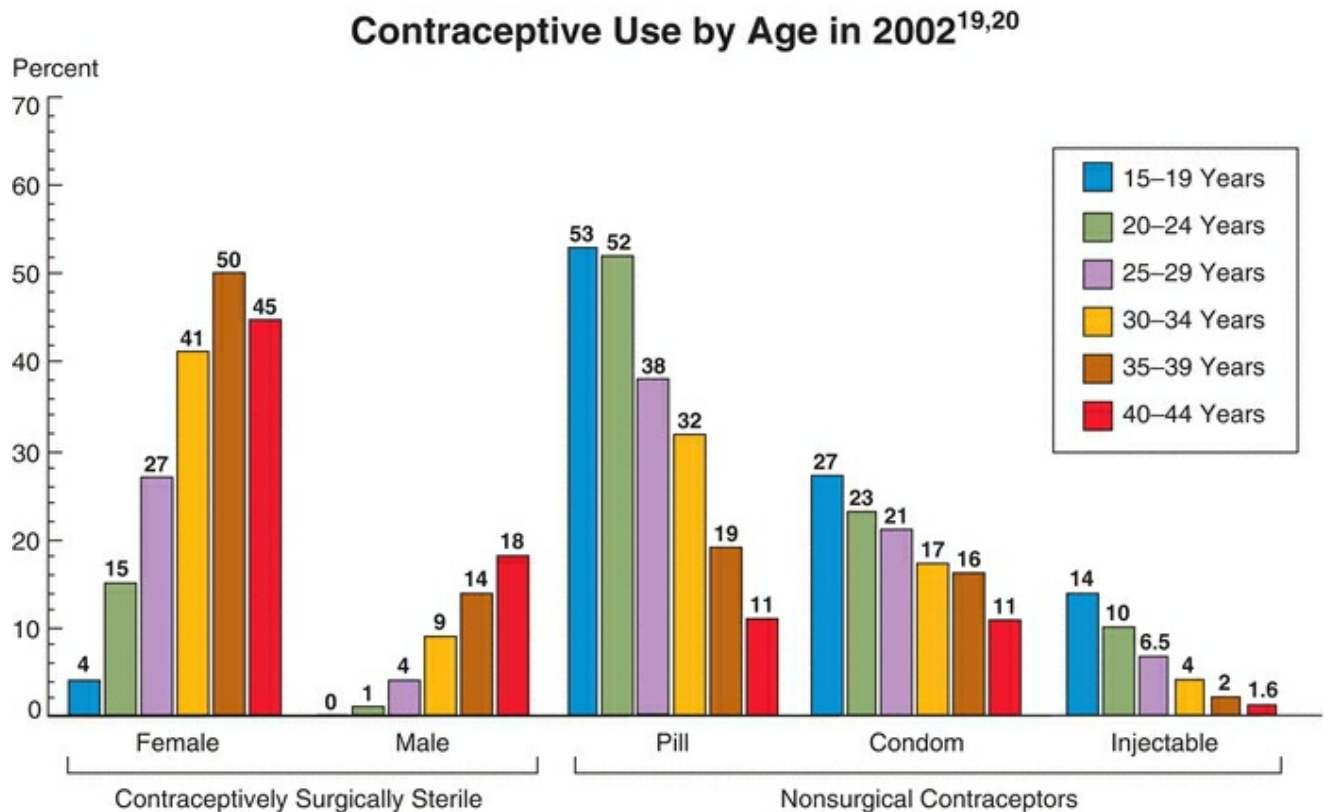

The National Survey of Family Growth is conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention. Data are available from 1972, 1976, 1982, 1988, 1995, 2002, 2006–2010, and 2011–2013.<sup>12,19,20,21,22,23,24</sup> The samples are very large; therefore, the estimates are very accurate.

Pregnancy rates in the 1990s declined for women in their 20s by 8% and increased in women in their 30s by 3%. The percent of married couples using sterilization as a method of contraception more than doubled from 1972 to 1988 and has remained stable since then. The use of oral contraception reached a high in 1992, slightly decreased in 1995, especially among Hispanic and Black Americans, and has remained around approximately 27% since then. Among never-married women, heterosexual cohabiting women, and women under age 25, oral contraception is the leading method of birth control. Approximately 49% of contracepting women under age 25 were using oral contraception between 2006 and 2010. From 1988 to 2002, oral contraception use rose to 32% of contraceptors aged 30–34 and 11% of those aged 40–44. By the 2010 data point, this had decreased to 25% and 9% of contraceptors, respectively. About 3.7% of contraceptors in 2010 were using the 3-month injectable method, and 3.5% were using transdermal, vaginal ring, and implant methods.

In the 1990s, there was an increase in condom use by never-married and formerly married women, women younger than 25, Black women, and Hispanic women. These changes reflected the concern regarding sexually transmitted infections (STIs), including human immunodeficiency virus (HIV). But in 2002, the use of condoms alone returned to the level observed in the 1980s, probably because of the use of transdermal, vaginal ring, implant, and injectable methods. About one-third of condom users in 2002 were using more than one method, especially younger and never-married women, including the use of an oral contraceptive and a condom in 14% at first intercourse! Most importantly, the percentage of women who used a contraceptive method at their first premarital intercourse increased from 43% before 1980 to 79% in 2002. Condom use at first intercourse increased from 22% before 1980 to 67% in 2002.

In 1982, 56% of US women, 15–44 years of age, were using contraception, and this has increased to 62%. In 2010, contraceptive sterilization (male and female) was utilized by 37% of contraceptors (the next leading method was oral contraception, 28%). The number of reproductive-aged women using the IUD nadired in 1995 at 0.8%, but has risen to 11.6% in 2012. IUD use was traditionally higher in married women over 35, but is more prevalent in younger populations now. In 1982, about 8% of contraceptors used the diaphragm, but use of the diaphragm has nearly disappeared in

the United States (0.1% of contracepting women in 2010) ([Figure 21.2](#)).

**FIGURE 21.2**

The oral contraceptive pill (47%) and condoms (21%) are the most popular methods of contraception among teenagers. However, studies have repeatedly documented that the use of the implant, injectable methods, and IUDs is associated with lower discontinuation rates and a lower rate of repeat pregnancies following delivery.<sup>25,26,27,28</sup> This warrants continuing efforts to extend the use of these methods to younger age groups.

In 2013, 62% of all women 15–44 years of age were using some method of contraception, whereas 38% of women of reproductive age were not using a method of contraception for the following reasons:

- 19%—Not sexually active
- 9.5%—Pregnant or trying to get pregnant
- 2.2%—Male and female sterility
- 1%—Sterilized for medical reasons

## 7%—At risk for an unintended pregnancy

The women at risk for an unintended pregnancy accounted for more than half of unintended pregnancies in the United States. Of the rest, about 43% are a consequence of incorrect contraceptive use; only 5% can be attributed to method failure.<sup>12,17</sup> In our view, these numbers reflect problems of contraceptive access, affordability, and correct use in the United States. The number of unintended pregnancies is highest among low-income women, women aged 15–24, unmarried women, and members of racial or ethnic minority groups.<sup>3</sup>

US couples have made up for the lack of contraceptive effective use and availability by greater reliance on voluntary sterilization. Between 1973 and 1982, oral contraception and sterilization changed places as the most popular contraceptive method among women over the age of 30. Approximately one-half of American couples choose sterilization within 15–20 years of their last wanted birth. During the years of maximal fertility, oral contraceptives are the most common method peaking at age 20–24. The use of condoms is the second most widely used method of reversible contraception, rising from about 9% in the mid-1980s to approximately 26% of contracepting women in 1995, decreasing to 15% in 2013.<sup>12,20</sup>

Overall use of contraception among women at risk of unintended pregnancy decreased from 92.5% in 1995 to 89.9% in 2013.<sup>12</sup> The use of contraception among poor women at risk of pregnancy decreased from 92.1% in 1995 to 86.3% in 2002. Women at or below the poverty line rely on sterilization for contraception (40.9% of contraceptors) more heavily than do women above it or compared to those with private insurance (22.3%). For various reasons, American women have a history of difficulty in obtaining effective contraception.

Women at each end of the economic spectrum, the poorest and the wealthiest, experienced a decrease in failure rates from 1995 to 2002, although the poorest women continued to have a higher failure rate than did the better-off women. Although the difference in overall failure rate was not statistically significant between 1995 and 2002, there was about a 2.5% improvement. This change is probably due to an increase in pill and injectable method use and a decrease in condom use during this period of time. Women living in poverty who must rely on condoms or withdrawal (male-dependent methods) have about a twofold increase in failure rates, but if they can use the pill, their failure rates are the same as those of better-off women. The message is clear: we need to make the more effective contraceptive methods available for poor women.

What do women have to do to achieve good contraceptive efficacy or to switch to a more effective one? Choices must be available for various methods. The method of

choice must be compatible with an individual and her lifestyle. Some methods require partner cooperation. Once chosen and obtained, the individual must exert dedication to its use. Increase in IUD usage from 2009 to 2012, the Affordable Care Act, and a small increase in couples actively desiring pregnancy may all contribute to the decrease in unintended pregnancy rate from 2009 to 2013. However, the United States still has room to improve in order to decrease unintended pregnancy rates to a level comparable to other developed countries. This will depend on improvements in contraceptive education to Americans and further policy changes.

The pattern of contraceptive use in Canada is similar to that of the United States, with a similar percentage of oral contraceptive use (about 44% of women 15–44 years of age), higher use of male condoms (54%), and a lower use of IUDs (4.3%) and sterilization (7%).<sup>29</sup> In England, the primary method of contraception is oral contraception (28%) followed by condoms (24%), the IUD (4%), and injectable methods (3%); 7% of the reproductive-aged women and 10% of the men have been sterilized.<sup>30</sup> In France, 41% of reproductive-aged women use oral contraceptives. IUD use is increasing in France in all ages between 2010 and 2013. In women aged 20–24, 5% use this method, and in women aged 25–29, 16% use IUDs.<sup>31</sup>

# THE IMPACT OF THE WORLDWIDE USE OF CONTRACEPTION

The world population is expected to stabilize at above 10 billion after 2180, with a fertility rate of 2.1 children per woman.<sup>32</sup> Approximately 96% of the population growth now occurs in developing countries, so that by 2050, 10% of the population will live in developed countries, a decrease from the current 25%. Today, the fertility rate is about 1.6–1.9 children per women in Eastern and Western Europe, North America, Japan, Australia, and New Zealand.<sup>33</sup> Sometime after 2020, all of the growth in global population will occur in developing countries (**Figure 21.3**).

**FIGURE 21.3**

Throughout the world, 63% of married women of reproductive age practice contraception. However, there is significant variation from area to area, for example, more than 75% in the United States but only 15% in Nigeria, one of the fastest growing countries.<sup>33</sup> About 225 million women living in developing countries are at risk of an

unplanned pregnancy.<sup>34</sup> The 76% of the world's population living in developing countries account for:

- 85% of all births
- 95% of all infant and childhood deaths
- 99% of all maternal deaths

In the developing world, maternal morbidity and mortality are real risks. The ability to regulate fertility has a significant impact on infant, child, and maternal mortality and morbidity. A pregnant woman has an 80 times greater chance of dying if she lives in a developing country rather than in a developed country.<sup>35</sup> The health risks associated with pregnancy and childbirth in the developing world are far greater than risks secondary to the use of modern contraception.

In recent years, there has been an appropriate shift from a narrow focus on contraception to a broader view that encompasses the impact of poverty, emphasizes overall well-being and the rights of individuals, endorses gender equality, and examines the interactions among these issues.

# THE IMPACT OF USE AND NONUSE

---

Inadequate access to contraception is associated with a high induced abortion rate. Effective contraceptive use largely, although not totally, replaces the resort to abortion. The combination of restrictive abortion laws and the lack of safe abortion services continues to make unsafe abortion a major cause of morbidity and mortality throughout the world, especially in many developing countries where abortion services are illegal.<sup>35,36</sup> Both safe and unsafe abortions can be minimized by maximizing contraceptive services. However, the need for safe abortion services will persist because contraceptive failures account for about half of the 1.2 million annual induced abortions in the United States.<sup>37</sup>

In the United States, money spent on public funding for family planning saves money spent on medical, welfare, and nutritional services.<sup>38,39</sup> States with higher family planning expenditures have fewer induced abortions, low-birth weight newborns, and premature births.<sup>40</sup> The investment in family planning leads to short-term reductions in expenditures on maternal and child health services and, after 5 years, a reduction in costs for education budgets. It was estimated that for every government dollar spent on contraceptive services, \$7.09 was saved.<sup>38</sup> Cutting back on publicly funded family planning services largely affects poor women, increasing the number of unintended births and abortions.

# SEXUALLY TRANSMITTED INFECTIONS AND CONTRACEPTION

---

The interaction between clinician and patient for the purpose of contraception provides an opportunity to control STIs. The modification of unsafe sexual practices reduces the risk of unplanned pregnancy and the risk of infections of the reproductive tract. A patient visit for contraception is an excellent time for STI screening; if an infection is symptomatic, it should be diagnosed and treated during the same visit in which contraception is requested. A positive history for STIs should trigger both screening for asymptomatic infections and counseling for safer sexual practices. Attention should be given to the contraceptive methods that have the greatest influence on the risk of STIs.

# THE ENVIRONMENT AND CONTRACEPTION

---

In the midst of politics and philosophy heavily promoting a “green” effort to limit global warming, a very important point is being ignored. **Even small increases in population have a major impact on the global environment, including excessive consumption of resources in affluent societies.**

Thomas Robert Malthus, an English clergyman, mathematician, and political economist, published six editions of his famous book, **An Essay on the Principle of Population**, between the years 1798 and 1826. The Malthusian hypothesis can be expressed very simply: the human population will outgrow the world’s resources needed for its support. Malthus argued that population could be controlled only by a high death rate or a low birth rate. Overpopulation would lead to poverty, an animalistic competition for food, and a general loss of civilization.

The Malthusian hypothesis has been resurrected in recent times. There is a growing awareness that our planet has a limited amount of clean air, potable water, and specific agricultural and mineral commodities, but an ever-growing population. Optimists look to the power of technology and human creativity to solve this Malthusian problem, but the acute need for effective contraception cannot be ignored. Effective family planning programs benefit not only individuals but also national economies and the global environment. The need and demand for family planning are extant in every part of our world, although greatest in the developing countries. Lacking is the required political and financial commitment.

# CONTRACEPTION AND LITIGATION

---

Clinicians are concerned about the prospect of bad outcomes associated with contraceptive use leading to litigation. Multimillion dollar verdicts and settlements in favor of plaintiffs who have used products as innocent as spermicides capture national attention. Actually, these events are very unusual compared with the widespread use of contraception.

The best way to avoid litigation is good patient communication. Patients who sue usually claim there were contraindications or risks that were not conveyed by the clinician. The best way to influence litigation is to keep good records. Good clinician's records are the most formidable weapon for the defense. Documentation is vital, but it is useless without thorough history taking. Good records and good history taking put the responsibility on the patient's honesty in response to the clinician.

**Document that the risks and benefits of all methods were discussed.**

**Document a plan for follow-up.**

**Document all interactions with the patient, including phone calls.**

# THE FUTURE

From 1970 to 1986, the number of births in women older than 30 quadrupled; from 1990 to 2005, the fertility rate among women older than 30 remained relatively stable, but in 2005 and 2006, the birth rates for women over 30 and for women over 40 increased.<sup>20,21,24</sup> As couples deferred pregnancy until later in life, the use of sterilization under age 35 declined, and the need for reversible contraception increased.

Until 2005, the highest number of births in the United States occurred between 1947 and 1965—the post–World War II baby boom (a demographic phenomenon shared by all parts of the developed world). The entire cohort of women born in this period reached their 45th birthday around 2010. We have experienced, therefore, an unprecedented number of women in the later childbearing years. This group of women not only increased in number but changed its fertility pattern.

The deferment of marriage is a significant change in our society. However, only a small percentage of the decline in the total fertility rate is accounted for by the increase in the average age at first marriage. Most of the decline in total fertility rate is accounted for by changes in marital fertility rates. In other words, postponement of pregnancy in marriage is the more significant change. This combination of increasing numbers, deferment of marriage, and postponement of pregnancy in marriage is responsible for the fact that we are seeing more older women who need reversible contraception. In short, there will continue to be longer duration of contraceptive use in younger women and greater use in older women, a pattern that began in 1990 (Table 21.2).

**TABLE 21.2 Change in U.S. Female Demographics 1980–2010<sup>5,160</sup>**

Age	1980	1990	2000	2005	2010	% Change 1980–2010
15–24	21 million	18.1 million	19.1 million	20.6 million	20.9 million	–0.4%
25–34	18.7	21.6	19.7	19.9	20.3	+8.6
35–44	13.1	18.9	22.7	21.8	20.6	+57.3
Total 15–44	52.8	58.6	61.5	62.3	61.8	+17

Fortunately, clinicians and patients recognized that low-dose steroid contraception is very safe for healthy, nonsmoking, older women. Between 1988 and 1995, the use of oral contraceptives doubled among women aged 35–39 and increased sixfold in women

older than age 40.<sup>23</sup> However, as the previously mentioned statistics indicate, its use is still not sufficient to meet the need. In addition to fulfilling a need, this population of women has a series of benefits to be derived from steroid contraception that tilt the risk/benefit ratio to the positive side ([Chapter 22](#)).

The growing need for reversible contraception would also be served by increased use of the IUD. A return to IUD use by American couples is both warranted and desirable.

A major problem in the United States is the prevalence of misconceptions. More than half of women, even well-educated women, are not accurately aware of the efficacy or the benefits and side effects associated with contraception.<sup>41, 42, 43, 44</sup> Unfortunately, a significant percentage of women still do not know that there are many health benefits with the use of steroid contraception. Misconceptions regarding contraception have, in many instances, achieved the stature of myths. Myths are an obstacle to good utilization and can only be dispelled by accurate and effective educational efforts.

Contraceptive advice is a component of good preventive health care. The clinician's approach to contraceptive counseling is key. While this is an era of informed choice by the patient, there is no doubt that patients, especially young patients, are influenced in their choice by their clinicians' advice and attitude. Although the role of a clinician is to provide the education necessary for the patient to make proper choices, one should not lose sight of the powerful influence exerted by the clinician in the choices ultimately made. In the 1970s, we approached the patient with great emphasis on risk. In the 1990s, studies effectively documented the risks and benefits of contraception. Now, counseling the patient should highlight the benefits and the greater safety of appropriate contraception.

# STERILIZATION

---

Contraceptive methods today are very safe and effective; however, we remain decades away from a perfect method of contraception for either women or men. Because reversible contraceptive methods are not perfect, more than a fourth of American couples use sterilization instead, and sterilization is now the predominant method of contraception in the world, with 222 million women relying on it for their method of family planning.<sup>45</sup>

Over the past 20 years, over 1 million Americans each year have undergone a sterilization operation, more women than men. Currently, 20% of reproductive-aged American women (33% of American women who use contraception) rely on contraceptive sterilization: 25% undergo tubal occlusion, and 8% depend on their partners' vasectomies.<sup>11</sup> Similarly in Great Britain, more than 32% of men and women have had a sterilization procedure.<sup>45</sup>

# History

James Blundell proposed in 1823, in lectures at Guy's Hospital in London, that tubectomy ought to be performed at cesarean section to avoid the need for repeat sections.<sup>46</sup> He also proposed a technique for sterilization, which he later described so precisely that most believe he performed the operation. The first report was published in 1881 by Samuel Lungren of Toledo, Ohio, who ligated the tubes at the time of cesarean section, as Blundell had suggested 58 years earlier.<sup>47</sup> The Madlener procedure was devised in Germany in 1910 and reported in 1919. Because of many failures, the Madlener technique was supplanted in the United States by the method of Ralph Pomeroy, a prominent physician in Brooklyn, New York (**Figure 21.4**). This method, still popular today, was not described to the medical profession by Pomeroy's associates until 1929, 4 years after Pomeroy's death. Frederick Irving of the Harvard Medical School described his technique in 1924 (**Figure 21.5**), and the Uchida method was not reported until 1946 (**Figure 21.6**).

**The Pomeroy**

### The Uchida

**FIGURE 21.6**

Few sterilizations were performed until the 1930s when “family planning” was first suggested as an indication for surgical sterilization by Sir Dugald Baird in Aberdeen. He required women to be older than 40 and to have had eight or more children. Mathematical formulas of this kind persisted through the 1960s. In 1965, Baird

delivered a remarkable lecture, entitled “The Fifth Freedom,” calling attention to the need to alleviate the fear of unwanted pregnancies and the important role of sterilization.<sup>48</sup> By the end of the 1960s, sterilization was a popular procedure.

Laparoscopic methods were introduced in the early 1970s. The annual number of vasectomies began to decline, and the number of tubal occlusion operations increased rapidly. By 1973, more sterilization operations were performed for women than for men. This is accurately attributed to dramatic decreases in costs, hospital time, and pain because of the introduction of laparoscopy and minilaparotomy methods. The use of laparoscopy for tubal occlusion increased from only 0.6% of sterilizations in 1970 to more than 44% by 1996.<sup>102</sup> Since 1975, minilaparotomy, a technique popular in the less developed world, has been increasingly performed in the United States, especially immediately postpartum. These methods have allowed women to undergo sterilization operations at times other than immediately after childbirth or during major surgery.

Laparoscopy and minilaparotomy have led to a profound change in the convenience and cost of sterilization operations for women. In 1970, the average woman stayed in the hospital 6.5 days for a tubal sterilization. By 1975, this had declined to 3 days, and today, women rarely remain in the hospital overnight. The shorter length of stay achieved from 1970 to 1975 represented a savings of more than \$200 million yearly in health care costs and a tremendous increase in convenience for women eager to return to work and their families.<sup>50</sup> Unlike some advances in technology, laparoscopy and minilaparotomy sterilization are technical innovations that have resulted in large savings in medical care costs.

The great majority of sterilization procedures are accomplished in hospitals by physicians in private practice, but a rapidly increasing proportion is performed outside of hospitals in ambulatory surgical settings, including physicians' offices. In either hospital or outpatient settings, female sterilization is a very safe operation. Deaths specifically attributed to sterilization accounted for a fatality rate of only 1.5 per 100,000 procedures in 1989, the most recent year for which these data are available, a mortality rate that is lower than that for childbearing (about 18 per 100,000 births in the United States).<sup>51, 52</sup> When the risk of pregnancy from contraceptive method failure is taken into account, sterilization is the safest of all contraceptive methods.

Vasectomy has long been more popular in the United States than anywhere else in the world, but why don't more men use it? One explanation is that women have chosen laparoscopic sterilization in increasing numbers. Another is that men have been frightened by reports, often from animal data, of associations with autoimmune diseases, atherosclerosis, and, most recently, prostatic cancer. Large epidemiologic studies have failed to confirm any definite adverse consequences.<sup>53</sup> When patients consider sterilization, we can assure them that vasectomy has not been demonstrated to have any

harmful effects on men's health.<sup>49</sup> In addition, vasectomy is less expensive than tubal sterilization, morbidity is less, and mortality is essentially zero.

# EFFICACY OF STERILIZATION

Laparoscopic sterilizations are not only convenient but also highly effective at preventing pregnancy. Vasectomy is also highly effective once the supply of remaining sperm in the vas deferens is exhausted. Approximately 50% of men will reach azoospermia at 8 weeks, but the time to achieve azoospermia is highly variable, reaching only about 60–80% after 12 weeks<sup>54,55</sup> (Table 21.3).

**TABLE 21.3 Failure Rates During the First Year of Use, United States<sup>15,16,17</sup>**

Age	1980	1990	2000	2005	2010	% Change 1980–2010
15–24	21 million	18.1 million	19.1 million	20.6 million	20.9 million	–0.4%
25–34	18.7	21.6	19.7	19.9	20.3	+8.6
35–44	13.1	18.9	22.7	21.8	20.6	+57.3
Total 15–44	52.8	58.6	61.5	62.3	61.8	+17

In addition to the specific operation used, the skill of the operator, age of the patient at sterilization, and time since the sterilization procedure all contribute to efficacy. Up to 50% of failures are due to technical errors. The methods using complicated equipment, such as spring-loaded clips and Silastic rings, fail for technical reasons more commonly than do simpler procedures such as the Pomeroy tubal ligation.<sup>56</sup> Interestingly, the hysteroscopic placement of tubal microinserts has a reported 0% failure rate after hysterosalpingogram has confirmed tubal blockage.<sup>57</sup> However, without confirmation of tubal occlusion, failure rates are considerably higher. Looking at patient characteristics, patients younger than 35 years were 1.5 times more likely to become pregnant.<sup>56</sup> These findings reflect the greater fecundity of younger women and the greater amount of time sterilization has to remain effective until menopause.

Significant numbers of pregnancies after tubal occlusion were in reality already present before the procedure. For this reason, some clinicians routinely perform a uterine evacuation or curettage prior to tubal occlusion.<sup>58</sup> It seems more reasonable (and cost-effective) to exclude pregnancy by careful history taking, physical examination, and an appropriate pregnancy test prior to the sterilization procedure. In addition, procedures can be timed to the follicular phase when pregnancy can be reliably avoided.

Because method, operator, and patient characteristics all influence sterilization

failures, it is difficult to predict which individual will experience a pregnancy after undergoing a tubal occlusion. Therefore, during the course of counseling, all patients should be made aware of the possibility of failure as well as the **intent** to cause permanent, irreversible sterility. It is important to avoid giving patients the impression that the tubal occlusion procedure is foolproof or guaranteed. Individual clinicians must be cautious judging their own success in accomplishing sterilization because failure is infrequent and many patients who become pregnant after sterilization never reveal the failure to the original surgeon.

Ectopic pregnancies can occur following tubal occlusion, and the incidence is much higher with some types of tubal occlusion.<sup>59</sup> Bipolar tubal coagulation is more likely to result in ectopic pregnancy than is mechanical occlusion. The probable explanation is that microscopic fistulae in the coagulated segment connecting to the peritoneal cavity permit sperm to reach the ovum. Ectopic pregnancies following tubal ligation are more likely to occur 3 or more years after sterilization, rather than immediately after. The proportion of ectopic pregnancies is 3 times as high in the 4th through the 10th years after sterilization as in the first 3 years.<sup>59</sup> For laparoscopic methods, the cumulative rate of ectopic pregnancy continues to increase for at least 10 years after surgery, reaching 17 per 1,000 for bipolar coagulation.<sup>59</sup> Overall, however, the risk of an ectopic pregnancy in sterilized women is lower than if they had not been sterilized. Nevertheless, approximately one-third of the pregnancies that occur after tubal sterilization are ectopic.<sup>59</sup>

Vaginal tubal sterilization procedures have higher failure rates than laparoscopy or minilaparotomy; however, the principal disadvantage is a higher rate of infection. Intraoperative infection is a rare complication of minilaparotomy or laparoscopic techniques, but in vaginal procedures, abscess formation approaches 1%.<sup>60</sup> This risk can be reduced by the use of prophylactic antibiotics administered intraoperatively, but laparoscopy is usually easier and safer than vaginal sterilization even in obese women.

# Sterilization and Ovarian Cancer— A Benefit of Sterilization

Serous ovarian cancer, the most common ovarian cancer, originates in the fimbriae of the fallopian tubes.<sup>61,62,63</sup> Evidence consistently indicates that tubal sterilization is associated with a major reduction in the risk of ovarian cancer.<sup>64,65,66,67,68</sup> Evidence from the Nurses' Health Study indicated that tubal sterilization was associated with a 67% reduced risk of ovarian cancer.<sup>64</sup> In the prospective mortality study conducted by the American Cancer Society, women who had undergone tubal sterilization experienced about a 30% reduction in the risk of fatal ovarian cancer.<sup>65</sup> Recently, there has been a push to perform complete salpingectomies for sterilization to potentially minimize the future risk of ovarian cancer even further. Concerns about increased surgical time, blood loss, increased risk of infection, and risk of loss of ovarian reserve have been evaluated. Studies to date have shown no increased morbidity or mortality with performing a salpingectomy at the time of cesarean section, postpartum, or in an interval manner.<sup>69,70</sup>

# FEMALE STERILIZATION TECHNIQUES

---

Because laparoscopy permits direct visualization and manipulation of the abdominal and pelvic organs with minimal abdominal disruption, it offers many advantages. Hospitalization is not required; most patients return home within a few hours, and the majority return to full activity within 24 hours. Discomfort is minimal, the incision scars are barely visible, and sexual activity need not be restricted. In addition, the surgeon has an opportunity to inspect the pelvic and abdominal organs for abnormalities. The disadvantages of laparoscopic sterilization include the cost, the expensive equipment, the training required, and the risks of inadvertent bowel or vessel injury.

Laparoscopic sterilization can be achieved with a variety of methods, including occlusion with unipolar or bipolar electrocautery with or without transection of the tube, partial or complete resection of the tube, and occlusion by clips or Silastic rings. Most commonly, a diagnostic laparoscope is used with operating instruments passed through a second trocar. The “open” laparoscopic technique can be used in which the camera port is placed into the abdominal cavity under direct vision to potentially avoid the risk of bowel or blood vessel puncture on blind entry. However, while the open approach results in a decreased incidence of failed entry and decreased risk of vascular injury when compared to failed attempts with the closed technique, it has not been shown to be preventative for visceral injuries (Cochrane). Patient acceptance and recovery are approximately the same with all methods.

It is now apparent that the long-term failure rates for all methods are higher than previous estimates; overall, 1.85% of sterilized American women experience a failure within 10 years.<sup>56</sup> The higher failure rates with Silastic rings and the Hulka-Clemens clip reflect the greater degree of skill required for these methods. Because of the effect of declining fecundity with increasing age, younger sterilized women are more likely to have a failure, including ectopic pregnancy, compared with older women. For these reasons, younger women seeking sterilization should consider the use of the IUD or implants, reversible methods that offer very low failure rates (Table 21.4, Figure 21.7).

## TABLE 21.4 Female Tubal Sterilization Methods 10-Year Cumulative Failure Rates<sup>56,71,72</sup>

Unipolar coagulation	0.75%
Postpartum tubal excision	0.75%
Filshie clip	0.56%
Silastic (Falope or Yoon) ring	1.77%
Interval tubal excision	2.01%
Bipolar coagulation	2.48%
Hulka-Clemens clip	3.65%

**FIGURE 21.7**

# Tubal Sterilization by Electrosurgical Methods

If electrons from an electrosurgical generator are concentrated in one location, heat within the tissue increases sharply and desiccates the tissue until resistance is so high that no more current can pass. Monopolar methods of sterilization create a dense area of current under the grasping forceps of the unipolar electrode. To complete the circuit, however, these electrons must spread through the body and be returned to the generator via a return electrode (the ground plate) that has a broad surface to minimize the density of the current to avoid burns as the electrons leave the body. “Monopolar” refers to the method that requires the patient to be grounded.

Monopolar electrosurgery can create a unique electrical “capacitance” problem. A capacitor is any device that can hold an electric charge and can exist wherever an insulated material separates two conductors that have different potentials. This property of capacitance explains some of the inadvertent bowel burns that occurred with laparoscopic sterilization.<sup>73</sup> The operating laparoscope is a hollow metal tube surrounding an active electrode, the forceps used to grasp and coagulate the tubes. When current passes through the active electrode, the laparoscope itself becomes a capacitor. Up to 70% of the current passed through the active electrode can be induced into the laparoscope. If the bowel or other structures touch a laparoscope, which is insulated from the abdominal incision (e.g., by a plastic cannula), the stored electrons will be discharged at high density directly into the vital organ. This potential hazard is eliminated by using a metal trocar sleeve rather than a nonconductive sleeve. Because there is little pressure behind the electrons from a low-voltage generator, not enough heat is generated to burn the skin as the capacitance current leaks out into the patient’s body through the metal sleeve. Even if the active electrode comes in direct contact with the laparoscope, as when a two-incision technique is used, the current will leak harmlessly through the metal trocar sleeve. The risk of inadvertent coagulation of the bowel or other organs cannot be completely eliminated because all body surfaces offer a path back to the ground plate.

The monopolar electrosurgical technique is straightforward. The isthmus portion of the fallopian tube is grasped and elevated away from the surrounding structures, and the electrical energy is applied until the tissue blanches, swells, and then collapses. The tube is then grasped, moving toward the uterus, and recoagulated, and the steps are repeated until 2–3 cm of the tube has been coagulated. Some surgeons advise against cornual coagulation for fear it may increase the risk of ectopic pregnancy due to fistula formation.

The coagulation and transection technique is performed in a similar fashion with the same instruments. In order to transect the tube, however, an instrument designed to cut tissue must be used. The transection of tissue increases the risk of possible bleeding and

does not, by itself, reduce the failure rate over coagulation alone. The specimens obtained by this method are usually coagulated beyond microscopic recognition and, therefore, will not provide pathologic evidence of successful sterilization.

The bipolar method of sterilization eliminates the ground plate required for unipolar electrosurgery and uses a specially designed forceps. One jaw of the forceps is the active electrode, and the other jaw is the ground electrode. Current density is great at the point of forceps contact with tissue, and the use of a low-voltage, high-frequency current prevents the spread of electrons. By eliminating the return electrode, the chance of an aberrant pathway through the bowel or other structures is greatly reduced. There is, however, a disadvantage with this technique. Because electron spread is decreased, more applications of the grasping forceps are necessary to coagulate the same length of tube than with unipolar coagulation. As desiccation occurs at the point of high current density, tissue resistance increases, and the coagulated area eventually provides resistance to flow of the low-voltage current. Should the resistance increase beyond the voltage's capability to push electrons through the tissue, incomplete coagulation of the endosalpinx can result.<sup>74</sup> **Bipolar coagulation is very effective only if three or more sites are coagulated on each tube.**<sup>71</sup>

Bipolar cautery is safer than unipolar cautery with regard to burns of abdominal organs, but most studies indicate higher failure rates. Although the bipolar forceps will not burn tissues that are not actually grasped, care must be taken to avoid coagulating structures adherent to the tubes. For example, the ureter can be damaged when the tube is adherent to the pelvic sidewall.

# Tubal Occlusion with Clips and Rings

Female sterilization by mechanical occlusion eliminates the safety concerns with electrosurgery. However, mechanical devices are subject to flaws in material, defects in manufacturing, and errors in design, all of which can alter efficacy. Three mechanical devices have been widely used and have low failure rates with long-term follow-up: the Hulka-Clemens (spring) clip, the Filshie clip, and the Silastic (Falope or Yoon) ring. Each of the three requires an understanding of its mechanical function, a working knowledge of the intricate applicator necessary to apply the device, meticulous attention to maintenance of the applicators, and skillful tubal placement. These devices are less effective when used immediately postpartum on dilated tubes.

## Hulka-Clemens Spring Clip (Figure 21.8)

## FIGURE 21.8

The spring clip consists of two plastic jaws made of Lexan, hinged by a small metal pin 2 mm from one end. Each jaw has teeth on the opposed surface, and a stainless steel spring is pushed over the jaws to hold them closed over the tube. A special laparoscope for one-incision application is most commonly used, although the spring clip can also be used in a two-incision procedure. The spring clip is applied at a 90-degree angle to include some mesosalpinx at the proximal isthmus of a stretched fallopian tube. The spring clip destroys 3 mm of tube and has 1-year pregnancy rates of 2 per 1,000 women but the highest 10-year cumulative failure rate.<sup>56</sup>

Complications unique to spring clip sterilization result from mechanical difficulties. If the clip is dislodged or dropped into the abdomen during the procedure, it should be retrieved. Should incomplete occlusion or incorrect alignment of the clip occur, a second clip can be applied without hazard. The clip offers a chance for reanastomosis, more so than electrosurgical methods; however, a sterilization procedure should only be undertaken if the patient understands and agrees to its permanence.

### **Filshie Clip (Figure 21.9)**

## The Filshie Clip

**FIGURE 21.9**

The Filshie clip is made of titanium lined with silicone rubber. The hinged clip is locked over the tube using a special applicator through a second incision or operating laparoscope. The rubber lining of the clip expands on compression to keep the tube blocked. Only 4 mm of the tube is destroyed. Failure rates 1 year after the procedure approximate 1 per 1,000 women.<sup>56</sup> A 15-year follow-up study in Quebec reported a cumulative failure rate of 9 per 1,000 women, whereas the 10-year failure rate in the United Kingdom was 5.6 per 1,000 women.<sup>72,75</sup> Because the Filshie clip is longer, it is reported to occlude dilated tubes more readily than does the spring clip. Similar to the spring clip, the Filshie clip provides a good chance for tubal reanastomosis.

## **Silastic (Falope or Yoon) Ring (Figure 21.10)**

## The Silastic (Falope-Yoon) Ring

**FIGURE 21.10**

This nonreactive Silastic rubber band has an elastic memory of 100% if stretched to no more than 6 mm for a brief time (a few minutes at most). A special applicator, 6 mm in diameter, can be placed through a second cannula or through a standard offset operating laparoscope. The applicator is designed to grasp a knuckle of tube and release the Silastic band onto a 2.5-cm loop of tube. The avascular loop of tube can be resected with biopsy forceps to provide a pathology specimen, but this is rarely performed (it does not increase efficacy). Ten to fifteen percent of patients experience severe postoperative pelvic cramping from the tight bands (which can be alleviated by the application of a local anesthetic to the tube before or after banding).

As with application of clips, the ring should be placed at the junction of the proximal and middle third of each fallopian tube. Necrosis occurs promptly and a 2–3-cm segment of the tube is destroyed. Failure rates are about 1% after 2 years, and the 10-year cumulative rate is better only with unipolar coagulation, postpartum tubal excision, and the Filshie clip.<sup>56</sup>

Mesosalpingeal bleeding is the most common complication of Silastic ring application. It usually occurs when the forceps grabs not only the tube but also a vascular fold of mesosalpinx. The mesosalpinx can also be torn on the edge of the stainless steel cylinder as the tube is drawn into the applicator. If bleeding is noted, application of the Silastic band often controls it, with reasonable next steps including placement of additional bands or use of electrocoagulation to stop the bleeding.

Silastic rings are occasionally placed on structures other than the tube. If this mistake is recognized, the band can usually be removed from the round ligament or mesosalpingeal folds by grasping the band with the tongs of the applicator and applying gradual, increasing traction. If a gentle attempt fails, removal is not necessary. If rings are inadvertently discharged into the peritoneal cavity, they can safely be left behind.

Patients should be prepared for the use of electrosurgical instruments in case bands or clips cannot be applied (because of adhesions or bleeding).

# Minilaparotomy

Tubal ligation, accomplished through a small suprapubic incision, **minilaparotomy**, is the most frequent method of interval female sterilization in the developing world. Minilaparotomy is a safe, simple, and adaptable alternative to laparoscopy that can be performed with a sedative and local anesthesia.<sup>76</sup> The fallopian tubes can be occluded through the minilaparotomy incision with bands or clips, but a simple Pomeroy tubal ligation is the method most commonly used. Patient characteristics, such as obesity, previous pelvic infection, or previous surgery, are the principal determinants of complications.<sup>77</sup>

Minilaparotomy is accomplished through an incision that usually measures 2–4 cm in length. Tubal ligation through a suprapubic incision can be accomplished for obese patients, but the incision will necessarily exceed the usual length. Forceful retraction increases the pain associated with the procedure and the time of recovery. For these reasons, we believe that minilaparotomy for ambulatory tubal occlusion should be limited to patients who are not obese (usually <150–160 lb, 70 kg). Postpartum tubal ligation following vaginal delivery can also be performed in a similar fashion, though the small incision is placed infraumbilically due to the increased size of the recently gravid uterus.

Tubal occlusion is difficult to accomplish through a minilaparotomy if the uterus is immobile. Laparoscopic tubal occlusion, on the other hand, does not require extreme uterine elevation or rotation and is a better choice for a patient with a uterus fixed in position.

# The Transcervical Approach

Although current methods of sterilization are safe and effective, they require skillful surgeons and, in the case of laparoscopic operations, elaborate and expensive equipment. Simpler approaches could make sterilization available and acceptable to more women. Transcervical methods have used electrocoagulation, cryosurgery, or laser to destroy the interstitial portion of the tube, to inject sclerosing agents or tissue adhesives (Femcept) through the tubal ostia, and to mechanically obstruct the tubal lumen. Most of these methods and the formed-in-place silicone plugs applied hysteroscopically are either too complicated or have high failure rates. The most practical approach is the application of sclerosing agents to the tubal openings using cannulae or an IUD. Transcervical insertion of quinacrine pellets during the proliferative phase of the menstrual cycle occludes the tubes and is the most promising of the “nonsurgical” approaches, with a 1.2% 10-year failure rate after two treatments. Some concern about quinacrine being related to reproductive tract cancers decreased its popularity, but these concerns have been dispelled after over 20 years of follow-up of women who had received this treatment.<sup>78</sup>

**Essure** is a metal coil device with polyester fibers (polyethylene terephthalate), which when placed hysteroscopically within the proximal segment of the fallopian tube spanning the uterotubal junction expands when released, anchoring itself in place. The polyester fibers in the device stimulate a tissue reaction, which is fibrotic and occlusive. After backup contraception for 3 months, a hysterosalpingogram is performed to confirm occlusion. If occlusion is not present at 3 months, contraception is continued and hysterosalpingography is repeated 3 months later. The procedure is quick, performed in the outpatient setting, often without analgesia, and considerably less expensive than laparoscopy. Effective permanent sterilization was initially achieved in about 85–90% of women.<sup>79</sup> With greater experience, placement can reach a 96% rate.<sup>80,81</sup> The risk of pregnancy after 5 years was 2.6 per 1,000 women, with no ectopic pregnancies.<sup>82</sup> Essure will be voluntarily taken off the US market as of December 31, 2018, due to declining sales. **Adiana** is a two-step procedure that has also been discontinued by the manufacturer for financial concerns, but was similar to Essure in that a hysteroscopic placement of a device was performed, followed by hysterosalpingogram 3 months later to confirm permanent blockage. Successful placement is achieved in 92–95% of women, with a 1-year pregnancy rate of 1.1%.<sup>79,83</sup>

# The Vaginal Approach

Although vaginal techniques are still used for tubal sterilization, high rates of infection and occasional pelvic abscesses following these operations have caused most clinicians to abandon them.<sup>60</sup> An apparent advantage in obese patients is sometimes deceptive because omental fat can block access to the fallopian tubes. Open laparoscopy is usually easier and safer in obese women.

# COUNSELING FOR STERILIZATION

---

All patients undergoing a surgical procedure for permanent contraception should be aware of the nature of the operation, its alternatives, efficacy, safety, and complications. The operation can be described using drawings or pelvic models, slides, or recordings. The description of the operation should emphasize its similarities to and differences from laparoscopy and pelvic surgery, especially hysterectomy or oophorectomy that may be confused with simple tubal ligation. Women who undergo tubal sterilization by any method are four- to fivefold more likely to have a hysterectomy; no biologic explanation is apparent, and this may reflect patient attitudes toward surgical procedures.<sup>84</sup> Alternatives, including vasectomy, steroid contraception, long-acting hormone methods, barrier methods, and IUDs, should be reviewed. It is important to emphasize to the patient that tubal ligation is not intended to be reversible, that it cannot be guaranteed to prevent intrauterine or ectopic pregnancy, and that failures can occur long after the sterilization procedure. Informed consent is best obtained at a time when a patient is not distracted or distraught, for example, not immediately before or after an induced abortion.

# Sexuality

There is no detrimental effect on sexuality specifically due to sterilization procedures.<sup>85,86</sup> Indeed, sexual life is usually positively affected. Many couples are less inhibited and more spontaneous in their sexual encounters when they do not have to worry about an unwanted pregnancy.

# Menstrual Function

There was some concern that tubal sterilization was associated with higher rates of dysmenorrhea and changes in menstrual function.<sup>87,88</sup> As noted above, hysterectomy rates are higher for women who have had a tubal sterilization. It was initially speculated that extensive electrocoagulation of the fallopian tubes can cause ovarian tissue damage, changing ovarian steroid production. This was suggested as the reason why menstrual changes were detected with longer (4 years) follow-up, whereas no changes had been noted with the use of rings or clips.<sup>89,90,91</sup> However, attempts to relate poststerilization menstrual changes with extent of tissue destruction failed to find a correlation, and an increase in hospitalization for menstrual disorders after monopolar cautery could not be documented.<sup>89,91</sup> A long-term follow-up study (3–4.5 years) failed to document any significant changes in menstrual cycles.<sup>92</sup> Follow-up studies at 3 months, 6 months, 2 years, and 5 years after sterilization by bipolar coagulation or Hulka clip could detect no changes in day 3 measures of ovarian reserve (gonadotropins, estradiol, and inhibin) or luteal phase levels of estradiol and progesterone.<sup>93,94,95,96</sup> In patients who have had tubal sterilization procedures, hysterectomies for pelvic pain or for abnormal uterine bleeding have been shown to be most common in women who had those symptoms prior to their sterilization procedures.<sup>97</sup> In the United States, a prospective, long-term follow-up study of sterilization showed that the increased risk of hysterectomy after sterilization was concentrated in women who were treated for gynecologic disorders before tubal sterilization.<sup>84</sup>

**The U.S. Collaborative Review of Sterilization, the largest and most comprehensive assessment of sterilization, could find no evidence that tubal sterilization is followed at 2 years and again at 5 years by a greater incidence of menstrual changes or abnormalities.<sup>98</sup> The evidence indicates that tubal sterilization does not cause menstrual abnormalities.**

# Reversibility

An important objective of counseling is to help couples make the right decision about an irreversible decision to become sterile. The active participation of both partners is a critical factor.<sup>99</sup> Not all couples are pleased following sterilization; in one series, 2% of US women expressed regret 1 year later and 2.7% after 2 years.<sup>100</sup> At the 2-year mark, the main factors associated with regret were age less than 30 and sterilization at the convenient time of a cesarean section. In another long-term follow-up study of US women, women younger than the age of 30 at the time of sterilization were most likely to express regret, but no differences were observed comparing timing after cesarean delivery, vaginal delivery, or a year later.<sup>101</sup> In the 1995 National Survey of Family Growth, nearly 25% of US women with a tubal ligation expressed a desire for reversal, by either one of the partners or both.<sup>42</sup> The U.S. Collaborative Review of Sterilization reported that only 14.3% requested reversal information after 14 years of follow-up, but the percentage was nearly 4 times higher in women aged 18–24 at sterilization.<sup>103</sup> Other studies have shown that women obtaining tubal sterilization before age 30 are up to 18 times as likely to request information on tubal reversal or assisted reproductive therapy and up to 8 times as likely to actually undergo tubal reversal or in vitro fertilization than women who undergo the sterilization procedure after age 30.<sup>104</sup> Overall, however, only 1.1% of women obtained reversal. In Canada, 1% of men and women obtained a reversal within 5 years after sterilization; in the United States, reversal within 5 years was obtained by 0.2% of women and 0.4% of men, a difference that could reflect the lack of insurance coverage for this procedure in the United States.<sup>75,105</sup> In addition to young age at the time of sterilization, an important risk factor for regret was an unstable marriage.<sup>106</sup> A change in marital status is undoubtedly an important reason for a desire to reverse sterilization.<sup>107</sup> Young couples in unstable relationships need special attention in counseling. Furthermore, for many couples, tubal occlusion at the time of emergency cesarean section or immediately after a difficult labor and delivery is not the best time for the procedure. It is important to know that sterilized women have not been observed to develop psychological problems at a greater than expected rate.<sup>108,109</sup>

Microsurgery for tubal anastomosis is associated with excellent results if only a small segment of the tube has been damaged. Pregnancy rates correlate with the length of the remaining tube—a length of 4 cm or more is optimal—and age at reversal procedure. Pregnancy rates can approach 88% in women less than 30 who had a clip or ring procedure initially and are as low as 36% in women over 40 who had electrocoagulation initially.<sup>110</sup> About 2 per 1,000 sterilized women will eventually undergo tubal anastomosis.<sup>107</sup>

# MALE STERILIZATION: VASECTOMY

---

Vasectomy is safer, easier, and less expensive and has a lower failure rate than female sterilization.<sup>111</sup> The operation is almost always performed under local anesthesia, usually by a urologist in a private office.<sup>112</sup> Surgeons who do more than 10 operations yearly have lower complication rates.<sup>113</sup>

Hematomas and infection occur rarely and are easily treated with heat, scrotal support, and antibiotics. Most men will develop sperm antibodies following vasectomy, but no long-term sequelae have been observed, including no increased risk of immune-related diseases or cardiovascular disease.<sup>49,114,115</sup> Adverse psychological and sexual effects have not been reported.<sup>116</sup> Because the other constituents of semen are made downstream from the testes, men do not notice a decreased volume or velocity of ejaculate.

Prostate cancer is the most frequent cancer among men, with a lifetime risk of one in eight in the United States. An increased risk of prostate cancer after vasectomy was reported in several cohort and case-control studies.<sup>117,118,119,120</sup> However, there was disagreement because other studies could not support an association between prostate or testicular cancer risk and vasectomy.<sup>114,121,122,123,124,125,126</sup> In a very large mixed racial/ethnic (Black and White, Chinese Americans and Japanese Americans) case-control study of prostate cancer, no statistically significant increase in risk could be identified after vasectomy, including no effect of age at vasectomy or years since vasectomy.<sup>127</sup> Reviews of six cohort studies and five case-control studies concluded that there is no increased risk of cancer of the testis following vasectomy, and consideration of the studies examining the possible association between prostate cancer and vasectomy (six cohort and seven case-control studies) found the evidence to be equivocal and weak.<sup>128,129</sup> A meta-analysis of the literature concluded that there is no increased risk of prostate cancer in men who have undergone vasectomy.<sup>130</sup> A case-control study from New Zealand found no increase in prostate cancer even after more than 25 years since the vasectomy.<sup>131</sup> Observational studies cannot totally avoid potential biases, and the disagreement regarding prostate cancer is consistent with either no effect or an effect too small to escape confounding biases. It is worth noting that the countries with the highest vasectomy rates (China and India) do not have the highest rates of prostate cancer. Screening for prostate cancer should be no different in men who have had a vasectomy.

Animal studies had indicated that vasectomy accelerates the process of atherosclerosis. In the U.S. Physicians' Health Study (a large prospective cohort study), no increase in the risk of subsequent cardiovascular disease could be detected

following vasectomy.<sup>132</sup> Indeed, vasectomy has not been demonstrated to have any adverse consequences or harmful effects on men's health.<sup>49</sup>

Vasectomy does not change the secretion of HIV into semen, and vasectomy should not change the risk of HIV transmission.<sup>133</sup>

Vasectomy reversal is associated with pregnancy rates as high as 70–80%.<sup>134</sup> The prospect for pregnancy diminishes with time elapsed from vasectomy, decreasing significantly to 30% after 10 years; the best results are achieved when reversal is performed within 3 years after vasectomy.<sup>135</sup> In most cases, sperm can be collected at the time of the reversal procedure and frozen for potential future intracytoplasmic sperm injection in case the reversal is unsuccessful.

# MEDICAL METHODS FOR THE MALE

---

A reversible method of contraception for men has been sought for years. Hormonal contraception for men is inherently a difficult physiologic problem because, unlike cyclic ovulation in women, spermatogenesis is continuous and high numbers of sperm are produced.<sup>136</sup> Investigational approaches to inhibit production of sperm include the administration of sex steroids, the use of GnRH analogs, and the administration of gossypol, a derivative of cottonseed oil.<sup>137,138</sup>

The use of exogenous sex steroids reduces testosterone synthesis, which leads to loss of libido and development of female secondary sexual characteristics. Furthermore, despite the use of large doses, sperm counts are not adequately reduced in all subjects. Levonorgestrel, cyproterone acetate, and medroxyprogesterone acetate all have been studied combined with testosterone, given intramuscularly to provide the desired systemic androgen effects. GnRH analogs also decrease the endogenous synthesis of testosterone, and supplemental testosterone must be provided. The overall metabolic and health consequences of these approaches have not been assessed, and frequent injections are required. No methods are ready for clinical use.<sup>139</sup>

Gossypol effectively decreases sperm counts to contraceptive levels, apparently by incapacitating the sperm-producing cells. Experience in China revealed that a substantial number of men remain sterile after exposure to gossypol, and animal studies in the United States indicated that gossypol, or contaminants of the preparation, was toxic; thus, work on gossypol was discontinued.<sup>140</sup> Analogs of gossypol may offer potential, but are years away from development.

# INDUCED ABORTION

---

Contraception is more effective and convenient than ever, but even the most conscientious couples can experience contraceptive failure. In the past, failure of contraception meant another, sometimes unwanted, birth or recourse to dangerous, secret abortion. The most ancient medical texts indicate that abortion has been practiced for thousands of years. Induced abortion did not become illegal until the 19th century, as a result of changes in the teachings of the Catholic Church (life begins at fertilization), and in the United States, the efforts of the American Medical Association to have greater regulation of the practice of medicine.

In the 1950s, vacuum aspiration led to much safer abortion, and beginning in Asia, induced abortion was gradually legalized in the developed countries of the world. This trend reached the United States from Western Europe in the late 1960s when California, New York, and other states rewrote their abortion laws. The U.S. Supreme Court followed the lead of these states in 1973 in the “Roe versus Wade” decision that limited the circumstances under which “the right of privacy” could be restricted by local abortion laws. By 1980, legal abortion became the most common surgical procedure performed in the United States. The average cost of a nonhospital abortion with local anesthesia in 2012 was \$480.<sup>142</sup>

The number of abortions performed in the United States has been decreasing since a peak of 1.6 million was reached in 1981, declining to 962,000 in 2014, with the greatest decrease among teenagers.<sup>3</sup> This is partly because the number of pregnancies in the United States has been decreasing and the proportion of reproductive-aged women younger than age 30 is also decreasing.<sup>52</sup> However, better use of effective contraception made a major contribution to the decline in the abortion rate. In 2011 and 2012, 61% of induced abortions were obtained by women in their 20s and 12% by women younger than 20.<sup>142</sup>

Overall, 2.8 million (45%) of American pregnancies each year are unintended, but the percentage is only 38% among White women in contrast to 50% among Hispanics and 64% among Blacks.<sup>3</sup> Each year, 42% of unintended pregnancies are terminated by induced abortions. The rate of unintended pregnancies and abortions is about 4 times higher among poor women.

Worldwide, about 20% of all pregnancies end in induced abortion.<sup>1</sup> The number of induced abortions has declined in developed countries to less than 7 million annually. Most induced abortions occur in developing countries, about 35 million annually, where more than half are unsafe, illegal abortions. It is also worth emphasizing that in countries where there are legal restrictions on abortion, the abortion rates are not lower

compared with areas where abortion is legally permitted; however, these illegal abortions are associated with infection and hemorrhage, accounting for 13% of maternal deaths worldwide.<sup>143</sup> **Abortion restrictions do not reduce the rate of abortions, but do make the procedure less safe.**

# Safety of Induced Abortions

Public health authorities have demonstrated that the legalization of abortion reduced maternal morbidity and mortality more than any single development since the advent of antibiotics to treat puerperal infections and blood banking to treat hemorrhage. The number of American women reported as dying from abortion declined from nearly 300 deaths in 1961 to 4 in 2013, or about **0.6 deaths for every 100,000 legal abortions**.<sup>144</sup> For comparison, in 2011–2013, the maternal death rate for childbirth in the United States was 17 per 100,000 births.<sup>145</sup>

The most important determinants of abortion mortality are duration of gestation and type of anesthesia: later abortions and general anesthesia are more hazardous.<sup>146,147,148</sup> As with mortality, morbidity rates vary primarily with duration of pregnancy, but other factors are important as well, including the type of operation, age of patient, type of anesthesia, operator's skill, and method of cervical dilation. More experienced surgeons and younger, healthier women are less likely to have complications.

Major and minor complications in a series of 170,000 first-trimester abortion patients were as follows<sup>149</sup> (Table 21.5).

## TABLE 21.5

## Major Complications (Hospitalization Required)

Retained tissue	27.7 per 100,000 induced abortions
Sepsis	21.2
Uterine perforation	9.4
Hemorrhage	7.1
Inability to complete	3.5
Intrauterine plus tubal pregnancy	2.4

## Minor Complications (Managed in Clinic or Office)

Mild infection	462.0 per 100,000 induced abortions
Reaspiration same day	180.8
Reaspiration later	167.8
Cervical stenosis	16.5
Cervical tear	10.6
Underestimated gestation	6.5
Convulsive seizure	4.0

The possibility that abortion can result in longer-term complications has been examined

in more than 150 studies.<sup>150</sup> There is no evidence for any adverse consequences of vacuum aspiration abortion for subsequent fertility<sup>150,151</sup> or increased risk for ectopic pregnancy.<sup>141,152,153</sup> Second-trimester abortions do not increase the rate of preterm delivery or midtrimester fetal losses, nor do they seem to have an impact on future fertility.<sup>154,155</sup> Multiple induced abortions do not increase the risk of a subsequent ectopic pregnancy.<sup>156</sup> Recent meta-analyses show that induced surgical abortion may be associated with a slightly increased risk of preterm birth in subsequent pregnancies.<sup>156,157,158</sup> The long-term effects of second-trimester abortion may depend on the method used.<sup>159</sup> A French study disagrees with these conclusions, finding a slightly increased risk of ectopic pregnancy in women with a prior induced abortion and no previous ectopic pregnancy, and Chinese and Danish studies found a small increase in the risk of spontaneous miscarriage following surgically induced abortions.<sup>161,162,163</sup>

The psychological sequelae of elective abortion have been studied and debated. The evidence indicates that depression is less frequent among women postabortion compared with postpartum, that women denied abortion experience resentment for years, and that the children born after an unwanted pregnancy have social, occupational, and interpersonal difficulties lasting into early adulthood.<sup>164</sup> Extensive reviews of the evidence, including one by the American Psychological Association, concluded that first-trimester induced abortions do not increase the risk for mental health problems.<sup>165,166</sup> Adverse psychological responses following induced abortion are influenced by a need for secrecy, perceptions of associated stigma, inadequate social support, and troubling personality characteristics such as low self-esteem or improper coping strategies, but the most important predictor of a negative mental reaction is a prior history of mental problems.<sup>166</sup>

Conflicting results were reported in over 20 studies examining the risk of breast cancer associated with the number of abortions (especially induced abortions) experienced by individual patients.<sup>167,168</sup> Concern for an adverse effect has been based on the theoretical suggestion that a full-term pregnancy protects against breast cancer by invoking complete differentiation of breast cells, but abortion increases the risk by allowing breast cell proliferation in the first trimester of pregnancy but not allowing the full differentiation that occurs in later pregnancy. In these studies, there was a major problem of recall bias; women who develop breast cancer are more likely to truthfully reveal their history of induced abortion than healthy women. **In studies that avoided recall bias (e.g., by deriving data from national registries instead of personal interviews), the risk of breast cancer was identical in women with and without induced abortions.**<sup>169,170</sup> More careful case-control and cohort studies, including the Nurses' Health Study, also failed to link a risk of breast cancer with induced or

**spontaneous abortions.** <sup>171,172,173,174</sup>

Safe abortion is still unavailable to many women. It is estimated that between 2010 and 2014, 25.1 million unsafe abortions were performed, 97% of these being in developing countries.<sup>175</sup> The fatality rate for unsafe abortions is up to 350 deaths for 100,000 abortions. These deaths are preventable. Family planning services that provide effective contraceptive choices as well as access to safe abortion early in pregnancy are essential in order for societies to achieve desired fertility rates and a healthy female population.

# Pretreatment Care of Abortion Patients

Approximately 90% of the 962,000 induced abortions performed in the United States yearly are performed during the first trimester of pregnancy, and a growing percentage is accounted for by medical abortion.<sup>3,176</sup> The vast majority (94%) of these procedures occur in freestanding abortion clinics.<sup>177</sup> The safety of outpatient abortion surgery under local anesthesia is well established.

The care of the patient who has decided to terminate a pregnancy begins with the diagnosis of intrauterine pregnancy and an accurate estimate of gestational age. Failure to accomplish this is the most common source of abortion complications and subsequent litigation. Vaginal ultrasound should be used when accurate dating is otherwise difficult or unsure.

Nearly all women who want to terminate a pregnancy in the first trimester are good candidates for an outpatient surgical procedure under local anesthesia. Possible exceptions include patients with severe cardiorespiratory disease, severe anemias or coagulopathies, mental disorders severe enough to preclude cooperation, and excessive concern about operative pain that is not alleviated by reassurance.

Surgical abortions should not be undertaken for women who have known uterine anomalies or leiomyomas or who have previously had difficult first-trimester abortion procedures, unless ultrasonography is immediately available and the surgeon is experienced in its intraoperative use. Previous cesarean section or other pelvic surgery is not a contraindication to outpatient first-trimester surgical abortion.

# Counseling Abortion Patients

Counseling has played a critical role in the development of efficient and acceptable abortion services and to ensure quality patient care. Counseling responsibilities include helping with decision-making; providing information about the procedure; obtaining informed consent; providing emotional support for the patient and her family before, during, and after the procedure; and providing information about contraception.<sup>178</sup> Referral opportunities should be provided for prenatal care and adoption for women who choose to carry an unplanned pregnancy to term. These responsibilities can be performed by a physician, nurse, psychologist, social worker, or a trained layperson. An informed consent document should unequivocally state the possibilities of common adverse outcomes, such as incomplete abortion, infection, uterine perforation, the need for laparotomy, ectopic pregnancy, and failed abortion. The counselor should document this discussion.

Nearly half of induced abortions in the United States are repeat abortions.<sup>179</sup> Repeat elective abortions are more common in older women, in women using a method of contraception, and in women reporting alcohol or drug abuse. Counseling after elective abortions should emphasize effective, long-term methods of contraception such as the IUD, implants, or sterilization.

# Methods for First-Trimester Abortions

The most widely used technique for first-trimester abortions is vacuum curettage.<sup>142,176</sup> The procedure is performed using local anesthesia (a paracervical block). Cervical dilation is accomplished with tapered Pratt dilators. Some surgeons recommend the preoperative insertion of cervical tents. These are osmotic dilators of dried seaweed or synthetic hydrophilic substances that are left in place from a few hours (synthetic) to overnight (seaweed).<sup>182</sup> Mifepristone (RU-486), the progesterone antagonist, produces preoperative cervical dilation equally effectively, and the ease of its single oral dose makes it a more attractive choice, but oral mifepristone requires a long pretreatment (24–36 hours).<sup>181</sup> Buccal misoprostol (400 µg) dilates the cervix as effectively as laminaria when given 4 hours prior to the procedure, and it is relatively inexpensive.<sup>182</sup> After the procedure, the patient is observed for 1–2 hours before returning home.

Aspiration surgical abortion is safe and effective, but it is not available everywhere, and some women find it difficult to undergo a surgical procedure or to go to a clinic where they may be subject to loss of privacy or harassment. Nonsurgical methods make abortion available to more women and improve the circumstances under which pregnancies are terminated. The progesterone antagonist mifepristone (RU-486) and the antimetabolite methotrexate have both been demonstrated to effectively induce abortion early in pregnancy when combined with a prostaglandin.<sup>186,187</sup> Medical first-trimester abortions do not increase risks in future pregnancies, including ectopic pregnancy, spontaneous miscarriage, preterm birth, or low birth weight.<sup>183</sup> Although both medical and surgical abortion methods have a very low rate of serious complications, medical abortion is associated with more discomfort, bleeding, and incomplete abortion.<sup>180,184,185</sup>

France and China were the first countries to approve the marketing of the medical abortifacient mifepristone, a synthetic relative of the progestational agents in oral contraceptives. Mifepristone acts primarily, but not totally, as an antiprogestational agent. Both progesterone and mifepristone form hormone-receptor complexes that are similar, but the mifepristone complex has a slightly different conformational change (in the hormone-binding domain) that prevents full gene activation. The agonistic activity of this progestin antagonist is due to its ability to activate certain, but not all, of the transcription activation functions on the progesterone receptor. The dimethyl (dimethylaminophenyl) side chain at carbon 11 of mifepristone is the principal factor in its antiprogestone action. There are three major characteristics of its action that are important: a long half-life, high affinity for the progesterone receptor, and active metabolites.

A single oral dose of mifepristone may be followed a day later by the

administration of a prostaglandin analog. Several analogs have been used, but the most widely available and best tolerated was misoprostol, 800 µg administered vaginally.<sup>186</sup> When administered in the first 8 weeks of pregnancy, this medical termination carried success and complication rates similar to those achieved with vacuum curettage.<sup>187,188</sup>

Misoprostol is a stable, orally active synthetic analog of prostaglandin E<sub>1</sub>, available commercially for the treatment of peptic ulcer. Combined with mifepristone, it provides an effective, simple, inexpensive method that can be administered at home.<sup>188,189,190,191,192</sup> In the large US trial of 600 mg mifepristone followed by 400 µg misoprostol orally, there was a 1% failure rate under 7 weeks of pregnancy and 9% from 8 to 9 weeks.<sup>193</sup> Termination occurred in 50% of the women within 4 hours after misoprostol administration and 75% within 24 hours.

Based on worldwide experience, the regimen with the least side effects and cost, but equally good efficacy, was a combination of a lower dose of oral mifepristone (200 mg), followed 48 hours later by the vaginal administration of 800 µg misoprostol at home.<sup>188,191,194,195,196</sup> The vaginal administration of misoprostol allowed medical abortion up to 63 days after the last menstrual period.<sup>189</sup> However, because of a problem with infection, the protocol for medical abortion changed.

In 2005, the Centers for Disease Control and Prevention reported four cases of fatal toxic shock syndrome in California associated with *Clostridium sordellii* that occurred within 1 week after medical abortions (induced with 200 mg of oral mifepristone and 800 µg of vaginal misoprostol).<sup>197</sup> This prompted many clinicians and the Planned Parenthood Federation to switch to buccal administration of misoprostol, recognizing that *Clostridium* species are present in a small percentage of vaginal cultures.

Beginning in 2006, Planned Parenthood Federation clinics changed to a protocol that administered 800-µg misoprostol buccally 24–48 hours after 200 mg mifepristone and either to screen with vaginal cultures, especially for STIs, and treat appropriately or to provide prophylactically doxycycline 100 mg b.i.d. for 7 days beginning on the day of mifepristone. In 2008, the protocol was again changed, requiring prophylactic doxycycline treatment. The routine use of antibiotics was associated with a greater reduction in serious infection compared with the method of screen and treat. Following these changes, the number of serious infections decreased from 93 to 6 cases in 100,000 medical abortions, a decline of 93%.<sup>198</sup> **The buccal misoprostol protocol is 98% effective at up to 49 days' gestation and provides comparable efficacy to vaginal misoprostol up to 63 days' gestation, an expected outcome because the pharmacokinetics of misoprostol are essentially the same with either buccal or vaginal administration.**<sup>199,200,201</sup> **The buccal route of administration of misoprostol is now the recommended method.**

Infection with *Clostridium* species has been associated with spontaneous miscarriages, the postpartum period, after trauma or surgical procedures, and even when buccal misoprostol was used.<sup>202</sup> The best prevention of fatal toxic shock with this rare infection is awareness of the possibility and early recognition. Abdominal cramping as a presenting complaint makes the diagnosis difficult because this is a common symptom following medical abortion. Unique characteristics include the absence of fever, markedly elevated white counts, fluid effusions sufficient to produce hemoconcentration, and eventually tachycardia and hypotension. Specific antibiotics with demonstrated efficacy against *Clostridium sordellii* have not been identified, although doxycycline inhibits *Clostridium* growth in vitro. Early recognition of this rare infection would mandate consideration of aggressive surgery with hysterectomy, a lesson learned from the experience with septic abortions in the years before legalized abortion.

It is likely that abortion with mifepristone is the result of multiple actions. Although mifepristone does not induce labor, it does open and soften the cervix (this may be an action secondary to endogenous prostaglandins). Its major action is its blockade of progesterone receptors in the endometrium. This leads to a disruption of the embryo and the production of prostaglandins. The disruption of the embryo and perhaps a direct action on the trophoblast lead to a decrease in human chorionic gonadotropin (hCG) and a withdrawal of support from the corpus luteum. The success rate is dependent on the length of pregnancy—the more dependent the pregnancy is on progesterone from the corpus luteum, the more likely that the progesterone antagonist, mifepristone, will result in abortion. The combined mifepristone-prostaglandin analog method is usually restricted to pregnancies that are not beyond 9 weeks' gestation. However, a regimen using a higher dose of misoprostol (administered vaginally) achieved a 95% complete abortion rate in women at 9–13 weeks' gestation.<sup>203</sup> Other progesterone antagonists have been developed, but only mifepristone has undergone extensive abortion trials.

Mifepristone is most noted for its abortifacient activity and the political controversy surrounding it. However, the combination of its agonistic and antagonistic actions can be exploited for many uses, including contraception, therapy of endometriosis and fibroids, induction of labor, treatment of Cushing syndrome, and, potentially, treatment of various hormone-dependent cancers. Doses of 2–5 mg/day inhibit ovulation and produce amenorrhea in over 90% of cycles, and in a pilot study of 50 women, there were no pregnancies.<sup>204</sup> A clinical trial indicated that a daily dose of 5 mg mifepristone would be an effective oral contraceptive.<sup>205</sup>

Methotrexate was tested as an abortifacient in the same dose used to treat ectopic pregnancy, 50 mg intramuscularly per square meter of body surface area.<sup>206</sup> Later, a single 75-mg intramuscular dose was demonstrated to be as effective.<sup>207</sup> Methotrexate

has also been administered orally in doses of 25 or 50 mg.<sup>208</sup> As with mifepristone, a prostaglandin is added to promote expulsion of the uterine contents. The first trials demonstrated that if the prostaglandin (800 µg misoprostol vaginally) was given a week after the injection of methotrexate, this method could be almost as, **but not as**, effective as mifepristone.<sup>209</sup> Efficacy diminishes with advancing gestation beyond 7 weeks since the last menstrual period.<sup>210,211,212</sup> Because methotrexate takes longer to act than mifepristone, the prostaglandin is used a week after the initial treatment and is repeated a day later if expulsion has not occurred. Methotrexate is easily available and inexpensive. It has been used in low doses to treat psoriasis and rheumatoid arthritis, as well as ectopic pregnancy, without adverse effects. It is, however, a known teratogen that can be deadly in high doses, and its use as an abortifacient results in prolonged bleeding and a prolonged time to abortion (up to a month in some cases). Mifepristone is preferred by clinicians who have experience with both methods, but there are no direct comparison studies of methotrexate and mifepristone.

Another approach uses the combination of tamoxifen and misoprostol. The administration of tamoxifen (20 mg daily for 4 days) followed by misoprostol (800 µg vaginally, with a second dose if necessary 24 hours later) was associated with a 92% rate of complete abortion in 100 women with pregnancies less than 9 weeks' gestational age.<sup>213</sup> Similar good results were obtained in a comparison of tamoxifen (20 mg b.i.d. for 4 days) with methotrexate.<sup>214</sup>

The use of prostaglandin alone has also been pursued.<sup>215</sup> Relatively high success rates have been reported with multiple dosing,<sup>216</sup> but the most effective regimen and the best method of administration remain to be determined.<sup>217</sup> The administration of 800 µg misoprostol daily for 3 days has been reported to be very effective late in the first trimester (10–12 weeks).<sup>218</sup> In very early gestation, a single vaginal dose of 800 µg misoprostol or multiple doses within 24 hours is as effective as the usual combination of mifepristone and oral misoprostol.<sup>216,219</sup>

One word of caution regarding misoprostol, the synthetic prostaglandin E<sub>1</sub> analog: it is now recognized that infants born to pregnant women exposed to misoprostol have an increased risk of abnormal vascular development resulting in Möbius syndrome (congenital facial paralysis with or without limb defects) and defects such as equinovarus and arthrogyposis.<sup>220,221,222</sup> Although the risk is low, this possibility must be considered in decision-making when the various methods for first-trimester abortion are considered.

Careful prospective follow-up assessments can detect no health differences in women who have medical abortions compared with women who have abortions by vacuum aspiration.<sup>223</sup> Although women having medical abortions experience more

bleeding and cramping, with appropriate counseling and support, women are equally satisfied with surgical and medical abortions.<sup>224</sup>

# Complications of Abortions

Postoperative complications of elective abortions are classified as either immediate or delayed. Uterine perforation and uterine atony are examples of immediate complications. Delayed complications can occur several hours to several weeks after the operation. These usually present according to the major complaint: bleeding, pain, and continuing symptoms of pregnancy.

## Bleeding

By far, the most common cause of unusually heavy postabortal bleeding is retained products of conception. Rates in large series vary from 0.2% to 0.6%.<sup>149</sup> Patients with retained products of conception occasionally present several weeks after an abortion, but most report excessive bleeding within 1 week. Severe pain or pelvic tenderness suggests that infection is also present. Treatment is prompt aspiration of the uterus with the largest cannula that will pass the cervix.

## Infection

Infection is sometimes marked by uterine bleeding; although without retained products of conception, the volume of blood loss is usually modest. Fever and uterine tenderness are the most common signs of postabortal endometritis, occurring in about 0.5% of cases.<sup>149</sup> Some studies indicate that prophylactic antibiotics reduce the risk of surgical postabortal infection.<sup>225,226</sup> Most clinicians agree that women at risk of pelvic infection benefit from the use of prophylactic antibiotics prior to induced abortion; others state that women who have not had a previous delivery should receive prophylaxis, and still others believe that all abortion patients would benefit from prophylactic antibiotics.<sup>227,228</sup> A meta-analysis of antibiotics at the time of surgically induced abortion unequivocally concluded that prophylactic antibiotics should be routinely used without exceptions, and, as noted previously, prophylactic antibiotics are now advocated for medical abortions.<sup>198,229</sup> Because both gonorrhea and chlamydia, as well as other organisms, can cause postabortion infections, a tetracycline seems the best drug for prophylaxis. Doxycycline, 100 mg an hour before the surgical abortion and 200 mg 30 minutes afterward, is the most convenient and comprehensive regimen.<sup>230</sup> Tetracycline, 500 mg once before and once after the operation, is also acceptable. Metronidazole, 400 mg an hour before and 4–8 hours afterward, has been tested and is effective treatment for patients with bacterial vaginosis detected at the time of abortion.<sup>231,232</sup> The treatment of choice for medical abortions is doxycycline 100 mg b.i.d. for 7 days beginning on the day of mifepristone.

Patients who present with uterine tenderness, fever, and bleeding require uterine aspiration and antibiotic treatment. Patients who have fevers higher than 38°C (101°F), signs of peritoneal inflammation, and uterine tenderness require hospitalization and intravenous antibiotics active against anaerobes, gonorrhea, and chlamydia. Outpatient treatment with doxycycline, 100 mg b.i.d. for 14 days, should be reserved for patients whose signs and symptoms are confined to the uterus.

## **Dysfunctional Uterine Bleeding Following Abortion**

Women may present with uterine bleeding but without signs or symptoms of retained products of conception or infection. When these two diagnoses have been ruled out by absence of fever, a closed cervix, and a nontender uterus, the bleeding itself can be treated hormonally. Curettage is rarely necessary unless bleeding is excessive.

## **Ectopic Pregnancy**

Failure to diagnose ectopic pregnancy at the time of induced abortion can cause a patient to return with complaints of persistent bleeding with or without pelvic pain. Careful examination of the uterine aspirate for villi at the time of abortion should make a missed ectopic pregnancy an unusual cause of delayed bleeding. If, however, a patient presents with this possibility, quantitative measurement of chorionic gonadotropin and vaginal ultrasonography should be used for accurate diagnosis and management. Further, while quite rare, a heterotopic pregnancy may have been present initially resulting in villi present in the aspirate and a persistent ectopic pregnancy.

## **Cervical Stenosis**

Patients who experience amenorrhea or hypomenorrhea and cyclic uterine pain after first-trimester abortion may have stenosis of the internal os. This condition occurs in about 0.02% of cases and is more common among women whose abortions are performed in the early first trimester with a minimum of cervical dilation and a small-diameter, flexible plastic cannula.<sup>149</sup> Possibly, the tip of this type of cannula abrades the internal os, and the minimal dilation allows the abraded areas to heal in contact. The condition is easily treated with cervical dilation with Pratt dilators under paracervical block.

## **Other Late Complications**

Amenorrhea, usually without pain, can be caused by Asherman syndrome, destruction and scarring of the endometrium. This condition is very rare and usually follows endometrial infection. This problem is best diagnosed and treated at hysteroscopy.

While complete scarring of the endometrial cavity is rare, increased risk of intrauterine adhesion formation is associated with the use of a sharp curette and multiple surgical procedures.<sup>233</sup>

Sensitization of Rh-negative women should be prevented. Approximately 4% of these women become sensitized following an induced abortion (the later the abortion, the higher the proportion).<sup>260</sup> Subsequent hemolytic disease of the newborn can be prevented by administering 50  $\mu$ g (250 IU) Rh immunoglobulin to all Rh-negative, D-negative women undergoing early abortion. The standard calculated dose is administered for second-trimester abortion.

# ABORTION IN THE SECOND TRIMESTER

---

The great majority (90%) of induced abortions occur in the first trimester. Four percent of abortions occur after 16 weeks' gestation.<sup>234</sup> The most common reasons for delays in seeking abortion are a failure to recognize pregnancy, a poor understanding of payment mechanisms, and awkward or confusing referral processes.<sup>235</sup>

Second-trimester abortions can be accomplished surgically or medically. After about 14 weeks of pregnancy, the surgical procedure is termed dilation and evacuation (D&E). Several approaches have been used for the medical termination of pregnancy. These include the vaginal, intramuscular, or intra-amniotic administration of prostaglandins and the intra-amniotic injection of hypertonic saline or urea, but these medications have been replaced by misoprostol and mifepristone. The D&E procedure has been considered safer and less expensive than the medical methods and better tolerated (and thus preferred) by patients.<sup>236,237,238,239,240</sup>

With surgical abortion in the second trimester, the training, experience, and skills of the surgeon are the primary factors that limit the gestational age at which abortion can be safely performed. Advanced gestational age by itself incurs increased risks for all types of complications. These are multiplied when the duration of pregnancy is discovered, after beginning uterine evacuation, to be beyond the experience and skill of the surgeon or capacity of the equipment. Uterine perforation, infection, bleeding, amniotic fluid embolism, and anesthetic reactions are increased as gestational age increases.<sup>236</sup>

When errors in estimating gestational age require the surgeon to use unfamiliar instruments or techniques that are not frequently practiced, the increased duration of the procedure can cause problems. Efforts to sedate or relieve pain by administering additional drugs increase the risk of toxic reactions or overdose. If a change from local to general anesthesia is undertaken, the patient is at much greater risk of anesthetic complications. Finally, if complications caused by advanced gestational age necessitate transfer of the patient to physicians who are not familiar with uterine evacuation techniques, the patient may undergo unnecessarily extensive surgery, such as hysterectomy, with all the risks inherent in emergency procedures.

Preoperative cervical dilation with osmotic dilators makes first-trimester abortion safer and easier and is essential for second-trimester abortion. Local anesthesia instead of general anesthesia also makes abortion safer.<sup>241,242</sup> Some patients are not good candidates for surgical procedures of any kind under local anesthesia, and others may have special reasons to prefer that an abortion be performed under general anesthesia. Patient requests should be seriously considered, but the clinician also has a responsibility to inform the patient of the risks and benefits of local versus general

anesthesia.

The medical method of induced abortion in the first trimester is also effective for second-trimester abortions. A combination of the progesterone antagonist, mifepristone, (a single oral 200-mg dose of mifepristone administered 36 hours before prostaglandin treatment) and 800-mg misoprostol administered orally or vaginally is highly effective.<sup>243,244</sup> If mifepristone is unavailable, misoprostol on its own, 400 mg every 3 or 4 hours for a total of five doses, can be used, as well as oxytocin.<sup>245</sup>

# POSTABORTION CONTRACEPTION

---

Despite improvements in contraceptive technology, unintended pregnancies lead to millions of spontaneous and voluntary abortions, unwanted births, and ectopic pregnancies in the United States and worldwide.<sup>1</sup> Social and economic disparities are associated with high rates of unintended pregnancies and induced abortions, especially among adolescents.<sup>246</sup> Contraception plays an important role in rectifying disparities and protecting women's health; at no time is access to effective methods more important than immediately after induced abortion. Adolescents are especially receptive to contraception counseling that is provided immediately after an induced abortion.<sup>247</sup>

Barriers to effective contraceptive use vary around the world. In the United States, where nearly half of induced abortions are repeat procedures, failure to receive contraception and alcohol and drug use are strongly associated with an increased risk of repeat abortion.<sup>179</sup> Comprehensive counseling about contraceptive options is not always incorporated into abortion care, and this failure explains many repeat abortions.<sup>248</sup> Studies indicate that family planning counseling in an abortion clinic is well accepted and promotes modern contraceptive use.<sup>248,249</sup>

Women who terminate pregnancies are at high risk of having another unintended pregnancy.<sup>250</sup> Clinicians should seize the opportunity to assist women who are highly motivated to implement contraception. An ideal time to provide contraception is promptly after treatment for an unsafe abortion, especially in women at high risk of subsequent unintended pregnancies because of lack of access to contraception.<sup>251</sup> Postabortion contraceptive counseling and initiation of contraceptive methods on the day of abortion are associated with increased continuation rates.

The safety of immediate placement of an IUD, etonogestrel implant, injection of depot medroxyprogesterone acetate, and initiation of oral contraceptives following first- and second-trimester abortions is well documented. Data regarding other methods (progestin-only pills, Norplant, transdermal, and vaginal methods) can be extrapolated from studies of postpartum women.<sup>252</sup>

Immediate post-first-trimester abortion IUD placement is known to be safe and effective, but information about the second trimester is more limited. A prospective cohort study of 256 women demonstrated a low rate of expulsion (3%) and discontinuation (8.3%), with a high rate of IUD acceptance, following a second-trimester surgical abortion.<sup>253</sup> The rate of infection was not significantly increased. A Cochrane meta-analysis of postabortion IUD placement (nine randomized trials including first- and second-trimester abortions) concluded that expulsion rates were higher with all IUD types than in interval placement.<sup>254</sup> More recently, a randomized

trial of IUD insertion after first-trimester surgical abortion indicated no major difference in expulsion rates comparing immediate insertion with delayed insertion and no increase in the risk of infection.<sup>255,256</sup> Of note is the study indicating that the risk of repeat abortion is decreased among IUD users compared with other methods.<sup>257</sup>

Etonogestrel implant insertion at the time of mifepristone administration before 8 weeks' gestation was not shown to decrease the efficacy of the medical regimen and was shown to decrease subsequent pregnancy in the next 6 months as compared to routine insertion of the implant.<sup>258</sup> A second study showed once again that the etonogestrel implant placed at the time of mifepristone did not decrease efficacy of the abortion, but also did not show decreased pregnancy rates. It did show that patients assigned to immediate placement were more satisfied with their care.<sup>259</sup>

In summary, IUD insertion, etonogestrel implant insertion, and the immediate start of depot medroxyprogesterone acetate, progestin-only pills, and barrier methods are indicated following either a first- or second-trimester abortion. After the elective termination of a pregnancy of less than 12 weeks, estrogen-progestin contraception can be started immediately. After a pregnancy of 12 or more weeks, estrogen should not be started until the 3rd postpartum week to avoid the postpartum risk of venous thromboembolism. Information about the rates of subsequent unintended pregnancies for newer methods of contraception following second-trimester abortion is limited; however, initiation of all hormonal methods of contraception immediately following a second-trimester abortion is endorsed by the World Health Organization and reduces the risk of repeat abortion. The vaginal ring and the contraceptive patch are assumed to have the same efficacy and safety as oral contraceptives. The abortion setting is an ideal time to provide a contraceptive method like IUDs and implants, which require a skilled clinician for insertion.

# Hormonal Contraception

Contraception is commonly viewed as a modern event, a recent development in human history. On the contrary, efforts to limit reproduction predate our ability to write about it. It is only contraception with synthetic sex steroids that is recent.

# THE HISTORY OF ORAL CONTRACEPTION

---

It was not until the early 1900s that inhibition of ovulation was observed to be linked to pregnancy and the corpus luteum. Beginning in 1920, Ludwig Haberlandt, professor of physiology at the University of Innsbruck, Austria, demonstrated that ovarian extracts given orally could prevent fertility in mice. Haberlandt is acknowledged as the first to perform experiments with the aim of producing a method of hormonal contraception; he called it “hormonal sterilization.”<sup>1</sup> In the 1920s, a Viennese gynecologist, Otfried Otto Fellner, conducting experiments in his spare time, and administering ovarian and placental extracts to a variety of animals, also reported hormonal sterilization.<sup>2</sup> By 1931, Haberlandt proposed the administration of hormones for birth control. An extract named Infecundin was produced in collaboration with the Hungarian pharmaceutical company Gedeon Richter, but Haberlandt’s early death of a heart attack in 1932, at age 47, brought an end to this effort. Fellner disappeared after the annexation of Austria to Hitler’s Germany. At this time, extraction and isolation of a few milligrams of the sex steroids required starting points measured in gallons of urine or thousands of pounds of organs.

# Russell Marker

The supply problem was solved by a cantankerous iconoclast, Russell E. Marker, who completed his thesis, but not the coursework, for his Ph.D. at the University of Maryland. The following story is derived from an autobiographical article and from a 2-hour interview for the oral history archives of the Chemical Heritage Foundation in Philadelphia.<sup>3,4</sup> Marker moved to Penn State in 1935 to pursue the goal of an abundant and inexpensive supply of progesterone, and for several years, he concentrated on urine from pregnant animals. Then in 1939, Marker devised the method, called the Marker degradation, to convert a sapogenin molecule into a progestin.

Marker was convinced that the solution to the problem of obtaining large quantities of steroid hormones was to find plants in the family that includes the lily, the agave, and the yam that contained sufficient amounts of diosgenin, a plant steroid and a sapogenin, that could be used as a starting point for steroid hormone production. Marker's search for an appropriate plant took him to North Carolina, California, Arizona, and Texas. He spent his summer vacations in the Southwest and Mexico collecting sapogenin-containing plants, and his laboratory analyzed more than a hundred thousand pounds of over four hundred different species of plants. Marker discovered that the roots of the *Dioscorea* plant (a wild yam) were the richest source of sapogenins.

On a visit to Texas A&M University, Marker found a picture of a large *Dioscorea* (*Dioscorea mexicana*) in a book that he just happened to pick up and browse through while spending the night at the home of a retired botanist who was helping him collect diosgenin-containing plants. He had to make several chaotic trips to Mexico for this *Dioscorea*, plagued by lack of a plant-collecting permit, unwilling help from Mexican botanists, the entry of the United States into World War II, and his lack of ability to speak Spanish. Eventually, 10 miles outside of Orizaba, Mexico, he found a willing accomplice in a native American country store owner named Alberto Moreno.

Moreno did not speak English, but somehow, Marker conveyed his desire to obtain the *Dioscorea* that was known locally as "cabeza de negro," black tubers—and Moreno delivered. Marker took the two plants Moreno provided on a bus back to Orizaba and eventually was able to smuggle one 9–12-inch-long tuber back to Pennsylvania.

Marker used only a portion of the plant to isolate diosgenin. In February 1942, he took the remainder to the Parke-Davis chemists in Detroit with whom he had previously collaborated. Demonstrating his process for obtaining diosgenin, Marker convinced the director of research, Oliver Kamm, that he was on to something, a source for raw material that could provide for the commercial production of hormones. Unfortunately, they could not convince the president of Parke-Davis, nor could Marker convince anyone at several other companies.

Unable to obtain support from the pharmaceutical industry, Marker drew on half of his life savings and returned to Mexico in October 1942. He arranged with Albert Moreno to collect the roots of the Mexican yam. Marker paid Mexican medical students to collect the yams. The students were arrested when farmers reported that their yams were being stolen, but not before Marker had enough to prepare a syrup.

Back in the United States with his syrup, Marker arranged to work in the New York laboratory of a friend, Norman Applezweig, an organic chemist involved in steroid research, in return for one-third of whatever progesterone his syrup could yield.<sup>5</sup> He isolated diosgenin and synthesized 3 kg of progesterone, the largest lot of progesterone ever produced. US pharmaceutical companies still refused to back Marker, and even his university refused, despite Marker's urging, to patent the process.

Luckily, before Marker left Mexico, he looked through the yellow pages in a Mexico City telephone directory and found a company called "Laboratorios Hormona," owned by a lawyer who was a Hungarian immigrant, Emeric Somlo, and a German immigrant who had both a medical degree and a Ph.D. in chemistry, Frederick A. Lehman.<sup>6</sup> Visiting the company, Marker met Lehman, who had the good sense to see where this was going. From his reading of the literature, he knew who Marker was; he knew the value of steroids; and he was a businessman. Lehman called his partner who was visiting New York and convinced him to return as soon as possible. The three men agreed to form a Mexican company for the production of hormones called Syntex (from **synthesis** and **Mexico**).

In December 1943, Marker resigned from Pennsylvania State College and went to Mexico where he collected tons of *D. mexicana* roots, chopped them up with a machete, and left the pieces to dry in the sun across from Moreno's store in a small structure for drying coffee. It took 2 months of work in an old pottery shed in Mexico City to prepare several pounds of progesterone, worth \$160,000, with the help of several young women who had little education and spoke no English. Marker moved into a new four-room laboratory and, over the next year, produced over 30 kg of progesterone and 10 kg of dehydroepiandrosterone. The price of progesterone fell from \$200 to \$50 a gram.

Marker left Syntex in May 1945 due to not being paid his salary and quoted share of stocks. He took some of his young female workers with him and started a new company in Texcoco, called Botanica-Mex. He changed to *Dioscorea barbasco*, which gave a greater yield of diosgenin, and the price of progesterone dropped to \$10 a gram and later to \$5.

Marker's new company was allegedly harassed, legally and physically, by Syntex, and in 1946, it was sold to Gedeon Richter, which moved it to Mexico City and renamed it Hormosynth. Eventually, it came under the ownership of Organon of Holland, which still uses it under the name of Quimica Esteroides. By the 1960s, several

pharmaceutical companies were benefiting from the root-gathering operations in Mexico, closely regulated by the Mexican government that imposed annual quotas, about 43 thousand tons, to balance harvesting with the new annual growth. Mexican yams provided the starting material for the manufacture of oral contraceptives for about 15 years, giving way to other sources, such as soya beans, methods for total synthesis, or microbial fermentation.<sup>7</sup> In 1987, Marker was granted an honorary doctorate in science from the University of Maryland, the degree he failed to receive in 1926.

In 1990, Marker was planning on a quiet visit to Mexico to present a plaque made in his honor by Pennsylvania State University to Adolfina Moreno, the daughter of Alberto, the owner of the small country store whom Marker met in 1942. Mexican scientists and pharmaceutical people learned of the visit, and that summer, a chartered busload of 50 people retraced Marker's trip from Mexico City to Orizaba.<sup>6</sup> Marker rode in a car with Frederico Lehman's son, Pedro, who had become a distinguished chemist. When they reached the small store now owned by Adolfina, she tearfully thanked him and pointed to a nearby photo, her marriage picture from 50 years ago, with Marker in the wedding group. At the age of 92, Russell Earl Marker died in Wernersville, Pennsylvania, in 1995, from complications after a broken hip.

# The Race for Cortisone

When Marker left Syntex, he took his know-how with him. Fortunately for Syntex, there still was no patent on his discoveries. They invited George Rosenkranz, a Hungarian chemist stuck in Havana after the Pearl Harbor bombing, to take over Syntex's production of steroid hormones. Rosenkranz's task was complicated by Marker's secretiveness—he knew of Marker's published techniques but this was insufficient to replicate the process entirely. He found reagents labeled with code words; Marker's workers identified solvents by their weight and smell. Rosenkranz gave up on reconstructing Marker's process and worked out his own commercial manufacture of progesterone and testosterone from Mexican yams, and soon Syntex was making large profits providing the sex hormones as raw material to other pharmaceutical companies. Rosenkranz now had a large active laboratory that attracted a young chemist, Carl Djerassi. These men knew each other, meeting and interacting with each other at the Laurentian Hormone Conference, the annual meeting organized and directed by Gregory Pincus.

Carl Djerassi, aged 16, and his physician mother fled the Nazi Anschluss in Vienna and emigrated to the United States in 1939.<sup>8</sup> A Jewish refugee aid organization placed Djerassi with a family in Newark, New Jersey. He received a scholarship to Tarkio College in Tarkio, Missouri, and another scholarship from Kenyon College in Ohio, where he pursued chemistry. Djerassi received his graduate degree from the University of Wisconsin and then responded to an invitation to visit Syntex. Rosenkranz proposed that Djerassi head a research group to concentrate on the synthesis of cortisone, a position he accepted in 1949 at the age of 26.<sup>9</sup>

Synthetic cortisone was desirable because earlier in 1949, Philip S. Hench, a Mayo Clinic rheumatologist, showed a movie at a medical meeting documenting crippled arthritic patients before treatment and the same patients active, even dancing, after daily injections with cortisone.<sup>10</sup> Cortisone can be converted to the more active cortisol (also called hydrocortisone), the major product of the adrenal cortex, by hydroxylation, which converts the oxygen attached at the 11 position to a hydroxyl group by adding a hydrogen.

Hench had obtained the very expensive cortisone through a biochemist at the Mayo Foundation, Edward C. Kendall, who had isolated it from extracts of the adrenal cortex and from cattle bile. In 1950, Hench and Kendall were awarded the Nobel Prize in Physiology or Medicine. It was recognized that continuing regular treatment would be necessary, and the race was on to develop an easy and cheap method to synthesize cortisone and related drugs.

In Mexico City, Carl Djerassi was using the plant steroid diosgenin from the

Mexican yam as the starting point. In 2 year's time, Syntex achieved the partial synthesis of cortisone, reported in 1951.<sup>11</sup> The Syntex method never reached commercialization, however, because a more efficient process was developed by the Upjohn Company. However, Djerassi's laboratory produced Syntex's topical corticoid anti-inflammatory products, Synalar and Neo-Synalar. In 1959, Djerassi left Syntax and moved to head the chemistry department at Stanford University—a professorial position he held for the next 25 years.

The Upjohn Company and G.D. Searle & Company joined the competition to synthesize cortisone, with Upjohn, the bigger company, devoting over 150 scientists and technicians to the task. Upjohn leadership assigned a symbol to represent the project, a blowtorch, making it clear that this was a heated race they wished to win.<sup>12</sup> G.D. Searle was a smaller company, but its participation in this race would cement a long-term relationship with Gregory Pincus.

By 1949, Albert L. Raymond and the G.D. Searle company were supporting steroid research at the Worcester Foundation for Experimental Biology in Massachusetts, and Gregory Pincus, the cofounder of the Worcester Foundation, was a Searle consultant.<sup>13</sup> Oscar Hechter, a fellowship awardee at G.D. Searle, saw Hench's movie that year about the miraculous transformation of arthritic patients after being given cortisone and listened to his results. Hechter returned to the foundation and urged that his project be given top priority. Pincus and Oscar Hechter developed a perfusion method, pumping blood, serum, or a serum-like solution through fresh endocrine glands (adrenal glands, testicles, or ovaries) held in a glass apparatus and collecting the perfused fluid.<sup>14</sup> Using the enzymes in the glands, precursors in the perfusing fluid were converted to the final products, hydrocortisone or the sex steroids. This was a method that could be used to produce commercial amounts of cortisone products, and it was patented in 1946.<sup>15</sup>

However, the perfusion system was complicated. It required the development of methods to maintain the animal organs, a web of glassware to infuse and collect appropriate perfusing solutions, and the separation and identification of the steroid products. Responding to Pincus and Hechter's success, the Searle company constructed rows of perfusion systems in their Skokie plant. Each contained a periodically replaced fresh beef adrenal gland, producing every few hours a large volume of perfused solution. The long-term plan was to engineer a more economical and profitable system. But in the meantime, Searle was able to provide substantial amounts of cortisone to clinical researchers throughout the United States.

At the same time, Merck ramped up a synthesizing process from bile acids, and by the end of 1950, they were selling cortisone acetate to clinicians for a price that had been reduced from \$200 per gram to \$35. In Kalamazoo, Michigan, Upjohn chemists were pursuing a method based on the process used to make penicillin, conversion of

precursors by microbes to the desired product. The work was headed by Durey H. Peterson, the son of Swedish immigrants. Peterson believed that lower microorganisms might possess the same enzymes used by adrenal glands to make cortisone, especially the difficult step of introducing an oxygen molecule to the structure.

Using paper chromatography methods developed by Alejandro Zaffaroni, Peterson and H.C. Murray attacked the problem, beginning in 1949. First, they needed a microorganism. This they acquired, a fungus of the *Rhizopus* species, by leaving an agar plate on the window sill of a laboratory at the Upjohn Company. In 1 year's time, the two chemists proved the value of microorganisms in chemical synthesis. Their method used *Rhizopus nigricans* to convert progesterone to 11-hydroxyprogesterone, which could in turn be processed into hydrocortisone.

By 1955, Upjohn had become the market leader, and Searle shut down its perfusion cells and quit the race. Upjohn's commercialization of the methods developed by Peterson and Murray led to popular and successful products. But the Searle people had gained valuable experience that would eventually pay off with other synthesized hormones and products.

The Upjohn method used progesterone as the starting point, available in the early 1950s only from Syntex. George Rosenkranz's laboratory at Syntex was also pursuing the industrial synthesis of cortisone, and in July 1951, Syntex was about to sign a contract with a large chemical firm to begin production. This never happened because of a phone call. Rosenkranz told the story: "I received a phone call from Upjohn asking me whether we would be able to accept an order for ten tons of progesterone at forty-eight cents a gram."<sup>7</sup> The quantity was unheard of, and Upjohn's order remained a puzzle until the microfermentation method was published. Rosenkranz accepted the order, and Syntex found itself as the key supplier of progesterone to other companies.

# The Synthetic Progestational Drugs, Norethindrone and Norethynodrel

Djerassi and other Syntex chemists turned their attention to the sex steroids. They discovered that the removal of the 19-carbon from yam-derived progesterone increased the progestational activity of the molecule. The clue for this work came from Maximilian Ehrenstein at the University of Pennsylvania, who reported in 1944 that a potent progestational compound he had produced appeared to be progesterone without its carbon at the 19 position; henceforth the 19-nor family of compounds indicated steroid chemical structures without the carbon atom at the 19 position.<sup>16</sup> Chemists at Schering AG in Berlin had produced orally active versions of estradiol and testosterone in 1938, by substituting an acetylene group in the 17 position of the parent compounds. The resulting ethinyl estradiol later became the estrogen component in oral contraceptives. The ethinyl testosterone product was known as ethisterone, marketed in 1941, and the Syntex chemists reasoned that removal of the 19-carbon would increase the progestational potency of this orally active compound.

On October 15, 1951, norethindrone was synthesized at Syntex; the final steps were performed by Luis Miramontes, working on his undergraduate thesis in chemistry under Djerassi's supervision.<sup>9</sup> The patent application was filed 6 weeks later on November 22, 1951, and the work was presented in April 1952 at the annual meeting of the American Chemical Society and published in 1954.<sup>12</sup> The greater potency of norethindrone, achieved by removing the 19-carbon of ethinyl testosterone, compared with progesterone was demonstrated in monkeys and then four women at the National Institutes of Health, reported in 1953, 1956, and 1957.<sup>17,18,19</sup> Syntex supplied norethindrone to many investigators, including Gregory Pincus. Edward T. Tyler first reported its clinical use in 1955 for the treatment of menstrual disorders.<sup>20</sup>

Frank Colton, a chemist at G.D. Searle and Company, filed a patent for norethynodrel, a compound closely related to norethindrone, differing only in the position of the double bond, on August 31, 1953. The Polish-born Colton received his Ph.D. in chemistry from the University of Chicago. From 1949 to 1951, he was a research fellow working with Edward Kendall at the Mayo Foundation on the synthesis of cortisone. Colton joined Searle in 1951, along with Byron Riegel, to develop steroid drugs, succeeding with Nilevar, the first commercial anabolic agent marketed in 1956, and Aldactone, the antialdosterone antihypertensive agent introduced in 1959.

Norethynodrel was the result of a deliberate and planned program to create orally active agents with progestational activity. Later, Colton pointed out that although the Syntex and Searle chemists followed a similar path, they were independently pursuing

the trail blazed by previous scientists.<sup>13</sup> Along the way, hundreds of compounds were sent to Pincus at the Worcester Foundation to test for ovulation inhibition in rabbits. Their best drug, norethynodrel, assigned the number SC-4642, was synthesized at Searle in a process that was considered to be significantly different from the Syntex method.<sup>13</sup>

Djerassi urged legal proceedings for patent infringement, claiming that norethynodrel was converted to Syntex's compound, norethindrone, by gastric acid, but Parke-Davis, the American company licensing norethindrone, did not want to make waves presumably because Parke-Davis was supplying the antihistamine component of Searle's best-selling product for motion sickness, Dramamine.<sup>13</sup> Pincus would ultimately choose the Searle compound, norethynodrel for clinical testing as an oral contraceptive, and Syntex, not having marketing capability, licensed norethindrone to other pharmaceutical companies. Norethindrone was tested as a contraceptive by Edward Tyler in Los Angeles and Joseph Goldzieher in San Antonio, Texas, but Parke-Davis chose not to pursue government approval, probably fearing religious reactions. Subsequently, Syntex turned to the Ortho Division of Johnson & Johnson. By 1964, Ortho, Parke-Davis, and Syntex (now in California) were marketing oral contraceptives containing norethindrone or its acetate.

The creation of norethindrone and norethynodrel by the chemists was essential in the development of oral contraception because the natural hormone progesterone is relatively impotent given orally, requiring very large doses that even then do not achieve a uniform response. The synthetic progestational agents are very active when administered orally, producing reliable effects with small doses.

A Wall Street entrepreneur, Charles Allen, acquired Syntex in 1956 for \$2 million cash and a loan of \$2 million to be paid from future profits.<sup>7</sup> Rosenkranz became president and CEO, and Alejandro Zaffaroni, an Italian who emigrated from Montevideo, Uruguay, became executive vice president. Zaffaroni obtained his Ph.D. in 1949 in biochemistry from the University of Rochester, developing a paper chromatography system that soon became a principal method of studying steroid hormones.<sup>21</sup> Rosenkranz met Zaffaroni at the Laurentian Hormone Conference in 1951. Their aim was to develop a pharmaceutical company on a foundation of research. Rosenkranz said, "We were the brilliant amateurs with a 'can do anything' attitude. We were like stem cells (though then none of us really knew the concept). We could differentiate into anything we desired. Production, finance, sales, marketing—all held no fear for us."<sup>7</sup>

In 1961, the company moved to Palo Alto, California, influenced by their third partner, Djerassi, who was teaching at Stanford University. The growth of the company was meteoric, with blockbuster hits like Synalar, a topical corticosteroid for the treatment of psoriasis, and Naproxen, a nonsteroidal, anti-inflammatory drug. Much of

this success was to an innovative philosophy in the pharmaceutical business, “patent and publish.”<sup>7</sup> The Syntex scientists were encouraged to promptly publish their results, gaining the peer recognition that is such a motivating force for basic scientists. In 1994, Roche Holdings acquired Syntex for \$5.3 billion.

# Gregory Pincus

Gregory Goodwin (Goody) Pincus was born in 1903 in New Jersey, the son of Russian Jewish immigrants who lived on a farm colony founded by a Jewish philanthropic organization.<sup>15</sup> Pincus was the oldest of six children and grew up in a home of intellectual curiosity and energy, but even his family regarded him as a genius.

Pincus graduated from Cornell and went to Harvard to study genetics, joining Hudson Hoagland and B.F. Skinner as graduate students of W.J. Crozier in physiology, receiving degrees in 1927. Crozier taught Pincus, Hoagland, and Skinner (respectively, in reproductive biology, neurophysiology, and psychology) to apply science to human problems. This was to be the cornerstone of Pincus's own philosophy.

Pincus performed pioneering studies of meiotic maturation in mammalian oocytes, in both rabbit and humans. In 1934, Pincus reported the achievement of in vitro fertilization of rabbit eggs, earning him a headline in the **New York Times** that alluded to Haldane and Huxley. An article in **Colliers** depicted him as an evil scientist. By 1936, Harvard had cited Pincus's work as one of the university's outstanding scientific achievements of all time, but Harvard denied him reappointment in 1937.

At Clark University, Hudson Hoagland was the chair of the two-person biology department. Hoagland, upset and angry over Harvard's refusal to grant reappointment to his friend (suspecting that this was because of anti-Semitism), invited Pincus to join him. Hoagland secured funds for Pincus from philanthropists in New York City, enough for a laboratory and an assistant. This success impressed the two men, especially Hoagland, planting the idea that it would be possible to support research with private money.

Min-Chueh Chang was born in Tai Yuan, China, and in 1933, he earned a bachelor's degree in animal psychology from the Tsing Hua University in Peking and stayed at the university as a teacher. Chang won a national competition in 1938 that funded study abroad. He chose to study agricultural science at Edinburgh University. After 1 year, he was pleased to receive an invitation from Arthur Walton to study the physiology of sheep sperm at the University of Cambridge, and he promptly accepted. Chang received his Ph.D. in animal breeding under the direction of Walton and Sir John Hammond at the University of Cambridge in 1941. It was virtually impossible to leave England during the early years of World War II, and Chang continued to work at the university. In 1944, Chang planned to return to China, but first he wanted to spend a year in the United States. He wrote three letters to American scientists, and only Pincus answered, offering a fellowship at Clark University. Chang mistakenly assumed that a fellowship in the United States was the same as at the University of Cambridge where a fellow was assured of a lifetime income. The successful recruitment of M-C. Chang by Pincus was

to pay great dividends. Years later, Chang would direct the testing of new progestins to effectively inhibit ovulation in animals.

Soon Hoagland had put together a group of outstanding scientists, but because of his ongoing antagonism with the president of Clark University, the group was denied faculty status. Working in a converted barn, they were totally supported by private funds. By 1943, 12 of Clark's 60 faculty were in the Department of Biology.

Frustrated by the politics of academia, Hoagland and Pincus had a vision of a private research center devoted to their philosophy of applied science. Indeed, the establishment of the Worcester Foundation for Experimental Biology, in 1944, can be attributed directly to Hoagland and Pincus, their friendship for each other, and their confidence, enthusiasm, ambition, and drive. It was their spirit that turned many members of Worcester society into financial supporters of biologic science.

Although named the Worcester Foundation for Experimental Biology, the Foundation was located in the summer of 1945 across Lake Quinsigamond in a house on an estate in Shrewsbury. From 1945 to the death of Pincus in 1967, the staff grew from 12 to 350 (scientists and support people), 36 of whom were independently funded and 45 were postdoctoral fellows. The annual budget grew from \$100,000 to \$4.5 million. One hundred acres of adjoining land were acquired, and the campus grew to 11 buildings. In its first 25 years, approximately 3,000 scientific papers were published.

But in those early years, Pincus was the animal keeper, Mrs. Hoagland was the bookkeeper, M-C. Chang was the night watchman, and Hoagland mowed the lawn. During the years of World War II, Pincus and Hoagland combined their interests in hormones and neurophysiology to focus on stress and fatigue in industry and the military.

Katharine Dexter McCormick (1875–1967) was a trained biologist, an early suffragist, and wealthy from both inheritance and marriage. She was the second woman to graduate from the Massachusetts Institute of Technology. Her intervention with money, energy, incisive thinking, and persistent dedication was instrumental in the development of oral contraception. Katharine's husband suffered from schizophrenia, and she established the Neuroendocrine Research Foundation at Harvard to study schizophrenia. This brought her together with Hoagland, who told her of the work being done by Chang and Pincus who were seeking orally active progestins to inhibit ovulation.

Pincus attributed his interest in contraception to his growing appreciation for the world's population problem and to a 1951 visit in New York with Margaret Sanger, at that time president of the Planned Parenthood Federation of America. Sanger promised a small amount of money and expressed hope that a method of contraception could be derived from the laboratory work being done by Pincus and Chang. During this meeting, Pincus formulated his thoughts derived from his mammalian research. He envisioned a progestational agent in pill form as a contraceptive, acting like progesterone in

pregnancy.

Margaret Sanger brought Pincus and Katharine McCormick together. On June 7, 1953, 78-year-old Katharine met with 50-year-old Pincus at the Worcester Foundation and wrote him a check for \$20,000. A week later, Pincus and Hoagland met with Katharine and her lawyer. They signed a contract outlining the goals, the decision-making process, and the timetable. Pincus received a second check for \$20,000, and Katharine agreed to fund laboratory improvements, which ended up as the completion of a new building in 1955.

Katharine's contract with the Worcester Foundation stipulated that Pincus would provide written reports every 2 weeks. In addition, Pincus and John Rock, the Boston gynecologist performing the initial oral contraceptive studies in his patients, made many visits to Katharine's home office on Beacon Street across the street from the Harvard Club. Katharine had Sara De Laney, her secretary, take careful notes in shorthand, and at the next visit, De Laney read the transcribed notes to her boss so that she would be prepared. Periodically the principals met at the Worcester Foundation. Katharine peppered Pincus, Chang, and Rock with questions and urged them to stop wasting time. She found Pincus "imaginative and inspirational; Rock was informative and very realistic about medical work." By now, everyone was familiar with Katharine's methods. She had earned their respect, and detailed reports on laboratory results, clinical planning, and budgets were immediately forthcoming. Time and time again, Katharine proved that she handled delays poorly, but she approached each meeting with an eagerness that slowly but surely was rewarded with success after 7 years and an expenditure of about \$2 million of Katharine's money.

In her last years, Katharine continued to support the work of Pincus and Chang. When testing the hundreds of compounds that yielded the progestational agents in birth control pills, Chang observed that some of them prevented implantation of fertilized eggs in rabbits. From 1962 to 1966, Chang and Pincus were pursuing a drug that could prevent pregnancy with one administration, a day or two after sexual intercourse. With Pincus's death, this project was abandoned. It is not certain whether Chang and Pincus coined the phrase the "morning after" pill, but it is accurate to state that the concept came from Chang.

When Pincus and Chang began their studies, the focus was on inhibition of ovulation, first by progesterone and then by synthetic progestins. Chang's contribution was easy to overlook. Chang worked away in his laboratory, and it was Pincus who was highly visible, raising the money and providing direction. Chang started by repeating the experiments reported by Makepeace in 1927, documenting that progesterone could inhibit ovulation. The first experiment was on April 25, 1951, and Chang quickly moved to testing the newly synthesized progestins from Searle and Syntex.

By December 1953, three synthetic progestins were selected as the most potent and effective in inhibiting ovulation: norethindrone from Syntex, and Searle's norethynodrel and norethandrolone. The animal and human results were published in **Science** in 1956.<sup>22,23</sup> In 1957, these three compounds were approved for the treatment of menstrual disorders with the trade names of Norlutin, Enovid, and Nilevar, respectively.

It was Pincus who made the decision to involve a physician because he knew human experiments would be necessary. John Rock, chief of gynecology and obstetrics at Harvard, met Pincus at a scientific conference and discovered their mutual interest in reproductive physiology. Rock and his colleagues pursued Pincus's work. Using oocytes from oophorectomies, they reported in vitro fertilization in 1944, the first demonstration of fertilization of human oocytes in vitro. Rock was interested in the work with progestational agents, not for contraception, however, but because he hoped the female sex steroids could be used to overcome infertility.

In their first collaborative study, Pincus and Rock administered oral progesterone, 300 mg/day. Pincus suggested a 20-day regimen beginning on day 5 of the menstrual cycle.<sup>24</sup> He had two reasons for choosing this regimen: (1) it covered the time period during which nearly all, if not all, ovulations occurred and (2) the withdrawal menstrual bleed at the conclusion of the treatment period would mimic the timing of a normal menstrual cycle and reassure the women that they were not pregnant. The first study involved 33 volunteers who ovulated regularly but had been infertile for 2 years. The women were treated for 1–3 cycles after a baseline control month. About 85% of the treated women did not ovulate during the treatment cycles. Not one became pregnant during treatment, pleasing Pincus who all along was aiming for contraception, and four became pregnant after treatment, pleasing Rock who initially was motivated by his pursuit of the “rebound” phenomenon for the treatment of infertility.

Sanger and McCormick needed some convincing that Rock's Catholicism would not be a handicap, but they were eventually won over because of his stature. Rock was a physician who literally transformed his personal values in response to his recognition of the problems secondary to uncontrolled reproduction. With the help of Luigi Mastroianni, the first administration of synthetic progestins to women was to Rock's patients in 1954. Of the first 50 patients to receive 10–40 mg of synthetic progestin (a dose extrapolated from the animal data) for 20 days each month, all failed to ovulate during treatment (causing Pincus to begin referring to the medication as “the pill”), and 7 of the 50 became pregnant after discontinuing the medication, again pleasing Rock, who all along was motivated to treat his infertile patients.

In 1956, with Celso-Ramon Garcia and Edris Rice-Wray, working in Puerto Rico, the first human trial was performed. The initial progestin products were contaminated with about 1% mestranol. In the amounts being used, this added up to 50–500 µg of

mestranol, a sufficient amount of estrogen to inhibit ovulation by itself. When efforts to provide a more pure progestin lowered the estrogen content and yielded breakthrough bleeding, it was decided to retain the estrogen for cycle control, thus establishing the principle of the combined estrogen-progestin oral contraceptive. Early clinical trials were also conducted by J.W. Goldzieher in San Antonio and E.T. Tyler in Los Angeles.

Pincus, a longtime consultant to Searle, picked the Searle compound for extended use and, with great effort, convinced Searle that the commercial potential of an oral contraceptive warranted the risk of possible negative public reaction. Pincus also convinced Rock, and together they pushed the U.S. Food and Drug Administration (FDA) for acceptance of oral contraception. In 1957, Enovid was approved for the treatment of miscarriages and menstrual disorders and, on June 23, 1960, for contraception. Neither Pincus nor the Worcester Foundation got rich on the pill; alas, there was no royalty agreement.

The pill did bring Pincus fame and travel. There is no doubt that he was very much aware of the accomplishment and its implications. As he traveled and lectured in 1957, he said: “How a few precious facts obscurely come to in the laboratory may resonate into the lives of men everywhere, bring order to disorder, hope to the hopeless, life to the dying. That this is the magic and mystery of our time is sometimes grasped and often missed, but to expound it is inevitable.”<sup>25</sup>

Pincus was the perfect person to bring oral contraception into the public world, at a time when contraception was a private, suppressed subject. Difficult projects require people like Pincus. A scientific entrepreneur, he could plow through distractions. He could be hard and aggressive with his staff. He could remain focused. He hated to lose, even in meaningless games with his children. Yet he combined a gracious, warm, charming manner with his competitive hardness. He was filled with the kind of self-confidence that permits an individual to forge ahead, to translate vision into reality. Pincus died in 1967 (as did Katharine McCormick at the age of 92), of myeloid metaplasia. Rock died in 1984, at the age of 94. Chang died in 1991 at the age of 82 and was buried in Shrewsbury, near his laboratory and close to the grave of Pincus.

Syntex, a wholesale drug supplier, was without marketing experience or organization. By the time Syntex had secured arrangements with Ortho for a sales outlet, Searle marketed Enovid in 1960 (150 g mestranol and 9.85 mg norethynodrel). Ortho-Novum, using norethindrone from Syntex, appeared in 1962. Wyeth Laboratories introduced norgestrel in 1968, the same year in which the first reliable prospective studies were initiated. It was not until the late 1970s that a dose-response relationship between problems and the amount of steroids in the pill was appreciated. Health care providers and patients, over the years, have been confronted by a bewildering array of different products and formulations. In reality, there are few, if any, meaningful,

clinically important distinctions between preparations. The practitioner should use the lowest dose that provides effective contraception.

# PHARMACOLOGY OF STEROID CONTRACEPTION

---

# The Estrogen Component of Combination Oral Contraceptives

Estradiol is the most potent natural estrogen and is the major estrogen secreted by the ovaries. The major obstacle to the use of sex steroids for contraception was reduced activity of the compounds when given orally. As described above, a major breakthrough occurred in 1938 when it was discovered that the addition of an ethinyl group at the 17 position increased oral activity. Ethinyl estradiol is a very potent oral estrogen and is the form of estrogen in most oral contraceptives. Another estrogen, present in older products and actually a precursor to the metabolically active ethinyl estradiol, was the 3-methyl ether of ethinyl estradiol, mestranol.

Mestranol and ethinyl estradiol are different from natural estradiol and must be regarded as pharmacologic drugs ([Figure 22.1](#)). In the human body, differences in potency between ethinyl estradiol and mestranol do not appear to be significant, certainly not as great as indicated by assays in rodents. This is now a minor point because, with the exception of contraceptives with estradiol valerate or estradiol, all of the low-dose oral contraceptives contain ethinyl estradiol ([Figure 22.1](#)). Estradiol valerate is an esterified form of estradiol, allowing oral administration with significant potency. The ester is rapidly hydrolyzed to estradiol. Combinations of several progestins with estradiol valerate have demonstrated good contraceptive efficacy.

**FIGURE 22.1**

The metabolism of ethinyl estradiol (particularly as reflected in blood levels) varies significantly from individual to individual and from one population to another.<sup>26,27</sup> There is even a range of variability at different sampling times within the same individual. Therefore, it is not surprising that the same dose can cause side effects in one individual and not in another.

The estrogen content (dosage) of the pill is of major clinical importance and has been tied to risk of thrombosis and, therefore, increased risk of death (in the past with high doses). The principal role of the estrogens in oral contraceptives is to augment the contraceptive efficacy of the progestin and stabilize the endometrium, thereby reducing breakthrough bleeding. The lowest dose of estrogen that prevents bleeding is preferred.

# The Progestin Component of Combination Oral Contraceptives

The discovery of ethinyl substitution and oral potency led (at the end of the 1930s) to the preparation of ethisterone, an orally active derivative of testosterone (Figure 22.2). In 1951, it was demonstrated that removal of the 19-carbon from ethisterone to form norethindrone did not destroy the oral activity, and most importantly, it changed the major hormonal effect from that of an androgen to that of a progestational agent (Figure 22.2). Accordingly, the progestational derivatives of testosterone were designated as 19-nortestosterones (denoting the missing 19-carbon). The androgenic properties of these compounds, however, were not totally eliminated, and minimal anabolic and androgenic potential remains within the structure.

**FIGURE 22.2**

The “impurity” of 19-nortestosterone, that is, androgenic as well as progestational

effects, was further complicated in the past by a belief that they were metabolized within the body to estrogenic compounds. Studies indicate that norethindrone can be converted to ethinyl estradiol; however, the rate of this conversion is so low that insignificant amounts of ethinyl estradiol can be found in the circulation or urine following the administration of the commonly used doses of norethindrone in premenopausal women.<sup>28</sup> In animal and human studies, however, only norethindrone, norethynodrel, and ethynodiol diacetate have estrogen activity, and it is very slight due to weak binding to the estrogen receptor.<sup>29</sup> Clinically, androgenic and estrogenic activities of the progestin component are insignificant due to the low dosage in the current oral contraceptives.

The norethindrone family contains the following 19-nortestosterone progestins: norethindrone, norethynodrel, norethindrone acetate, ethynodiol diacetate, lynestrenol, norgestrel, norgestimate, desogestrel, and gestodene (**Figure 22.3**).

**FIGURE 22.3**

A second group of progestins became available for use when it was discovered that

acetylation of the 17-hydroxy group of 17-hydroxyprogesterone produced an orally active but weak progestin. An addition at the 6 position is necessary to give sufficient progestational strength for human use, probably by inhibiting metabolism. Derivatives of progesterone with substituents at the 17 and 6 positions include the widely used medroxyprogesterone acetate (Figure 22.4). Chlormadinone and cyproterone acetate are progesterone derivatives with a 17 $\alpha$ -acetoxy group, marketed in a combination with ethinyl estradiol.

**FIGURE 22.4**

Most of the progestins closely related to norethindrone are converted to the parent compound. Thus, the activity of norethynodrel, norethindrone acetate, ethynodiol diacetate, and lynestrenol is due to rapid conversion to norethindrone.

Norgestrel is a racemic equal mixture of the dextrorotatory enantiomer and the levorotatory enantiomer. These enantiomers are mirror images of each other and rotate the plane of polarized light in opposite directions. The dextrorotatory form is known as D-norgestrel, and the levorotatory form is L-norgestrel (known as levonorgestrel).

Levonorgestrel is the active isomer of norgestrel.

Desogestrel undergoes two metabolic steps before the progestational activity is expressed in its active metabolite, 3-keto-desogestrel, known as etonogestrel. This metabolite differs from levonorgestrel only by a methylene group in the 11 position. Gestodene differs from levonorgestrel by the presence of a double bond between carbons 15 and 16; thus, it is  $\Delta$ -15 gestodene. It is metabolized into many derivatives with progestational activity, but not levonorgestrel. Several metabolites have the potential to contribute to the activity of norgestimate, a third-generation progestin.<sup>30,31</sup> Almost all of the biologic effects are attributed to the 17-deacetylated metabolite, now known as norelgestromin; the levonorgestrel metabolites are tightly bound to sex hormone-binding globulin (SHBG) (unlike norelgestromin) severely limiting their biologic activity.<sup>32</sup>

### **Definitions Used in Epidemiologic Studies**

**Low-Dose Oral Contraceptives—Products containing less than 50- $\mu$ g ethinyl estradiol**

**First-Generation Progestins—Products containing estranes derived from testosterone such as norethindrone, norethynodrel, norethindrone acetate, and ethynodiol diacetate and pregnanes derived from 17-OH progesterone such as medroxyprogesterone acetate and chlormadinone acetate**

**Second-Generation Progestins—Products containing gonanes derived from testosterone such as levonorgestrel and norgestrel**

**Third-Generation Progestins—Products containing desogestrel, gestodene, norgestimate/norelgestromin, and etonogestrel**

**Fourth-Generation Progestins—Products containing nonethylated estranes such as drospirenone and dienogest, or pregnanes (19-norprogesterones) such as Nestorone, nomegestrol acetate, and trimegestone**

Probably the greatest influence on the effort that yielded the new progestins was the belief throughout the 1980s that androgenic metabolic effects were important, especially in terms of cardiovascular disease. Cardiovascular side effects are now known to be due to a dose-related stimulation of thrombosis by estrogen and not secondary to metabolic effects such as lipid changes. In the search to find compounds that minimize androgenic effects, however, the pharmaceutical companies succeeded.

The new progestins include desogestrel, gestodene, and norgestimate (**Figure 22.5**).<sup>33</sup> In regard to cycle control (breakthrough bleeding and amenorrhea), the new

formulations are comparable with previous low-dose products. All progestins derived from 19-nortestosterone have the potential to decrease glucose tolerance and increase insulin resistance. The impact on carbohydrate metabolism of the previous low-dose formulations was very minimal, and the impact of the new progestins is negligible. Most changes are not statistically significant, and when they are, they are so subtle as to be of no clinical significance. The decreased androgenicity of the progestins in the newer products is reflected in increased SHBG and decreased free testosterone concentrations to a greater degree than the older oral contraceptives. This difference could be of greater clinical value in the treatment of acne and hirsutism, especially when using fourth-generation progestins.<sup>34,35</sup>

**FIGURE 22.5**

The new progestins, because of their reduced androgenicity, predictably do not adversely affect the cholesterol-lipoprotein profile. Indeed, the estrogen-progestin balance of combined oral contraceptives containing one of the new progestins even promotes favorable lipid changes. Thus, the new formulations have the potential to offer protection against cardiovascular disease, an important consideration as we enter an era of women using oral contraceptives for longer durations and later in life. But one must be cautious regarding the clinical significance of subtle changes, and it is unlikely that there will be a major impact.

Dienogest is a 19-nortestosterone that has a cyanomethyl group instead of an ethinyl group in the 17 position and an additional double bond, combining the properties of both the 19-nortestosterone family and the derivatives of progesterone (**Figure 22.6**).<sup>36</sup> It exerts antiandrogenic activity and is used in a 2-mg dose combined with 30 µg ethinyl estradiol or estradiol valerate as an oral contraceptive.<sup>37,38,39</sup> The combination oral contraceptive with estradiol valerate (Qlaira, Natazia) uniquely consists of four phases, with the estradiol valerate dose decreasing from 3 mg to 1 mg over 26 days, and dienogest provided in a dose of 2 mg on days 3–7 and 3 mg on days 8–24. This phasic administration of estradiol valerate and dienogest provides ovulation inhibition and a bleeding profile comparable to that of a standard, low-dose, monophasic oral contraceptive.<sup>38,39,40</sup>

**FIGURE 22.6**

Drospirenone is a progestin that is an analog of spironolactone (**Figure 22.7**). Its biochemical profile is very similar to progesterone, including a high affinity for the mineralocorticoid receptor that produces an antimineralocorticoid effect.<sup>41,42</sup> Contraceptive efficacy equal to that of other formulations is achieved in the combination of 3.0 mg drospirenone and 30 µg ethinyl estradiol (Yasmin). Because drospirenone is spironolactone-like with antiandrogenic and antimineralocorticoid activity, caution is recommended in regard to serum potassium levels, avoiding its use in women with abnormal renal, adrenal, or hepatic function. However, hyperkalemia and its complications have not been a clinical problem encountered with the use of a drospirenone-containing contraceptive in the general population.<sup>43</sup>

**FIGURE 22.7**

It has been suggested that the oral contraceptive that contains drospirenone is effective for treating premenstrual syndrome/premenstrual dysphoric disorder (PMDD). Earlier studies were done without placebo comparison. We have learned over the last decade that treatments for premenstrual syndrome must be studied in comparison with a placebo because of the powerful placebo response associated with this disorder. In a double-blind, placebo-controlled randomized trial, 82 women with established diagnoses of PMDD were assessed using the Calendar of Premenstrual Experiences scale.<sup>44</sup> A statistically significant reduction associated with Yasmin treatment was achieved in only one category, that measuring acne, appetite, and food cravings. The overall result was essentially not significant. Further, many oral contraceptives would likely have achieved similar results if directly compared.

In a multicenter 2-year study in Europe of 900 women, Yasmin was compared to Marvelon (the same dose of ethinyl estradiol and 150  $\mu\text{g}$  desogestrel).<sup>45</sup> Marvelon was associated with a small increase in body weight after the fifth cycle; the average body weight associated with Yasmin remained throughout the 2 years below the baseline level at the beginning of the study but increased to a level above the baseline at the end of the study. The early weight loss amounted to only 1% of body weight and may reflect diuretic action. This study also observed a small reduction in premenstrual symptoms with Yasmin. The evidence, therefore, for a beneficial impact on PMDD with Yasmin is minimal.

The 24-day version of this oral contraceptive, Yaz (3 mg drospirenone and 20  $\mu\text{g}$  ethinyl estradiol), demonstrated in a 3-month multicenter, double-blind, randomized trial symptomatic improvement in 450 women with PMDD.<sup>46</sup> The magnitude of the treatment response compared with placebo amounted to a need to treat eight women to achieve at least a 50% reduction in symptom severity in a single patient. **These results suggest that modest beneficial results in treating PMDD may be achieved with any**

**oral estrogen-progestin contraceptive administered in an extended regimen. We would expect similar results with the daily, continuous administration of any oral contraceptive.**

Nomegestrol acetate (NomAc), derived from progesterone with the elimination of the 19-carbon, is used in Europe in postmenopausal hormone therapy and recently combined with estradiol for contraception. The first 24 pills of a package contain 2.5 mg NomAc and 1.5 mg estradiol, and the last four are placebos in an extended regimen typical of newer oral contraceptives. NomAc has potent inhibitory effects on gonadotropin secretion, and no androgenic activity (in fact, it is somewhat antiandrogenic).<sup>47</sup> Unlike drospirenone, NomAc has no glucocorticoid or mineralocorticoid activity.<sup>48</sup> Its relative lack of endometrial effects has been associated with an increase in irregular bleeding in some clinical trials.

# Different Oral Formulations

The multiphasic preparation alters the dosage of both the estrogen and progestin components periodically throughout the pill-taking schedule. The aim of these new formulations is to alter steroid levels in an effort to achieve lesser metabolic effects and minimize the occurrence of breakthrough bleeding and amenorrhea, while maintaining efficacy. However, metabolic studies with the multiphasic preparations indicate no differences or very slight improvements over the metabolic effects of low-dose monophasic products.

An estrophasic approach (Estrostep) combines a continuous low dose of a progestin with a low but gradually increasing dose of estrogen.<sup>49</sup> This approach minimizes estrogen exposure at the beginning of the cycle, yielding a low rate of side effects such as nausea. The increasing estrogen results in a marked increase in SHBG that produces a very low androgenic state by reducing the bioavailability of circulating free androgens, and this formulation is very effective for treating acne.<sup>50,51</sup>

## Extended Regimens

Two clinical concerns prompted the development of an oral contraceptive regimen with a reduction in the pill-free interval: (1) breakthrough bleeding and (2) ovarian activity during pill taking that could lead to ovulation and failure of contraception. Extending the active pill cycle by several days is aimed at decreasing breakthrough bleeding and spotting and reducing the length of withdrawal bleeding without compromising efficacy or safety and perhaps increasing contraceptive protection by a greater suppression of ovarian activity. This strategy has produced several new 24-day products: Loestrin 24 Fe (1 mg norethindrone acetate/20 µg ethinyl estradiol with 4 iron-containing placebo pills), Yaz (3 mg drospirenone/20 µg ethinyl estradiol), and Minesse (60 µg gestodene/15 µg ethinyl estradiol).

The traditional combination oral contraceptive pill, consisting of estrogen and progestin components, is given daily for 3 of every 4 weeks, for a total of 21 days. Despite multiple contraceptive actions, there has been concern that the current lower-dose products allow follicular development in some individuals, especially in those who metabolize and clear steroid hormones rapidly.<sup>52</sup> Even with greater follicular activity with the lowest-dose oral contraceptives, ovulation is still effectively prevented in most women.<sup>53</sup> Nevertheless, recognition of follicular growth emerging during the standard pill-free interval with oral contraceptives and awareness that ovarian activity is greater with the lowest-dose estrogen formulations, along with the problem of breakthrough bleeding, provided the motivation to shorten the pill-free interval.

A move to low doses of estrogen in combined oral contraceptives has been fueled by a desire to minimize estrogen-linked, serious cardiovascular side effects. Breakthrough bleeding rates are higher with the lower-dose (20 µg ethinyl estradiol) oral contraceptives, although not dramatically.<sup>54,55,56</sup> Breakthrough bleeding is higher in women who smoke and in smokers who use formulations with 20 µg ethinyl estradiol.<sup>57</sup> Breakthrough bleeding gives rise to fears and concerns; it is aggravating and even embarrassing. These are reasons why although breakthrough bleeding during oral contraceptive use is considered a **minor** side effect, it can have a **major** consequence: interruption of adherence to therapy resulting in unwanted pregnancies. A nationwide survey identified irregular bleeding as the primary reason for discontinuation of oral contraception.<sup>58</sup> It is important to emphasize that there is no evidence that the onset of bleeding is associated with decreased efficacy, no matter what oral contraceptive formulation is used, even the lower-dose products. Indeed, in a careful study, breakthrough bleeding did not indicate decreases in the contraceptive blood levels of the estrogen and progestin components.<sup>59</sup>

The most frequently encountered breakthrough bleeding occurs in the first few months of use as the endometrium adjusts to the pharmacologic impact of the oral contraceptive. The incidence is greatest in the first 3 months, ranging from 10% to 30% in the first month to less than 10% in the third. However, the differences among the various 21-day formulations containing 20 µg ethinyl estradiol are of minimal clinical significance. For this reason, the new approach evolved, increasing the number of days with active drug treatment to 24.

Ovarian follicles begin to grow during the 7-day pill-free interval in traditional regimens of oral contraceptives because follicle-stimulating hormone (FSH) levels begin to rise after 4 pill-free days.<sup>60</sup> These follicles can reach impressive size; ovarian follicles more than 10 mm in diameter have the potential to continue growth as a dominant follicle.<sup>61</sup> The successful conversion to a dominant follicle marks the “selection” of a follicle destined to ovulate, the process whereby, with rare exception, only a single follicle succeeds.<sup>62,63</sup> However, follicles that reach sizes consistent with dominant follicles, even preovulatory follicles, are not assured of ovulation in women using oral contraceptives in a compliant fashion. Some stop growing, while others continue to grow but fail to ovulate, almost assuredly because of suppression of the luteinizing hormone (LH) surge.<sup>64,65,66</sup> Nevertheless, evidence indicates that dominant follicles can emerge, secrete preovulatory levels of estradiol, and ovulate, and in this case, contraceptive efficacy requires the other progestational actions.<sup>53,66,67</sup>

## Clinical Studies with Extended Regimens

The major clinical study with Loestrin 24 Fe was a 6-month, open-label, randomized, active-controlled study in 32 centers in the United States.<sup>68</sup> Nine hundred and thirty-eight patients were randomized to either the 24-day product or the 21-day formulation (1 mg norethindrone acetate/20 µg ethinyl estradiol) in a 4:1 ratio that yielded 705 women in the treated group and 181 in the comparison group available for analysis. A strength of this study was that it compared the 24-day product to an identical 21-day formulation. The study was not powered to determine a significant difference in efficacy comparing the two products. The Pearl Index for the 24-day schedule was 1.82 (1.78 for subjects 35 years old and younger). The cumulative pregnancy rate for 6 months was 0.9%. These numbers are typical for all oral contraceptives.

The number of days with breakthrough bleeding or spotting was comparable in both groups, but the 24-day group demonstrated a steady decline in breakthrough bleeding/spotting days, so that in cycle 6 the mean number of bleeding days was significantly lower in the 24-day group (0.95 vs. 1.63). Among the women in the 24-day group, those who switched from another oral contraceptive had a lower mean number of bleeding days compared to new users, probably reflecting suppression of endometrial growth by the previous use. Each cycle with the 24-day product demonstrated a shorter duration of withdrawal bleeding (bleeding beginning after the last day of active drug intake), achieving statistical significance in the second cycle. Combining breakthrough bleeding and withdrawal bleeding, the total number of days over the entire 6 treatment cycles with bleeding was significantly less in the 24-day group: 18.6 for the 24-day schedule compared with 23.2 for the 21-day regimen.

A reasonable concern with extending the days of active treatment is the resulting increase in overall hormone exposure. The accumulative dosages over 6 cycles, however, were not notably different. The 24-day schedule totaled 144 mg of norethindrone acetate and 2.88 mg ethinyl estradiol, compared with 126 mg norethindrone acetate and 2.52 mg ethinyl estradiol in the 21-day group. There were no demonstrable differences in adverse events.

A 21-day product has been compared with extending the schedule to 23 days, using 75 µg gestodene/20 µg ethinyl estradiol.<sup>69,70,71</sup> The 23-day regimen produced a greater suppression of ovarian activity as measured by lower estradiol levels and less follicular activity as assessed by ultrasonography; however, the incidence of bleeding and spotting days was similar in the two treatment groups. The 23-day regimen was associated with shorter withdrawal bleeding periods compared with the 21-day schedule.

Ovarian activity was compared in a group of women using 60 µg gestodene/15 µg

ethinyl estradiol for 24 days compared to a group using the same product on the standard 21-day regimen.<sup>72</sup> The women using the 21-day regimen experienced greater follicular activity with larger follicles and higher estradiol levels. Breakthrough bleeding was more prevalent with the 24-day schedule; however, the number of treatment cycles in this small study was not large enough to assess bleeding control. A larger study compared the 24-day regimen of 60 µg gestodene/15 µg ethinyl estradiol with a 21-day regimen using 150 µg desogestrel/20 µg ethinyl estradiol and reported a greater incidence of breakthrough bleeding with the 24-day regimen; however, the length of bleeding was shorter and the intensity of bleeding was reduced.<sup>73</sup> The 1-year overall incidence of breakthrough bleeding with this 24-day, 15-µg ethinyl estradiol product has been reported to be 19.3%.<sup>74</sup>

In a short study of only three treatment cycles, the 24-day 3-µg drospirenone/20-µg ethinyl estradiol product was compared to a 21-day regimen of the same formulation.<sup>75</sup> The 24-day schedule was associated with greater follicular suppression and only one ovulation in cycle 3 compared with four ovulations in the 21-day regimen when the initial 3 tablets in the 3rd month were substituted with placebos. A study of 12 women using this formulation for either 23 days or 24 days documented greater suppression of FSH, LH, inhibin B, and estradiol during the pill-free interval when compared to women using the same product for 21 days.<sup>60</sup>

# Clinical Recommendation

The 24-day regimen of low-dose oral contraceptives achieves its goals. Both bleeding and ovarian activity are reduced. Indeed, the two are related. **Diminished ovarian follicular activity is responsible for less fluctuation in endogenous estrogen levels, resulting in a more quiescent and stable endometrium.** Extended (and continuous dosing) regimens compared with the standard 21-day regimen are associated with a decrease in menstrual discomfort, headaches, and bloating.<sup>76,77,78</sup>

Another clinical advantage of the 24-day regimen is a reduction in the risk of “escape” follicular activity if a patient inadvertently starts a new package 1 or 2 days late. Randomized studies that extended the pill-free interval by 2 or 3 days observed that women taking a 20- $\mu$ g ethinyl estradiol formulation had a greater increase in follicular activity compared with women using a 35- $\mu$ g ethinyl estradiol product.<sup>79,80</sup> Ovarian follicular activity is greater with products containing 20  $\mu$ g ethinyl estradiol, and the maximal follicular size reached is larger. In one study, a greater proportion of women on a 20- $\mu$ g product, around 30%, achieved follicular diameters of 15 mm or greater, compared with a 35- $\mu$ g formulation when the pill-free interval was extended from 7 to 9 days.<sup>80</sup> Once follicles achieve a diameter greater than 10 mm, an increasing percentage goes on to ovulate even in the presence of oral contraceptive treatment.<sup>81</sup> The lower-dose formulations produce less suppression of gonadotropin secretion, documented in these studies by higher FSH, LH, and estradiol blood levels among the users of the 20- $\mu$ g ethinyl estradiol product.

Not only does the 24-day product allow a day or two grace period, but the extended hormone exposure suppresses gonadotropin and follicular activity to a greater degree. Thus, even in patients with good compliance, a greater reduction in follicular activity can reduce the possibility of breakthrough ovulations and contraceptive failure. This would be difficult and expensive to document because it would require a clinical trial with a very large number of patients.

A regimen is available that supplies a package containing the number of pills required for 84 days of daily administration, a reduction of menstrual frequency to 4 per year.<sup>82</sup> This approach includes Seasonale (20  $\mu$ g ethinyl estradiol and 100  $\mu$ g levonorgestrel), with 7 placebo pills after 84 active pills, and Seasonique, with 7 pills of 10  $\mu$ g ethinyl estradiol after 84 active pills. The combination with 7 days of estrogen was a response to the discovery that 84 active pill days are rapidly followed by a rise in FSH with stimulation of follicular growth.<sup>83</sup> A slighter higher rate of breakthrough bleeding with this regimen improves with time, but overall, bleeding is less with Seasonique because of better FSH suppression.<sup>84,85</sup>

**Steroid contraception in the currently used low doses has been demonstrated to be very safe for healthy women. Efforts to improve steroid contraception are now focusing on maximizing adherence to treatment and minimizing pregnancies from contraceptive failures. The 24-day regimen offers clinicians and patients the important advantage of reduced bleeding and the possible advantage of greater efficacy because of better compliance as well as a reduction in ovarian activity.**

## Continuous Dosing

More and more women are embracing the idea that fewer menstrual periods provide a welcome relief from bleeding and menstrual symptoms. Clinicians for years have prescribed unlimited daily oral contraceptives to treat conditions such as endometriosis, bleeding disorders, menstrual seizures, and menstrual migraine headaches, even to avoid bleeding in athletes and busy individuals. Many women do not require the periodic experience of vaginal bleeding to assure themselves they are not pregnant. And of course, modern society is long past the notion that menstrual bleeding is a cleansing event, a detoxification. It is not necessary for women using oral contraceptives to experience any withdrawal bleeding. Monthly bleeding, periodic bleeding, or no bleeding—this is an individual woman's choice. Any combination oral contraceptive can be used on a daily basis; even the lowest-estrogen dose formulations provide excellent bleeding and side effect profiles in a continuous regimen.<sup>77,86,87,88</sup> **Oral contraceptives with the lowest doses of estrogen should be used for overweight and older women, but progestin-only methods are an even better choice.**

Eliminating a pill-free interval also reduces symptoms associated with menstruation, such as headaches, dysmenorrhea, and bloating.<sup>89,90,91</sup> As with the extended regimen, continuous dosing provides greater ovarian suppression, reducing the potential for breakthrough and escape ovulations.<sup>92</sup> A further benefit of continuous use is simplification of the pill-taking schedule with the potential of better compliance and a lower failure rate. Continuous dosing can also be achieved with the contraceptive vaginal ring and the contraceptive patch. The return of ovulation and achievement of pregnancy are not delayed after discontinuation of continuous dosing.<sup>92,93</sup>

# Generic Products

Generic products are therapeutically equivalent drugs, containing the same amount of active ingredients in the same concentration and dosage form. These products are less expensive, marketed by pharmaceutical companies after patent expiration of the original drug. Generic oral contraceptives need only meet the test of bioequivalence; studies to demonstrate efficacy, side effects, and safety are not required. Meeting the test of bioequivalence requires demonstration in a small number of subjects that absorption, concentrations, and time curves are comparable to the reference drug. The generic product will be approved if the bioequivalence testing ranges from 80% to 125% of the values for the reference drug (differences no greater than 20% lower or 25% higher). Approved, patented products must not vary more than  $\pm 10\%$ ; therefore, a generic oral contraceptive could contain only 70% of the standard dose. In the lowest-dose oral contraceptives, this could impair efficacy. However, we should hasten to point out that there has been no evidence or even anecdotal suggestions that generic oral contraceptives have reduced efficacy or cause more side effects such as breakthrough bleeding. Patients should be forewarned that generic products differ in shape, packaging, and color.

# VAGINAL ESTROGEN-PROGESTIN CONTRACEPTION

---

The vagina provides an ideal site for contraceptive steroid absorption. The stratified squamous epithelium, unlike the skin, is not cornified, permitting easier steroid penetration to the underlying lamina propria, made of collagen and elastin, which is richly vascularized. A muscular layer under the epithelium has smooth muscle fibers running in both circular and longitudinal directions. The final layer of areolar connective tissue contains a second vascular plexus. There are no fat cells, glands (secretions are transudates, not glandular), or hair follicles to interfere with drug absorption.<sup>94</sup>

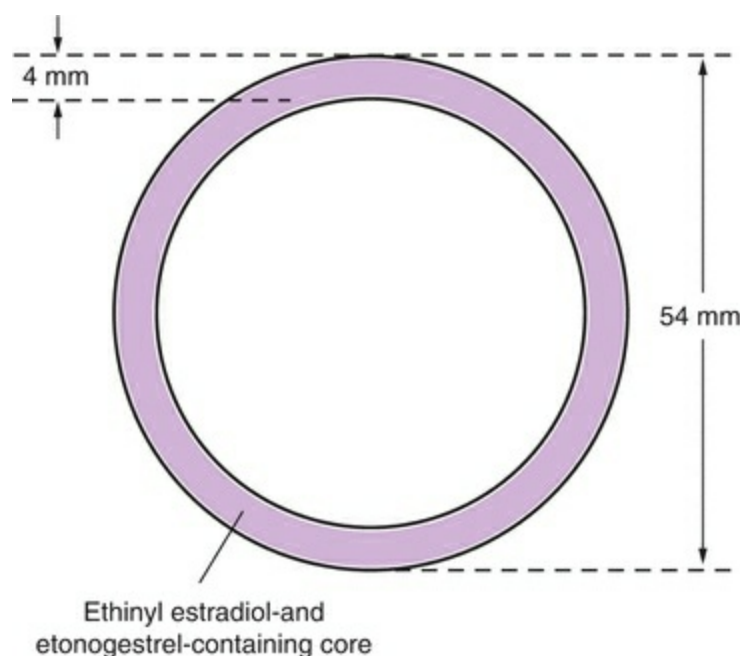

Like subcutaneous, intramuscular, transdermal, and intrauterine contraceptive methods, the vaginal route avoids gastrointestinal absorption and the first-pass liver effect. Absorption from the gastrointestinal tract can be unpredictable and may be compromised by vomiting, drug-drug interference, or decreased intestinal absorption capacity. The gastrointestinal lumen and the liver are sites of elimination for many compounds, and avoidance of the first-pass effect is particularly advantageous for compounds that undergo a high degree of hepatic metabolism; orally administered natural estrogens, for example, are 95% metabolized by the liver. Oral administration results in marked fluctuations of contraceptive steroid serum concentrations that may lead to side effects like irregular bleeding and nausea. These daily changes are lower with vaginal than with oral or transdermal administration and lowest with implant and intrauterine methods.<sup>95,96</sup>

Six progestin-only and seven different estrogen-progestin combined vaginal contraceptive rings have been designed to provide 1 week to 1 year of contraception with weaker progestins like progesterone and medroxyprogesterone in short-acting rings (1 week) and more potent levonorgestrel and Nestorone in long-acting ones (up to a year). The “NuvaRing” vaginal combined steroid contraceptive is available in the United States, and the Federal Drug Administration has approved “Annovera,” which will be available starting in 2019 or 2020. They are both flexible, soft, transparent rings. “NuvaRing” is made of ethylene vinyl acetate copolymer in which are contained crystals of etonogestrel and ethinyl estradiol. This ring is covered with a 2- $\mu$ m-thick membrane of ethylene vinyl acetate. The ring is available in only one size, 4 mm in thickness and 54 mm in diameter (smaller than a diaphragm), that fits all women. “Annovera” is a silicone elastomer 56 mm in diameter and 8.4 mm in thickness, with two 3-mm cores, one of which secretes segesterone acetate and one of which secretes segesterone acetate and ethinyl estradiol. “Annovera” can provide contraception for up to 1 year.<sup>96,97,98</sup>

Rings that contain only progesterone or Nestorone are being developed for use in breast-feeding women.

# The Vaginal Ring Method

The use of vaginal contraception in the United States has steadily increased since its introduction, and it is now one of the more popular methods. An important advantage of vaginal steroid contraception is an improvement in compliance achieved by the elimination of a daily regimen of treatment. The NuvaRing releases 15 mg ethinyl estradiol and 120 mg etonogestrel/day.<sup>99</sup> Because the progestin and estrogen are mixed in the ethylene vinyl acetate core, in the unlikely event of damage to the ring, leakage or higher release of the hormones does not occur. Circulating estrogen and progestin levels reach target concentrations within 24 hours. The circulating estrogen levels reach a maximum level after 2–3 days; etonogestrel reaches maximum level after 7 days and remains stable for 35 days.<sup>100</sup> **The ring is inserted by the patient and worn for 3 weeks. The vaginal ring can be initiated in the same fashion as oral contraceptives, on the first day of menses, a Sunday start, or an immediate, same-day start. Routine use requires the insertion of a new ring every 4 weeks to allow for withdrawal bleeding, but an acceptable and easier method is to insert a new ring on the first of every month. Continuous use is an appropriate option.<sup>100</sup> Because the ring contains enough steroid hormone to inhibit ovulation for at least a total of 5 weeks,<sup>101</sup> when used continuously, a new ring can be inserted every 5 weeks. Breakthrough bleeding with continuous use is effectively managed by a 4-day hormone-free interval<sup>102</sup> (Figure 22.8).**

**FIGURE 22.8**

The NuvaRing produces circulating progestin and estrogen levels that are only 40% and 30%, respectively, of the **peak** levels associated with an oral contraceptive containing 150 mg desogestrel and 30 mg ethinyl estradiol (**Figure 22.9**).<sup>95</sup> These levels effectively inhibit ovulation, providing pregnancy rates of less than 1% in clinical trials.<sup>99,101,103,104</sup> **If the vaginal ring is removed and not replaced within 3 hours, the manufacturer recommends backup contraception until the ring has been in place for 7 days.**

**FIGURE 22.9**

Annovera releases 0.15 mg/day of segesterone acetate and 0.013 mg/day of ethinyl estradiol when placed vaginally for up to 21 days at a time. It is then removed and stored for 7 days before being replaced. Annovera can be used for 13 cycles. Circulating estrogen and progestin levels reach a maximum at 2 hours after insertion with the initial cycle, with average circulating levels of segesterone acetate ranging from 94 to 191 pg/mL depending on the cycle number and average circulating levels of ethinyl estradiol ranging from 19 to 44 pg/mL depending on the cycle number. Similarly to the NuvaRing, Annovera can be started with menses, Sunday start, or immediately. If started immediately or switching from a different contraceptive method, the manufacturer recommends backup contraception for 7 days.<sup>98</sup> Currently, women with body mass indices greater than 29 kg/m<sup>2</sup> are excluded from using Annovera due to potential higher risk of venous thromboembolic disease in this group in clinical trials.

Taking into account bioavailability as influenced by protein binding, systemic

exposure to etonogestrel is similar comparing the vaginal ring to an oral contraceptive containing 150 mg desogestrel; however, the systemic exposure to ethinyl estradiol is about 50% of that of an oral contraceptive containing 30 mg ethinyl estradiol.<sup>95</sup> Vaginal administration is associated with the lowest estrogen exposure as measured by “area under the curve,” compared with oral and transdermal methods.<sup>101</sup> This may explain the low incidence of estrogen-related side effects such as dysmenorrhea, nausea, and breast tenderness.<sup>95,99,102</sup> Breakthrough bleeding and spotting rates are lower (around 6%) when compared with an oral contraceptive containing 30 mg of ethinyl estradiol and much lower than with 15- or 20-mg pills.<sup>99,103,104</sup> Bleeding and spotting occur more frequently with extended or continuous regimens.<sup>96</sup>

It is not necessary to place the vaginal ring in a specific position; it need only be in contact with vaginal mucosa and need not surround the cervix. The vaginal ring is intended to be placed in a normal vagina; infections and anatomic abnormalities are reasons for clinicians and patients to consider other methods. The most common reasons for discontinuation (about 2–4% in the clinical trials) have been vaginal discomfort, unwanted awareness of the ring’s presence, coital problems, or expulsion (during a year of use about 2–3% of women experience spontaneous expulsion). Women report that the ring is easy to insert and remove, and, although about 15% of women and 30% of partners report feeling the ring during intercourse, this is not a common reason for discontinuation.<sup>99,105</sup> **Removal for sexual intercourse is not recommended, but efficacy is maintained if the ring is replaced within 3 hours.** Postmarketing surveillance studies documented a high rate of satisfaction with good cycle control.<sup>106,107</sup>

# TRANSDERMAL ESTROGEN-PROGESTIN CONTRACEPTION

Transdermal contraceptive dosing, like vaginal dosing, increases compliance as it does not need to be remembered daily. The transdermal contraceptive patch (Ortho Evra) has an area of 20 cm<sup>2</sup> (4.5 cm × 4.5 cm) and three layers in a matrix-type arrangement. The backing outer polyester layer provides support for the middle layer that contains the adhesive and the hormones, and the inner layer is a polyester liner that is removed from the adhesive layer just before application. The size is that required to deliver an effective dose of the steroid hormones. The patch contains 750 mg ethinyl estradiol and 6 mg of norelgestromin and delivers 20 mg ethinyl estradiol and 150 mg norelgestromin each day when applied to discrete locations on the lower abdomen, upper outer arm, the buttock, or the upper torso (excluding the breast) (Figure 22.10). Norelgestromin is the primary active metabolite of orally administered norgestimate and was previously known as 17-deacetylnorgestimate. Norelgestromin still undergoes liver metabolism with transdermal application; however, the resulting metabolite, levonorgestrel, is highly bound to SHBG, limiting its biologic impact. About 97% of norelgestromin is bound to albumin, and 3% is unbound.<sup>32</sup>

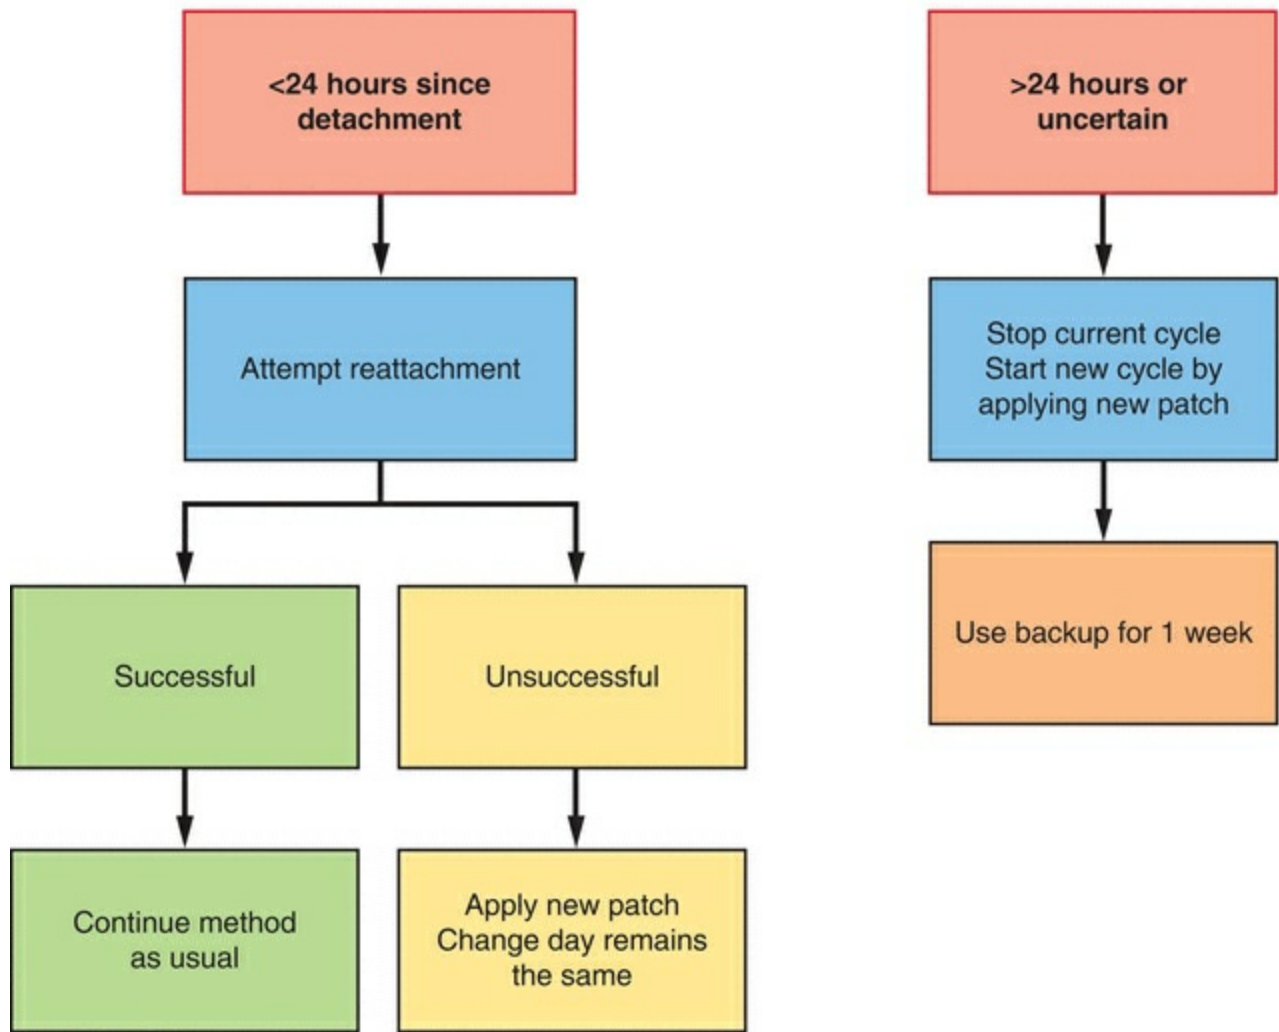

FIGURE 22.10

# The Transdermal Method

The patch is applied on the same day, but not on the exact same site, once each week for 3 weeks, followed by a week without use of the patch. **As with oral contraceptives, patient and clinician may choose to use the contraceptive patch continuously, eliminating withdrawal bleeding.** Timing on the day of application need not be precise; the patch is very forgiving. Instructions for first-day starts, Sunday starts, or immediate same-day starts of oral contraception are also recommended for the patch (backup contraception for 7 days unless the starting day is also day 1 of the menstrual period). Application should be chosen with care to avoid contact with tight clothing, and pressure should be applied for at least 10 seconds, making sure that the edges stick. The skin should be clear, clean, and dry and free of irritation or creams and lotions. The patches are stored in their protective pouches at room temperature. **Many women are bothered by the lint ring that forms around the edges of transdermal patches. In our experience, this problem can be eliminated by lightly dusting talcum powder (“baby” powder) around the edges after application. If a ring does form, it is easily removed with mineral oil.**

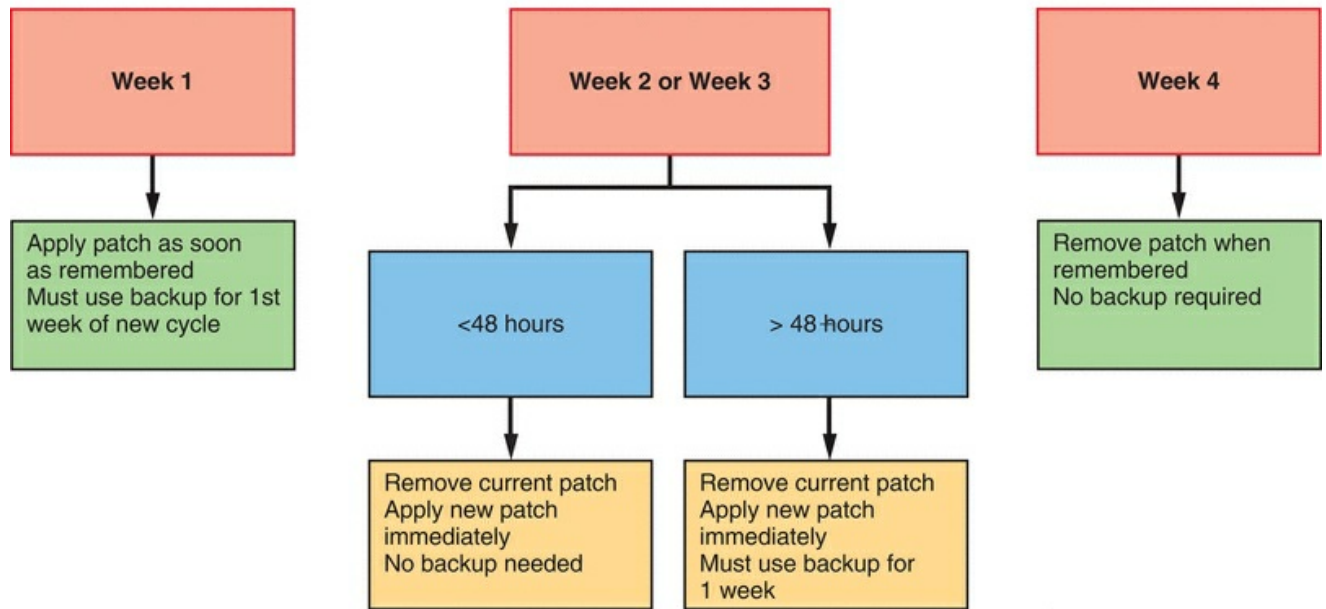

Detachment occurs with about 5% of patches, and about half occur in cycle 1 with inexperienced patients.<sup>108,109</sup> In studies of at least a year’s duration, about 2–5% of patches were replaced.<sup>110,111</sup> Use of the patch requires common sense; anything other than a secure adhesion deserves a conservative approach. If the patch seems loose or has been partially or totally off for less than 24 hours, the same patch can be reapplied or replaced with a new patch (the patch change day remains the same). Single extra patches are provided for this (**Figures 22.11 and 22.12**) purpose by pharmacies and clinics if the clinician writes a separate prescription for an extra patch along with the regular prescription. If the patch has been detached for more than 24 hours, a new patch is applied initiating a new cycle and new change day (backup contraception for 7 days is recommended). Delay of a new patch cycle requires a new start with the usual 7-day backup. **A delay within the patch cycle of no more than 2 days has no risk and does not change the cycle, but a delay more than 2 days also requires the initiation of a new cycle and change day with backup.** However, in a study that compared three treatment-free days in oral contraceptive and patch users, ovulation occurred significantly less with the patch compared with oral contraception.<sup>67</sup>

## Recommendations for Patch Detachment

**FIGURE 22.11**

### Recommendations for When a New Patch Is Forgotten

**FIGURE 22.12**

**Transdermal contraception produces the same spectrum of actions associated with oral contraceptives, achieving the same high level of efficacy in clinical trials.** The avoidance of the liver first-pass effect offers the potential for less interaction with other drugs, but this is not known, and patients on medications that affect liver metabolism should choose an alternative contraceptive. Tetracycline administration does not affect the blood concentrations of the steroid hormones with transdermal contraception, a neutral impact as seen with oral contraceptives.<sup>112</sup>

Serum hormonal concentrations are achieved rapidly after application: an average of about 0.7 ng/mL, with a range of 0.6–1.2 ng/mL for norelgestromin, and an average of about 50 pg/mL, with a range of 25–75 pg/mL for ethinyl estradiol. These are ranges that are maintained by an oral formulation containing 250 mg norelgestromin and 35 mg ethinyl estradiol.<sup>113,114</sup> However, the kinetics are not identical to orally administered hormones; daily fluctuations are avoided. These blood levels allow maintenance of contraceptive efficacy if patch replacement is delayed up to 2 days.<sup>115</sup> Gonadotropin levels return to baseline values by 6 weeks after discontinuation.<sup>114</sup> Daily use has been well studied, and activities such as exercise, bathing, swimming, and the use of a sauna or hot tub do not cause detachment or changes in the blood levels of the hormones<sup>116</sup> (Figure 22.13).

**FIGURE 22.13**

# OFF-LABEL USES OF STEROID CONTRACEPTION

---

Steroid contraception is often used for noncontraceptive purposes. The list is long, including treatment of acne, dysmenorrhea, heavy or irregular vaginal bleeding, menses-associated mood changes, the polycystic ovary syndrome, and endometriosis. For most of the oral contraceptives' 50-year history, all of these have been "off-label" applications, but recently pharmaceutical companies have conducted trials to obtain label "indications" to use in advertising directed to both clinicians and consumers. In order to acquire such an indication, the company simply has to demonstrate that their formulation is better than a placebo at, for example, improving acne or relieving the symptoms of PMDD. Because these trials usually compare a product to a placebo or just to another contraceptive formulation, the studies do not reveal whether the product receiving approval for an "indication" is really better than others. Prices and formularies restrict patient access to the full range of oral contraceptives<sup>117</sup>; therefore, clinicians must make judgments by comparing findings from unrelated studies and experience to decide which pill to use for a specific purpose in an individual patient. In most cases, as we will emphasize, it is unlikely that there are major differences among similar products.

# POTENCY

---

For many years, clinicians, scientists, medical writers, and even the pharmaceutical industry attempted to assign potency values to the various progestational components of oral contraceptives. An accurate assessment, however, has been difficult to achieve for many reasons. Progestins act on numerous target organs (e.g., the uterus, the mammary glands, and the liver), and potency varies depending on the target organ and endpoint being studied. In the past, animal assays, such as the Clauberg test (endometrial change in the rabbit), were used to determine progestin potency. Although these were considered acceptable methods at the time, a better understanding of steroid hormone action and metabolism and a recognition that animal and human responses differ have led to greater reliance on data collected from human studies.

Historically, this has been a confusing issue because publications and experts used potency ranking to provide clinical advice. Oral contraceptive progestin potency is no longer a consideration when it comes to prescribing oral contraception, because the potency of the various progestins has been accounted for by appropriate adjustments of dose. Clinical advice based on potency ranking is an artificial exercise that has not stood the test of time. Oral contraceptives should be judged by their clinical characteristics: efficacy, side effects, risks, and benefits.

# MECHANISM OF ACTION

---

The combination pill, consisting of estrogen and progestin components, prevents ovulation by inhibiting gonadotropin secretion via an effect on both pituitary and hypothalamic centers. The progestational agent in the pill primarily suppresses LH secretion (and thus prevents ovulation), while the estrogenic agent suppresses FSH secretion (and thus prevents the emergence of a dominant follicle). Therefore, the estrogenic component significantly contributes to the contraceptive efficacy. However, even if follicular growth and development were not sufficiently inhibited, the progestational component would prevent the surge-like release of LH necessary for ovulation. The transdermal patch and vaginal ring's progestational and estrogenic components both work similarly.<sup>99,110,111</sup>

The estrogenic components serve two other purposes. It provides stability to the endometrium so that irregular shedding and unwanted breakthrough bleeding can be minimized, and the presence of estrogen is required to potentiate the action of the progestational agents. The latter function of estrogen has allowed reduction of the progestational dose in the pill. The mechanism for this action is probably estrogen's effect in increasing the concentration of intracellular progestational receptors. Therefore, a minimal pharmacologic level of estrogen is necessary to maintain the efficacy of the combination pill.

Because the effect of a progestational agent takes precedence over estrogen (unless the dose of estrogen is increased many, manyfold), the endometrium, cervical mucus, and perhaps tubal function reflect progestational stimulation. The progestin component produces an endometrium that is not receptive to ovum implantation, a decidualized bed with exhausted and atrophied glands. The cervical mucus becomes thick and impervious to sperm transport. It is possible that progestational influences on secretion and peristalsis within the fallopian tubes provide additional contraceptive effects.<sup>118,119</sup> Even if there is some ovarian follicular activity (especially with the lowest-dose products), these actions serve to ensure high contraceptive efficacy.<sup>120</sup>

# EFFICACY

---

In view of the multiple actions of combined hormonal contraceptives, it is hard to understand how the omission of a pill or two can result in a pregnancy (Table 22.1). Indeed, careful review of failures suggests that pregnancies usually occur because initiation of the next cycle is delayed allowing escape from ovarian suppression. Strict adherence to 7 pill-free or ring-free days is critical in order to obtain reliable, effective contraception. For this reason, the 28-day pill package, incorporating 7 pills that do not contain steroids, is a very useful aid to ensure adherence to the necessary schedule. Even better, the use of extended regimens or continuous dosing offers the potential to minimize, if not eliminate, pill failures.

**TABLE 22.1 Failure Rates During the First Year of Use, United States<sup>123,124</sup>**

Method	Percent of Women with Pregnancy	
	Lowest Expected	Typical
No method	85%	85%
Combination pill	0.3%	8.7%
Progestin only	0.5%	3.0%
IUDs:		
Levonorgestrel IUD	0.1%	0.1%
Copper T 380A	0.6%	1.0%
Implant	0.05%	1.0%
Injectable		
3-month	0.3	0.3%
1-month	0.05	3.0%
Patch	0.3	8.0%
Vaginal ring	0.3	8.0%
Female sterilization	0.5%	0.7%
Male sterilization	0.1%	0.2%
Spermicides	18.0%	29.0%
Periodic abstinence		25.3%
Calendar	9.0%	
Ovulation method	3.0%	
Symptothermal	2.0%	
Postovulation	1.0%	
Withdrawal	4.0%	18.4%
Cervical cap		
Parous women	26.0%	32.0%
Nulliparous women	9.0%	16.0%
Sponge:		
Parous women	20.0%	32.0%
Nulliparous women	9.0%	16.0%
Diaphragm and spermicides	6.0%	16.0%
Condom		
Male	2.0%	17.4%
Female	5.0%	27.0%

The most prevalent problems that can be identified associated with apparent oral contraceptive failures are vomiting and diarrhea.<sup>121,122</sup> **Even if no pills have been missed, patients should be instructed to use a backup method for at least 7 days after an episode of gastroenteritis. An alternative is to place the pill in the vagina during the illness.**

The contraceptive effectiveness of the new progestin oral contraceptives, multiphasic formulations, and lowest-estrogen dose products are unequivocally comparable with older low-dose (<50- $\mu$ g estrogen) and higher-dose monophasic combination birth control pills.<sup>123,124</sup>

In randomized trials ranging from 4 cycles to 13 cycles, about 10–20% more of the participants demonstrated good compliance with the transdermal method compared with oral contraception.<sup>108,110</sup> Most importantly, young women, especially those younger than age 20, demonstrated greater compliance with transdermal contraception compared with oral contraceptives than did older women.<sup>125</sup> Indeed, compliance is better at all ages comparing the patch to the pill.<sup>126</sup> Similarly, randomized control trials show better compliance with the NuvaRing than oral contraception, but no head-to-head comparison of failure rates has been completed.<sup>127,128</sup>

# **NONCONTRACEPTIVE EFFECTS OF ORAL CONTRACEPTION**

---

# Cardiovascular Disease

## The Coagulation System

Thrombosis can be divided into two major categories, venous thromboembolism and arterial thrombosis. Venous thromboembolism includes both deep vein thrombosis and pulmonary embolism. Arterial thrombosis includes acute myocardial infarction and stroke.

The goal of the clotting mechanism is to produce thrombin, which converts fibrinogen to a fibrin clot. Thrombin is generated from prothrombin by factor Xa in the presence of factor V, calcium, and phospholipids. The vitamin K–dependent factors include factors VII, IX, and X, as well as prothrombin. Antithrombin III is one of the body’s natural anticoagulants, an irreversible inhibitor of thrombin and factors IXa, Xa, and XIa. Protein C and protein S are two other major inhibitors of coagulation and are also vitamin K-dependent. Protein C and its helper, protein S, inhibit clotting at the level of factors V and VIII. Tissue plasminogen activator (t-PA) is produced by endothelial cells and released when a clot forms. Both t-PA and plasminogen bind to the fibrin clot. The t-PA converts the plasminogen to plasmin, which lyses the clot by degrading the fibrin. Deficiencies of antithrombin III, protein C, and protein S are inherited in an autosomal dominant pattern, accounting for 10–15% of familial thrombosis. The most common inherited causes of venous thromboembolism are the factor V Leiden mutation, followed distantly by a mutation in the prothrombin gene.<sup>129</sup>

### **Coagulation Factors:**

**Plasminogen activator inhibitor-1 (PAI-1)**

## Factors that favor clotting when decreased

### Antiplasmin

An inherited resistance to activated protein C has been identified as the basis for about 50% of cases of familial venous thrombosis, due in almost all cases to a gene alteration recognized as the factor V Leiden mutation.<sup>130,131</sup> The factor V Leiden mutation is found in approximately 30% of individuals who develop venous thromboembolism.<sup>132</sup> Activated protein C inhibits coagulation by degrading factors V and VIII. One of the three cleavage sites in factor V is the precise site of a mutation known as the factor V Leiden mutation that substitutes glutamine instead of arginine at this site (adenine for guanine at nucleotide 1691 in the gene).<sup>132</sup> This mutation makes factor V resistant to degradation and activation in fibrinolysis. The entire clotting cascade is then resistant to the actions of the protein C system.

Heterozygotes for the factor V Leiden mutation have an 8-fold increased risk of venous thrombosis, and homozygotes have an 80-fold increased risk, and this risk is further enhanced by oral contraceptive use. The highest prevalence (3–4% of the general population) of factor V Leiden is found in Europeans, and its occurrence in populations not of European descent is very rare, perhaps explaining the low frequency of thromboembolic disease in Africa and Asia, and in Native Americans.<sup>133</sup> The mutation is believed to have arisen in a single ancestor approximately 21,000–34,000 years ago<sup>134</sup> and was perhaps initially a useful adaptation in heterozygotes in response to life-threatening bleeding, such as with childbirth.

The next most common inherited disorder after the factor V Leiden mutation is a mutation, a guanine to adenine change, in the gene encoding prothrombin.<sup>129,135</sup> The prevalence of this abnormality in the white population is estimated to range from 0.7% to 4%.<sup>136</sup> Oral contraceptive use has been reported to markedly increase the risk of venous thrombosis in carriers of the prothrombin mutation.<sup>137</sup> Perhaps other unidentified disorders make a contribution because an increased risk of venous thrombosis with oral contraceptives has been reported in women with elevated prothrombin levels despite an absence of the prothrombin gene mutation.<sup>138</sup>

The administration of pharmacologic amounts of estrogen as in high-dose oral contraceptives causes an increase in the production of clotting factors such as factor V, factor VIII, factor X, and fibrinogen.<sup>139</sup> The progestin component also influences the clotting factor responses.<sup>140</sup> Some studies of the blood coagulation system have concluded that both monophasic and multiphasic low-dose oral contraceptives have no significant clinical impact on the coagulation system. Slight increases in thrombin formation are offset by increased fibrinolytic activity.<sup>141,142</sup> Other studies of

formulations containing 30 and 35 µg of ethinyl estradiol indicate an increase in clotting factors associated with an increase in platelet activity.<sup>143</sup> However, these changes are essentially all within normal ranges and their clinical significance is unknown.<sup>144</sup> Transdermal administration has effects on clotting proteins and lipoproteins like those seen with low-dose oral contraceptives.<sup>145</sup>

Smoking produces a shift to hypercoagulability.<sup>137</sup> A 20-µg estrogen formulation has been reported to have no effect on clotting parameters, even in smokers.<sup>137,146</sup> One study comparing a 20-µg product with a 30-µg product found similar mild procoagulant and fibrinolytic activity, although there was a trend toward increased fibrinolytic activity with the lower dose.<sup>147</sup> These mixed reports make it essential to base clinical decisions on the epidemiologic studies of clinical events.

**There is no evidence of an increase in risk of cardiovascular disease among past users of oral contraception.<sup>148,149,150</sup> In the Nurses' Health Study, the Royal College of General Practitioners' study, and the Oxford Family Planning Association Study, long-term past use of oral contraceptives was not associated with an increase in overall mortality.<sup>151,152,153</sup> Part of the concern for a possible lingering effect of oral contraceptive use was based on a presumed adverse impact on the atherosclerotic process, which would then be added to the effect of aging and, thus, would be manifested later in life. Instead, the findings have been consistent with the contention that cardiovascular disease due to oral contraception is secondary to acute effects, specifically estrogen-induced thrombosis, a dose-related event.**

# Venous Thromboembolism

Older epidemiologic evaluations of hormonal contraceptives and vascular disease indicated that venous thrombosis was an effect of estrogen, limited to current users, with a disappearance of the risk by 3 months after discontinuation.<sup>154,155</sup> Thromboembolic disease was believed to be a consequence of the pharmacologic administration of estrogen, and the level of risk was believed to be related to the estrogen dose.<sup>156,157,158</sup> Smoking was documented to produce an additive increase in the risk of arterial thrombosis<sup>159,160,161</sup> but had no effect on the risk of venous thromboembolism.<sup>162,163</sup>

Is there still a risk of venous thromboembolism with the current low-dose (<50 µg ethinyl estradiol) formulations of oral contraceptives? In the first years of oral contraception, the available products, containing 80 and 100 µg ethinyl estradiol (an extremely high dose), were associated with a sixfold increased risk of venous thrombosis.<sup>164</sup> Because of the increased risks for venous thrombosis, myocardial infarction, and stroke, lower-dose formulations (<50 µg estrogen) came to dominate the market, and clinicians became more careful in their screening of patients and prescribing of oral contraception. Two forces, therefore, were at work simultaneously to bring greater safety to women utilizing oral contraception: (1) the use of lower-dose formulations and (2) the avoidance of oral contraception by high-risk patients. Because of these two forces, the Puget Sound study in the United States documented a twofold reduction in venous thrombosis risk.<sup>165</sup> The new studies also reflect the importance of these two forces, but they still indicate an increased risk.

The World Health Organization (WHO) Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception was a hospital-based, case-control study with subjects collected from 21 centers in 17 countries in Africa, Asia, Europe, and Latin America.<sup>166</sup> As part of this study, the risk of **idiopathic** venous thromboembolism associated with a formulation containing 30 µg ethinyl estradiol and levonorgestrel (doses ranging from 125 to 250 µg) was compared with the risk with preparations containing 20 or 30 µg ethinyl estradiol and either desogestrel or gestodene (data from 10 centers in 9 countries).<sup>167</sup> The users of the levonorgestrel formulations had an increased odds ratio of 3.5 compared with nonusers. Current users of a desogestrel or gestodene product had an increased risk of 9.1 compared with nonusers. Thus, the increased risk for desogestrel and gestodene was 2.6 times that of levonorgestrel, when adjusted for body weight and height.

The Transnational Study on Oral Contraceptives and the Health of Young Women analyzed 471 cases of deep vein thrombosis and/or venous thromboembolism from the United Kingdom and Germany.<sup>168</sup> Second-generation oral contraceptives were defined as products containing 35 µg or less of ethinyl estradiol and a progestin other than

desogestrel or gestodene. Comparing users of second-generation products to nonusers, the odds ratio was 3.2. Comparing users of desogestrel and gestodene products to users of second-generation oral contraceptives, the risk of venous thromboembolism was 1.5-fold greater.

A third major study was from Boston University, but the data were derived from the General Practice Research Database, a computerized system involving the general practitioners in the United Kingdom.<sup>169</sup> Using this cohort, the death rate from pulmonary embolism, stroke, and acute myocardial infarction was calculated in the users of levonorgestrel, desogestrel, and gestodene low-dose oral contraceptives. Over a 3-year period, they collected a total of 15 unexpected idiopathic cardiovascular deaths in users of these products, a **nonsignificant change**, and no difference in the risk comparing desogestrel and gestodene with levonorgestrel. The risk estimates for venous thromboembolism (adjusted for smoking and body size) were about 2 times greater for desogestrel and for gestodene, compared with levonorgestrel users. In an updated analysis from this same group and database, the findings were unchanged, except that smoking was found to be a risk factor for venous thromboembolism.<sup>170</sup> An American case-control study concluded that norgestimate- and levonorgestrel-containing oral contraceptives had similar risks for venous thromboembolism, but there was a small increase in risk associated with desogestrel.<sup>171</sup>

Similar results were reported when women with deep vein thrombosis in the Leiden Thrombophilia Study in the Netherlands were reanalyzed for their use of oral contraceptives.<sup>172</sup> As expected, the risk of deep vein thrombosis was markedly higher in women who were carriers of the factor V Leiden mutation and in women with a family history of thrombosis.

In Denmark, a hospital-based, case-control study of women with confirmed diagnoses of venous thromboembolism in 1994 and 1995 (in Denmark, all women with this diagnosis are hospitalized, and therefore, very few, if any, cases were missed) revealed a twofold increased risk of venous thromboembolism in current users of oral contraceptives, regardless of estrogen doses ranging from 20 to 50  $\mu\text{g}$ .<sup>173</sup> The increased risk was concentrated in the first year of use. **Because there were more short-term users of the new progestins and more long-term users of the older progestins, adjustment for duration of use resulted in no significant differences between the different types of progestins.** Those factors associated with an increased risk of thromboembolism included coagulation disorders, treated hypertension during pregnancy, family history of venous thromboembolism, and an increasing body mass index (BMI). Notably, conditions not associated with an increased risk of venous thromboembolism included smoking, migraine, diabetes, hyperlipidemia, parity, or age at first birth. There was still insufficient strength in this study to establish the absence or

presence of a dose-response relationship comparing the 20- $\mu\text{g}$  estrogen dose to higher doses; however, a 5-year update reported the following useful information<sup>174</sup>:

- The risk of venous thrombosis associated with current use of oral contraceptives declined with increasing duration of use.
- The risk was slightly greater with desogestrel or gestodene.
- Smoking more than 10 cigarettes per day increased the risk.
- Oral contraceptives with 20  $\mu\text{g}$  estrogen had a lower risk than products with 30–40  $\mu\text{g}$ .
- Progestin-only contraceptive products did not increase the risk.

Case-control studies using cases of venous thromboembolism derived from the computer records of general practices in the United Kingdom concluded that the increased risk associated with oral contraceptives was the same for all types and that the pattern of risk with specific oral contraceptives suggested confounding because of “preferential prescribing” (defined later).<sup>175,176</sup> **In these studies, matching cases and controls by year of birth eliminated differences between different types of oral contraceptives.** A similar analysis based on 42 cases from a German database again found no difference between new progestin and older progestin oral contraceptives.<sup>177</sup> Thus, in these two studies, more precise adjustments for age eliminated a confounding bias. An assessment of the incidence of venous thromboembolism in the United Kingdom before and after the decline in third-generation progestin use could detect no impact on the statistics (neither an increase nor a decrease).<sup>178</sup>

A reanalysis of the transnational case-control study considered the duration and patterns of oral contraceptive use, focusing on if low-dose estrogen contraceptives with different progestins had significantly different risks of thromboembolism.<sup>179,180</sup> This reanalysis focused on first-time users of second- and third-generation oral contraceptives. **Statistical analysis with adjustment for duration of use in 105 cases who were first-time users could find no differences between second- and third-generation products. A similar reanalysis of the U.K. General Practice Database could demonstrate no difference between different oral contraceptive formulations.**<sup>181</sup>

A case-control study in Germany assessed the outcome when the cases were restricted to hospitalized patients compared to results when all cases, both in-hospital and out-of-hospital, were considered.<sup>182</sup> The conclusion indicated that hospital-based studies overestimated the risk of venous thromboembolism and that there was no difference comparing progestins when all cases were included.

Former users discontinue oral contraceptives for a variety of reasons and often are

switched to what clinicians perceive to be “safer” products, a practice called **preferential prescribing**.<sup>183,184,185</sup> Individuals who do well with a product tend to remain with that product. Thus, at any one point in time, individuals on an older product will be relatively healthy and free of side effects—the **healthy user effect**. This is also called **attrition of susceptibles** because higher-risk individuals with problems are gradually eliminated from the group.<sup>186</sup> **Comparing users of older and newer products, therefore, can involve disparate cohorts of individuals.**

Because desogestrel- and gestodene-containing products were marketed as less androgenic and therefore “better” (a marketing claim not substantiated by epidemiologic studies), clinicians chose to provide these products to higher-risk patients and older women.<sup>183,184</sup> In addition, clinicians switched patients perceived to be at greater risk for thrombosis from older oral contraceptives to the newer formulations with desogestrel and gestodene. Furthermore, these products were prescribed more often to young women who were starting oral contraception for the first time (these young women will not have experienced the test of pregnancy or previous oral contraceptive use to help identify those who have an inherited predisposition to venous thrombosis). These changing practice patterns exert different effects over the lifetime of a product, and analytical adjustments are extremely difficult.

The initial studies were impressive in their agreement. All indicated increased relative risks associated with desogestrel and gestodene compared with levonorgestrel. Nevertheless, all of the early studies, somewhat similar in design, were influenced by the same unrecognized biases. **Persistent errors will produce consistent conclusions.**

Forty cases of venous thrombosis in drospirenone (Yasmin) users (two of which were fatal) were reported in Europe in 2002.<sup>187</sup> The Dutch College of General Practitioners issued a statement encouraging clinicians not to prescribe Yasmin. However, this is the similar story we experienced with “third-generation” progestins, only to learn that preferential prescribing and the healthy user effect probably biased the early case-control studies. In postmarketing surveillance, only one case of venous thrombosis occurred in a million cycles of Yasmin compared with five among users of other oral contraceptives.<sup>187</sup> In a subsequent monitoring study, the incidence of venous thromboembolism in new users was comparable to that seen with other low-dose oral contraceptives.<sup>188</sup> The European Active Surveillance Study (EURAS) was a large cohort study that enrolled **only new users** of oral contraceptives containing a variety of progestins, including drospirenone and levonorgestrel.<sup>189</sup> The incidence of cardiovascular events was similar for all progestins. An American cohort study also focused on new users of oral contraceptives, and thromboembolism occurred at a similar low rate comparing drospirenone users with other oral contraceptives.<sup>190</sup>

Investigators from Denmark and Netherlands continued their interest in hormonal contraception and venous thrombosis, performing a national cohort study using the reliable Danish national registries of events from 1995 to 2005 and a case-control study focusing on short-term users of desogestrel, gestodene, drospirenone, cyproterone, and levonorgestrel.<sup>191,192</sup> As in the earlier Danish case-control study,<sup>174</sup> the risk of venous thrombosis in current users of oral contraceptives decreased with duration of use and with the dose of estrogen and was slightly higher with products containing desogestrel, gestodene, drospirenone, and cyproterone as compared to levonorgestrel. Did these studies escape the problems of preferential prescribing and the healthy user effect? The incidence of thrombotic events in the comparator group (levonorgestrel users) was lower than that reported in other studies, suggesting that this group did demonstrate a healthy user effect. These studies were not limited to new users, a requirement in order to avoid the confounding due to attrition of susceptibles. Additionally, the Danish study was unable to control for BMI or family history of thrombosis, two important markers for women at high risk of venous thrombosis. Preferential prescribing remains a possible confounder in the Danish study; however, the problem of a healthy user effect is even more likely.

The International Active Surveillance Study of Women Taking Oral Contraceptives (INAS-OC), designed to record cardiovascular events in a cohort of more than 80,000 new oral contraceptive users, aimed to determine if different progestins paired with a low-dose estrogen in an oral contraceptive pill have different thromboembolic risks.<sup>193</sup> Six-year follow-up data comparing new users of the drospirenone-containing pill 24-day regimen and 21-day regimen, levonorgestrel-containing pills, and oral contraceptive pills not containing drospirenone show no difference in risk of thromboembolic disease, fatal outcomes, cancer, and severe depression.<sup>194</sup>

**The risk of venous thrombosis associated with modern oral estrogen-progestin contraceptives is increased about twofold but manifested primarily in the first years of use and concentrated in overweight women.<sup>189,195,196</sup> The risk, which increases with increasing body weight and age, is influenced in a major way by the estrogen dose, and the difference among progestin products is likely a reflection of biases and confounders. The impact of smoking on the risk of venous thrombosis is less than that on the risk of arterial thrombosis, but smoking, especially heavy smoking, may act synergistically with oral contraceptives.<sup>197</sup>**

**The risk of venous thromboembolism in the general population is now considered to be higher than previously estimated because of the prevalence of modern diagnostic methods. The new studies also indicate that the risk associated with low-dose oral contraceptives is lower than previously reported and more prevalent in high-risk individuals (Table 22.2) (obesity and inherited or acquired**

thrombophilias). Oral contraceptives with the lowest doses of estrogen should be used for overweight and older women, but progestin-only methods are an even better choice.

**TABLE 22.2 Relative Risk and Actual Incidence of Venous Thromboembolism<sup>193,195,205</sup>**

Population	Relative Risk	Incidence
Young women—general population	1	5–10/10,000/year
Pregnant women	12	60–120
High-dose oral contraceptives	6–10	30–100
Low-dose oral contraceptives	2	10–20
Leiden mutation carrier	6–8	30–80
Leiden carrier and oral contraceptives	10–15	50–100
Leiden mutation—homozygous	80	400–800

As for transdermal contraceptives, the FDA issued a press release on November 10, 2005, calling attention to the fact that women using the transdermal contraceptive patch are exposed over time to a greater amount of estrogen. Subsequently, the patch labeling was updated to include a warning about this higher exposure. Here are the facts:

1. The contraceptive patch delivers daily 20 mg ethinyl estradiol and 150 µg norelgestromin (the primary active metabolite of orally administered norgestimate).
2. The peak estrogen blood levels with the contraceptive patch are about 25–35% lower compared with oral products containing 30 or 35 mg ethinyl estradiol.<sup>198</sup>
3. Over time, without the peaks and nadirs experienced by oral contraceptive users, patch users are exposed to about 60% more estrogen compared with an oral

product containing 35 mg ethinyl estradiol.

Which is more important, a higher peak level or greater exposure over time? The first concern that there might be an increased risk of venous thrombosis with the patch was a consequence of stories in the media based on anecdotal reports provided to the FDA (a numerator without a denominator). In response, Johnson & Johnson, the parent company for the contraceptive patch, provided research funds for three epidemiologic studies, comparing transdermal and oral contraception.

The first case-control study of nonfatal venous thrombosis used information derived from a very large database that records prescriptions and diagnoses longitudinally in managed health care plans.<sup>199</sup> The study over a 3-year time period compared new users of the contraceptive patch with new users of an oral contraceptive containing 35 mg ethinyl estradiol and norgestimate. Sixty-eight cases of venous thrombosis and 266 controls were identified and matched for year of birth and for the date of the thrombotic episode (thus providing comparable dates for exposure). An extension of this study added 56 more cases of venous thrombosis.<sup>200</sup> A comparison of the patch to the oral contraceptive indicated no difference in the risk of venous thrombosis.

The second case-control study indicated that the use of the transdermal contraceptive system was associated with a 2.4-fold increase in the risk of venous thromboembolism compared with users of a 35-mg ethinyl estradiol and norgestimate oral contraceptive.<sup>201</sup> The study used insurance claims data from a major national provider of health insurance to identify women using transdermal or oral contraception. A limitation of the study was the inability to confirm diagnoses in 100% of the cases through review of medical records (completed for 83% of the cases). A strength of the study was the thorough attempt to control for factors that influence venous thrombosis. A strong point of both studies was a focus on new users, eliminating the problem known as attrition of susceptibles. Comparing new users, who are more likely to experience venous thrombosis, to old users would be comparing two different groups of subjects.

A postmarketing study compared the rate of venous thromboembolism in patch users and users of oral contraceptives containing levonorgestrel and 30 mg ethinyl estradiol.<sup>202</sup> The difference between the two methods was **not** statistically significant.

Comparing the two case-control studies, it is worth noting that the negative report had about 6 times as many cases as the positive report, giving it more statistical power. Indeed, in the overall case-control analysis in the positive report, there were only 20 cases among transdermal users and 37 cases among oral contraceptive users, and the odds ratio of 2.0 was close, but it did not reach statistical significance. After excluding cases and controls with high-risk factors, the odds ratio with 16 transdermal cases and 26 oral contraceptive cases achieved 2.4 with statistical significance, but with a

relatively very wide confidence interval, 1.1–5.5.

These are the only epidemiologic data on this important issue. One case-control study is reassuring; one case-control study is disturbing. Because the confidence intervals of the two studies are within the same range (i.e., they overlap), it is not certain that the different results do not reflect a chance finding. At this point in time, it seems that if there is a difference in the risk of venous thrombosis comparing transdermal and oral contraception, the difference has to be very small. Certainly, the available evidence does not indicate a major difference.

# Venous Thromboembolism and Thrombophilias

An inherited resistance to activated protein C, the factor V Leiden mutation, may account for a significant portion of the patients who experience venous thrombosis while taking oral contraceptives.

The factor V Leiden mutation is the most common inherited coagulation problem, transmitted in an autosomal dominant fashion.<sup>103,203</sup> Heterozygotes have a 6- to 8-fold increased risk of venous thromboembolism, and homozygotes an 80-fold increased risk. Oral contraceptive users who have this mutation (heterozygotes or homozygotes) have been reported to have a 30-fold increased risk of venous thrombosis.<sup>204,205</sup> Some have argued that this increase has been overestimated, and it is closer to 10–15-fold.<sup>206</sup> The risk of developing venous thrombosis is greatest in the initial months of use, and venous thrombosis occurring in the first month of exposure should make the clinician suspect the presence of a clotting disorder.<sup>207</sup>

Should screening for the factor V Leiden mutation (or for other inherited clotting disorders) be routine prior to prescribing contraceptives? The carrier frequencies of the Leiden mutation in the American population (the percentages are similar in men and women) are shown in [Table 22.3](#).<sup>208</sup>

## TABLE 22.3

Caucasian Americans	5.27%
Hispanic Americans	2.21%
Native Americans	1.25%
Black Americans	1.23%
Asian Americans	0.45%

These estimates are consistent with European assessments, indicating that this is a trait carried in people of European origin. About 1 in 5,000 individuals is homozygous for the Leiden mutation. In the United States, of the approximately 12 million women currently using oral contraceptives, about 540,000 are likely to carry the factor V Leiden mutation. However, because the incidence rate of venous thromboembolism is so low (5–10 per 10,000 young women per year), the number of women required to be screened to prevent one event is prohibitively large. The prevalence of all deficiencies is only about 0.5% in the asymptomatic population, and only one-third of patients at risk are detected by the present tests.<sup>209</sup>

Furthermore, because only a small number of women even with the Leiden mutation (<1 in 1,000) have a clinical event (99.85% of the individuals who test positive will NOT have a clinical event!), the finding of a positive screening test, especially considering the high rate of false-positive tests, would be a barrier to the use of oral contraceptives, and a subsequent increase in unwanted pregnancies would likely follow. Pregnancy, of course, has a much greater risk of venous thromboembolism than oral contraceptives. **Most experts believe that screening for inherited disorders should be pursued only in women with a previous episode of venous thromboembolism or a close positive family history (parent or sibling) of venous thrombosis.**

The second most prevalent inherited thrombophilia is the prothrombin gene 20210A mutation. A combination of the prothrombin gene mutation and the Leiden mutation is found in about 2% of venous thromboembolism cases.<sup>210</sup> Less frequent are genetic defects in coagulation inhibitors (antithrombin, protein C, and protein S), but these defects carry a substantial increase in risk.

Acquired thrombophilias include the presence of antiphospholipid antibodies (lupus anticoagulant and anticardiolipin) usually associated with autoimmune diseases.

**The inherited and acquired thrombophilias predispose to venous**

**thromboembolism in a synergistic manner with estrogen-containing contraceptives. However, the actual incidence of events is low, and identification of a thrombophilia does not predict a clinical event.**

# Arterial Thrombosis

Cerebral thrombotic attacks (thrombotic strokes and transient ischemic attacks) among young women carry a high rate of death and disability and are therefore an important side effect of hormonal contraception. Nevertheless, the incidence is low, and a small increase in the very low incidence of stroke in young women carries with it little increase in absolute risk. Because the incidence of cerebral thrombotic attacks is higher in women over age 40, we should do our best, as the following discussion will indicate, to make sure estrogen-progestin contraceptive users over age 40 are in good health and without significant risk factors for cardiovascular disease (especially hypertension, migraine with aura, and smoking).

Although it has been difficult to establish arterial thrombosis dose-response relationships with estrogen because these events are so rare, modern, lower estrogen doses are related to the risk of myocardial infarction and thrombotic strokes in case-control studies.<sup>211,212</sup> Thus, a rationale for advocating low-dose estrogen oral contraceptives continues to be valid.

# Arterial Thrombosis—Myocardial Infarction

A population-based, case-control study analyzed 187 cases of myocardial infarction in users of low-dose oral contraceptives in the Kaiser Permanente Medical Care Program.<sup>213</sup> **There was no statistically significant increase in the odds ratio for myocardial infarction in current oral contraceptive users compared with past or never-users.**

In the transnational case-control study of myocardial infarctions collected from 16 centers in Austria, France, Germany, Switzerland, and the United Kingdom, cigarette smoking carried a higher risk for myocardial infarction than oral contraceptives, and **nonsmoking users of oral contraceptives had no evidence of an increased risk.**<sup>214,215</sup> In addition, there was an indication that patient screening is important in minimizing the impact of hypertension on the risk of myocardial infarction. Similar results were reported in a case-control study based on subjects in England, Scotland, and Wales and another in America.<sup>216,217</sup>

In the WHO multicenter study, there were 368 cases of acute myocardial infarction.<sup>218</sup> Factors associated with an increased risk of myocardial infarction included smoking, a history of hypertension (including hypertension in pregnancy), diabetes, rheumatic heart disease, abnormal blood lipids, and a family history of stroke or myocardial infarction. Duration of use and past use of oral contraceptives did not affect risk. Although there was about a fivefold overall increased odds ratio of myocardial infarction in current users of oral contraceptives, essentially all cases occurred in women with cardiovascular risk factors. There was no apparent effect of increasing age on risk; however, there were only 12 cases among oral contraceptives users less than 35 years old. There was no apparent relationship with estrogen dose, and there was no apparent influence of type or dose of progestin, but the rare occurrence of this condition produced such small numbers that there was insufficient statistical power to accurately assess the effects of progestin type and estrogen and progestin doses. **The conclusion of this study was that the risk of myocardial infarction in women who use oral contraceptives is increased only in smokers.**

**In a Danish case-control study of acute myocardial infarction in young women, a statistically significant increase in risk was noted only in current users of 50 µg ethinyl estradiol.**<sup>216</sup> There was a progressive increase in risk with the number of cigarettes smoked (accounting for 80% of the acute myocardial infarctions in young women), increasing BMI, treated hypertension, treated hypertension in pregnancy, diabetes mellitus, hyperlipidemia, frequent migraine, and family history of myocardial infarction. However, only family history of myocardial infarction and smoking affected the risk associated with oral contraceptives; no influence on oral contraceptive risk was

apparent with diabetes, hypertension, and heart disease. No differences could be demonstrated according to type of progestin.

A case-control study from the Netherlands found that the risk of myocardial infarction was highest among users of oral contraceptives who smoked, had diabetes mellitus, or who were hypercholesterolemic.<sup>219</sup> The risk of myocardial infarction was not affected by the presence of the factor V Leiden mutation or the prothrombin gene mutation.

The Women's Lifestyle and Health Cohort Study is a prospective cohort study of 106,841 Norwegian and Swedish women, started in 1991, specifically designed to assess the long-term health effects of hormonal contraceptives.<sup>220</sup> Low-dose (<50 µg ethinyl estradiol) oral contraceptives were not associated with an increased risk of myocardial infarction. All previous cohort studies date back to oral contraceptive use with higher doses of estrogen in the 1970s and 1980s. For example, in the report from the Nurses' Health Study in 1988, an increased risk of myocardial infarction was found in current users.<sup>221</sup>

Case-control studies of low-dose estrogen oral contraceptives have concluded that an increased risk of arterial disease occurs only in women who have hypertension or are smokers.<sup>118,213,214,217,219</sup> The cohort studies don't help us with this important issue because the numbers are too small for definitive analyses of subgroups. Nevertheless, British and Finnish cohorts were reported to have increased risks of developing myocardial infarction in oral contraceptive users who smoked<sup>222,223</sup> (Table 22.4).

## **TABLE 22.4 Incidence of Myocardial Infarction in Reproductive-Age Women<sup>216</sup>**

**Overall Incidence<sup>222</sup>****5/100,000/year**

## Women &lt; age 35

Nonsmokers 4/100,000/year

Nonsmokers and OCs 4/100,000/year

Smokers 8/100,000/year

Smokers and OCs 43/100,000/year

## Women 35 years old and older

Nonsmokers 10/100,000/year

Nonsmokers and OCs 40/100,000/year

Smokers 88/100,000/year

Smokers and OCs 485/100,000/year

NOTE: The above incidences are estimates based on oral contraceptive use paired with cardiovascular risk factors prevalent in the general population. Effective screening would produce smaller numbers. The increased risks in the smokers and OC groups reflect the impact of undetected cardiovascular risk factors, especially hypertension.

A case-control study addressing new users of transdermal contraception with new users of oral contraception detected no difference in the rates of myocardial infarction or stroke.<sup>224</sup>

# Arterial Thrombosis—Stroke

Older case-control and cohort studies indicated an increased risk of cerebral thrombosis among current users of high-dose oral contraceptives.<sup>225,226,227</sup> However, new studies show overall that ischemic and hemorrhagic stroke does not appear to be increased in healthy, nonsmoking women with the use of oral contraceptives containing less than 50 µg ethinyl estradiol.<sup>228,229,230,231,232,233</sup> A case-control study of all 794 women in Denmark who suffered a cerebral thromboembolic attack during 1985–1989 concluded that there was an almost twofold increased relative risk associated with oral contraceptives containing 30–40 µg estrogen, though the risk was significantly influenced by both smoking and the dose of estrogen in additive (not synergistic) fashion.<sup>231</sup> Similarly, the transnational study found a threefold increase in the risk of ischemic stroke associated with the use of oral contraceptives, though with higher risks observed in smokers (more than 10 cigarettes per day), in women with hypertension, and in users of higher-dose estrogen products.<sup>230</sup>

A population-based, case-control study of 408 strokes from the California Kaiser Permanente Medical Care Program found no increase in risk for either ischemic stroke or hemorrhagic stroke on low-dose oral contraception.<sup>229</sup> The identifiable risk factors for ischemic stroke were smoking, hypertension, diabetes, elevated body weight, and low socioeconomic status. The risk factors for hemorrhagic stroke were the same plus greater body mass and heavy use of alcohol. **Current users of low-dose oral contraceptives did not have an increased risk of ischemic or hemorrhagic stroke compared with former users and with never-users.** There was no evidence for an adverse effect of increasing age or for smoking (for hemorrhagic stroke, there was a suggestion of a positive interaction between current oral contraceptive use and smoking, but the numbers were small, and the result was not statistically significant).

The World Health Organization data on stroke come from the same collaborative study that yielded the publications on venous thromboembolism. The results with stroke were published as two separate reports, one on ischemic stroke and the other on hemorrhagic stroke.<sup>234,235</sup>

This hospital-based, case-control study from 21 centers in 17 countries accumulated 697 cases of ischemic stroke, 141 from Europe and 556 from developing countries.<sup>234</sup> The overall odds ratio for ischemic stroke indicated about a threefold increased risk. In Europe, however, the risk was statistically significant only for higher-dose products and **not** statistically significant for products with less than 50 µg ethinyl estradiol. In developing countries, there was no difference in risk with low-dose and higher-dose oral contraceptives. This is believed to be due to the strong influence of hypertension. In Europe, it was uncommon for women with a history of hypertension to be using oral

contraceptives; however, this was not the case in developing countries. Duration of use and type of progestin had no impact, and past users did not have an increased risk, but smoking 10 or more cigarettes daily exerted a synergistic effect with oral contraceptives, increasing the risk of ischemic stroke, approximating the effect of hypertension and oral contraceptives. The risk was greater in women 35 years and older; however, this, too, was believed to be due to an effect of hypertension. **Thus, the conclusion of this study was that the risk of ischemic stroke is extremely low, concentrated in those who use higher-dose products, smoke, or have hypertension.**

In the WHO study on hemorrhagic stroke, there were 1,068 cases.<sup>235</sup> Current use of oral contraceptives was associated with a slightly increased risk of hemorrhagic stroke only in developing countries, not in Europe. This again probably reflects the presence of hypertension, because the greatest increased risk (about 10- to 15-fold) was identified in current users of oral contraceptives who had a history of hypertension. Current cigarette smoking also increased the risk in oral contraceptive users, but not as dramatically as hypertension. For hemorrhagic stroke, the dose of estrogen had no effect on risk, and neither did duration of use or type of progestin. **This study concluded that the risk of hemorrhagic stroke due to oral contraceptives is increased only slightly in older women, probably occurring only in women with risk factors such as hypertension.**

A second Danish case-control study included thrombotic strokes and transitory cerebral ischemic attacks analyzed together as cerebral thromboembolic attacks.<sup>222</sup> In this study, the 219 cases during 1994 and 1995 included 146 cases of cerebral infarction and 73 cases of transient ischemic attacks. There was a dose-response relationship with estrogen in the dose ranges of 20, 30–40, and 50 µg ethinyl estradiol, although the number of 20 µg users (5 cases, 22 controls) was not sufficient to establish a lower risk at this lower dose. An updated 5-year report of the Danish case-control study indicated that the odds ratio of cerebral thrombosis decreased from a high of 4.5 with 50-µg estrogen pills to 1.6 with 20–40-µg pills.<sup>236</sup> Hypertension increased the risk 5-fold, migraine 3.2 times, diabetes 5.6 times, and hyperlipidemia and coagulation disorders about 12-fold.

The Norwegian-Swedish Women's Lifestyle and Health Cohort Study supports the conventional wisdom of the last decade that low-dose oral contraceptives do not increase the myocardial infarction or stroke in healthy, nonsmoking women, regardless of age.<sup>237</sup> Screening for hypertension is especially important in that it is a major risk factor for stroke associated with oral contraceptive use.

Again, there was concern that drospirenone-containing low-dose contraceptive pills may have an increased risk of arterial thrombotic events. A cohort study looking comparing women on a drospirenone-30-µg ethinyl estradiol pill to levonorgestrel with

20–30 µg of ethinyl estradiol did find an increased hazard ratio of 2.01 for arterial thrombosis among drospirenone users aged 35–55, but this study did not control for obesity, family history of embolic disease, or smoking status.<sup>238</sup>

**In the absence of hypertension, the effect of smoking in women under age 35 is too small to be measured. In the presence of hypertension, it is currently believed that with medical control of blood pressure and close follow-up (blood pressure monitoring every 3 months), nonsmoking women under age 35 and otherwise healthy can use low-dose oral contraception (Table 22.5).**

## **TABLE 22.5 Incidence of Stroke in Reproductive-Age Women<sup>222, 226,231,232</sup>**

## **Conclusion—Myocardial Infarction and Stroke**

**Oral contraceptives containing less than 50 µg ethinyl estradiol do not increase the risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age.** The effect of smoking in women under age 35 is, as we have long recognized, not detectable in the absence of hypertension. After age 35, the subtle presence of hypertension makes analysis difficult, but the Kaiser study indicates that increasing age and smoking by themselves have little impact on the risk of stroke in low-dose oral contraceptive users. The screening of patients in the Kaiser program was excellent, resulting in few women with hypertension using oral contraceptives. **There is no reason to doubt that these conclusions apply as well to the transdermal and vaginal methods of steroid contraception.**

Epidemiologic studies fail to find any substantial risk of ischemic or hemorrhagic stroke with low-dose oral contraceptives in healthy, young women. The WHO study did find evidence for an adverse impact of smoking in women under age 35; the Kaiser study did not. This difference is explained by the confounding effect of hypertension, the major risk factor identified. In the WHO study, a history of hypertension was based on whether a patient reported ever having had high blood pressure (other than in pregnancy) and not validated by medical records. In the Kaiser study, women were classified as having hypertension if they reported using antihypertensive medication (<5% of oral contraceptive users had treated hypertension, and there were no users of higher-dose products). In the WHO study, the effect of using oral contraceptives in the presence of a high-risk factor is apparent in the different odds ratios when European women who received good screening from clinicians were compared with women in developing countries who received little screening; therefore, more women with cardiovascular risk factors in developing countries were using oral contraceptives. **The studies indicate that hypertension should be a major concern, especially in regard to the risk of stroke.**

Over the years, there has been recurring discussion over whether to provide oral contraceptives over-the-counter on a nonprescription basis. The data in the WHO study make an impressive argument against such a move. The increased risk of myocardial infarction was most evident in developing countries where 70% of the cases received their oral contraceptives from a nonclinical source. Deprived of screening, women with risk factors in developing countries were exposed to greater risk.

# Smoking and Oral Contraception

Smoking continues to be a difficult problem, not only for patient management but for analysis of data as well. In large US surveys in 1982 and 1988, the decline in the prevalence of smoking was similar in users and nonusers of oral contraception; however, 24.3% of 35- to 45-year-old women who used oral contraceptives were smokers.<sup>239</sup> In this group of smoking, oral contraceptive–using women, 85.3% smoked 15 or more cigarettes per day (heavy smoking). Despite the widespread teaching and publicity that smoking is a contraindication to oral contraceptive use over the age of 35, more older women who use oral contraceptives smoke and smoke heavily, compared with young women. This strongly implies that older smokers are less than honest with clinicians when requesting oral contraception or that clinicians do not all accurately screen for tobacco use; this further raises serious concern over how well this confounding variable can be controlled in case-control and cohort studies. Studies documenting the effects of smoking bans on hospital admissions for myocardial infarctions indicate a rapid reduction in 6 months to a year.<sup>240,241</sup> **A former smoker must have stopped smoking for at least 6 consecutive months and preferably 12 months to be regarded as a nonsmoker. Women who have nicotine in their bloodstream obtained from patches or gum should be regarded as smokers.**

# Lipoproteins and Oral Contraception

The balance of estrogen and progestin potency in a given oral contraceptive formulation can potentially influence cardiovascular risk by its overall effect on lipoprotein levels. Oral contraceptives with relatively high doses of progestins (doses not used in today's low-dose formulations) do produce unfavorable lipoprotein changes.<sup>242</sup> The levonorgestrel triphasic exerts no significant changes on HDL cholesterol, LDL cholesterol, and apoprotein B and no change or an increase in apoprotein A. The monophasic desogestrel and desogestrel pills have a favorable effect on the lipoprotein profile, while the triphasic norgestimate and gestodene pills produce beneficial alterations in the LDL/HDL and apoprotein B/apoprotein A ratios.<sup>243,244,245,246</sup> Like the triphasic levonorgestrel pills, norethindrone multiphasic pills have no significant impact on the lipoprotein profile over 6–12 months.<sup>247</sup> **In summary, studies of low-dose formulations indicate that the adverse effects of progestins are limited to the fixed-dose combination with a dose of levonorgestrel that exceeds that in the multiphasic formulation or in the low-dose products.** The formulation that contains 100 µg levonorgestrel and 20 µg ethinyl estradiol produces short-term changes in the lipid profile that are similar to those seen with other low-dose oral contraceptives, and with long-term use, the levels revert to those observed at baseline before treatment.<sup>248</sup> The effects of transdermal administration have been studied, and it appears triglycerides increase modestly, and the LDL/HDL ratio declines slightly.<sup>249</sup>

An important study in monkeys indicated a protective action of estrogen against atherosclerosis but by a mechanism independent of the cholesterol-lipoprotein profile. Oral administration of a combination of estrogen and progestin to monkeys fed a high-cholesterol, atherogenic diet decreased the extent of coronary atherosclerosis despite a reduction in HDL cholesterol levels.<sup>250,251,252</sup> In somewhat similar experiments, estrogen treatment markedly prevented arterial lesion development in rabbits.<sup>253,254,255</sup> In considering the impact of progestational agents, lowering of HDL is not necessarily atherogenic if accompanied by a significant estrogen impact. The estrogen component provides protection through a direct effect on vessel walls, especially favorably influencing vasomotor and platelet factors such as nitric oxide and prostacyclin.

This conclusion is reinforced by angiographic and autopsy studies. Young women with myocardial infarctions who have used oral contraceptives have less diffuse atherosclerosis than nonusers.<sup>256,257</sup> Indeed, a case-control study indicated that the risk of myocardial infarction in patients taking older, high-dose levonorgestrel-containing formulations is the same as that experienced with pills containing other progestins.<sup>170</sup>

In the past two decades, we were subjected to considerable marketing hype about the importance of the impact of oral contraceptives on the cholesterol-lipoprotein

profile. If indeed certain oral contraceptives had a negative impact on the lipoprotein profile, one would expect to find evidence that atherosclerosis caused an increase in subsequent cardiovascular disease. There is no such evidence. Thus, the mechanism of the cardiovascular complications is undoubtedly a short-term acute mechanism—thrombosis (an estrogen-related effect).

Remember too that the new progestins, because of their reduced androgenicity, predictably do not adversely affect the cholesterol-lipoprotein profile. The estrogen-progestin balance of combined oral contraceptives containing one of the new progestins even promotes favorable lipid changes.<sup>35</sup> Thus, the new formulations have the potential to offer protection against cardiovascular disease, an important consideration as we enter an era of women using oral contraceptives for longer durations and later in life. But one must be cautious regarding the clinical significance of subtle laboratory value changes in the absence of outcome data, and it is unlikely that oral contraceptives will have a clinically meaningful beneficial effect on the incidence of coronary heart disease.

# Hypertension

Oral contraceptive–induced hypertension was observed in approximately 5% of users of higher-dose pills. More recent evidence indicates that small increases in blood pressure can be observed even with 30- $\mu$ g estrogen, monophasic pills, including those containing the new progestins. However, an increased incidence of clinically significant hypertension has not been reported.<sup>258,259,260,261,262,263,264</sup> The lack of clinical hypertension in most studies may be due to the rarity of its occurrence. The Nurses' Health Study observed an increased risk of clinical hypertension in current users of low-dose oral contraceptives, providing an incidence of 41.5 cases per 10,000 women per year.<sup>265</sup> Therefore, an annual assessment of blood pressure is still an important element of clinical surveillance, even when low-dose oral contraceptives are used. Postmenopausal women in the Rancho Bernardo Study who had previously used oral contraceptives (probably high-dose products) had slightly higher (2–4 mm Hg) diastolic blood pressures.<sup>266</sup> Because past users do not demonstrate differences in incidence or risk factors for cardiovascular disease, it is unlikely this blood pressure difference has an important clinical effect.

Variables such as previous toxemia of pregnancy or previous renal disease do not predict whether a woman will develop hypertension on oral contraception.<sup>267</sup> Likewise, women who have developed hypertension on oral contraception are not more predisposed to develop toxemia of pregnancy. Overall, there is no evidence that previous oral contraceptive users have an increased risk of hypertension during a subsequent pregnancy.<sup>268,269</sup> The exception is the Nurses' Health Study, which indicated that recent users for a long duration (8 or more years) have a twofold increased risk of preeclampsia, a finding that was based on a small number of cases.<sup>270</sup> These epidemiologic associations are hard to establish because of the role of underlying hypertension in pregnancy-induced hypertension and the difficulty in assessing the efficacy of hypertension screening in oral contraceptive users.

The mechanism for an effect on blood pressure is thought to involve the renin-angiotensin system. The most consistent finding is a marked increase in plasma angiotensinogen, the renin substrate, up to 8 times normal values (on higher-dose pills). In nearly all women, excessive vasoconstriction is prevented by a compensatory decrease in plasma renin concentration. If hypertension does develop, the renin-angiotensinogen changes take 3–6 months to disappear after stopping combined oral contraception.

Women with treated hypertension using oral contraceptives have been reported to have poor control of blood pressure with higher diastolic pressures.<sup>271</sup> **In our view, with medical control of the blood pressure and close follow-up (at least every 3**

months), the clinician and the nonsmoking patient who is under age 35 and otherwise healthy may choose low-dose oral contraception. Close follow-up is also indicated in women with a history of preexisting renal disease or a strong family history of hypertension or cardiovascular disease. It seems prudent to suggest that patients with marginal cardiac reserve should utilize other means of contraception. Significant increases in cardiac output and plasma volume have been recorded with oral contraceptive use (higher-dose pills), probably a result of fluid retention.

**The epidemiologic data emphasize the importance of good patient screening.** The occurrence of thrombosis is essentially limited to older women who smoke or have cardiovascular risk factors, especially hypertension, or who have an inherited thrombophilia. **If a patient has a close family history (parent or sibling) or a previous episode of idiopathic thromboembolism, an evaluation to search for an underlying abnormality in the coagulation system is warranted.** It has been reported that family history of venous thromboembolism has low predictive value.<sup>272</sup> Another study indicated that testing for thrombophilia did not allow for prediction of recurrent events, but risk factors such as family history did provide prediction.<sup>273</sup> The conservative recommendation for a high-risk woman considering exposure to exogenous estrogen stimulation is to rule out an underlying thrombophilia. The importance of this issue is illustrated by the increased risk of a very rare event, cerebral sinus thrombosis, in women who have an inherited predisposition for clotting and use oral contraceptives.<sup>131,274</sup> When new transdermal contraceptive users are compared with new users of oral contraception, there is no increased or decreased risk of cerebral venous sinus thrombosis.<sup>275</sup>

The following measurements are recommended, and abnormal results require consultation with a hematologist regarding prognosis and prophylactic treatment. The list of laboratory tests is long, and because this is a dynamic and changing field, the best advice is to consult with a hematologist. If a diagnosis of a congenital deficiency is made, screening should be offered to other family members (Table 22.6).

**Combination estrogen-progestin contraception is contraindicated in women who have a history of idiopathic venous thromboembolism and also in women who have a close family history (parent or sibling) of idiopathic venous thromboembolism.** These women will have a higher incidence of congenital deficiencies in important clotting measurements, especially antithrombin III, protein C, protein S, and resistance to activated protein C.<sup>276</sup> Such a patient who screens negatively for an inherited clotting deficiency might still consider the use of oral contraceptives, but this would be a difficult decision with unknown risks for both patient and clinician, and it is more prudent to consider other contraceptive options. Other risk factors for thromboembolism that should be considered by clinicians include an acquired predisposition such as the presence of lupus anticoagulant or malignancy and immobility or trauma. Varicose veins are not a risk factor unless they are very extensive.<sup>164</sup> **Progestin-only methods, including implants, depot medroxyprogesterone acetate, and the levonorgestrel-releasing IUS, are recommended for high-risk women and for women who are anticoagulated.**

**The conclusion once again is that low-dose oral contraceptives are very safe for healthy, young women.** By effectively screening older women for the presence of smoking and cardiovascular risk factors, especially hypertension, we can limit, if not eliminate, any increased risk for arterial disease associated with low-dose oral contraceptives. And it is very important to emphasize that there is no increased risk of cardiovascular events associated with duration of use (long-term). In large cohort studies, the risk of overall mortality comparing users and nonusers of oral contraceptives is identical.<sup>160,161,162</sup> It is worth noting again that these conclusions likely also apply to transdermal and vaginal estrogen-progestin contraception.

# Summary: Oral Contraceptives and Cardiovascular Disease

The outpouring of epidemiologic data in the last two decades allows the construction of a clinical formulation that is evidence based. The following conclusions are consistent with the recent reports.

- Pharmacologic estrogen increases the production of clotting factors.
- Progestins have no significant impact on clotting factors.
- Past users of oral contraceptives do not have an increased incidence of cardiovascular disease.
- All low-dose oral contraceptives, regardless of progestin type, have an increased risk of venous thromboembolism, concentrated in the first 1–2 years of use. The actual risk of venous thrombosis with low-dose oral contraceptives is lower in the new studies compared with previous reports. Some have argued that this is due to preferential prescribing and the healthy user effect. However, it is also logical that the lower risk reflects better screening of patients and lower estrogen doses. The risk increases with increasing age and body weight.
- Smoking has a lesser effect on the risk of venous thrombosis compared with arterial thrombosis.
- Smoking and estrogen have an additive effect on the risk of arterial thrombosis. Why is there a difference between venous and arterial clotting? The venous system has low flow with a state of high fibrinogen and low platelets, in contrast to the high-flow state of the arterial system with low fibrinogen and high platelets. Thus, it is understandable why these two different systems can respond in different ways.
- Hypertension is a very important additive risk factor for stroke in oral contraceptive users.
- Low-dose oral contraceptives (<50- $\mu$ g ethinyl estradiol) do not increase the risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age.
- Almost all myocardial infarctions and strokes in oral contraceptive users occur in users of high-dose products or users with cardiovascular risk factors over the age of 35. In the Oxford Family Planning Association cohort, cardiac deaths occurred only in women who smoked 15 or more cigarettes per day.<sup>152</sup>
- Arterial thrombosis (myocardial infarction and stroke) has a dose-response relationship with the dose of estrogen, but there are insufficient data to determine whether there is a difference in risk with products that contain 20, 30, or 35  $\mu$ g ethinyl estradiol.

# CARBOHYDRATE METABOLISM

---

With the older high-dose oral contraceptives, an impaired glucose tolerance test was present in many women. In these women, plasma levels of insulin as well as the blood sugar were elevated. Generally, the effect of oral contraception is to produce an increase in peripheral resistance to insulin action. Most women can meet this challenge by increasing insulin secretion, and there is no change in the glucose tolerance test, although 1-hour values may be slightly elevated.

Insulin sensitivity is affected mainly by the progestin component of the pill.<sup>277</sup> The derangement of carbohydrate metabolism may also be affected by estrogen influences on lipid metabolism, hepatic enzymes, and elevation of unbound cortisol. The glucose intolerance is dose-related, and once again effects are less with the low-dose formulations. **Insulin and glucose changes with low-dose monophasic and multiphasic oral contraceptives are so minimal that it is now believed they are of no clinical significance.**<sup>264,278,279,280,281</sup> This includes long-term evaluation with hemoglobin A1c.

The observed changes in studies of oral contraception and carbohydrate metabolism are in the nondiabetic range. In order to measure differences, investigators have resorted to analysis by measuring the area under the curve for glucose and insulin responses during glucose tolerance tests. A highly regarded cross-sectional study utilizing this technique reported that even lower-dose formulations have detectable effects on insulin resistance.<sup>277</sup> The reason this is important is that it is now recognized that hyperinsulinemia due to insulin resistance is a contributor to cardiovascular disease.

Because long-term, follow-up studies of large populations have failed to detect any increase in the incidence of diabetes mellitus or impaired glucose tolerance (even in past and current users of high-dose pills),<sup>265,282,283</sup> the concern now appropriately focuses on the slight impairment as a potential risk for cardiovascular disease. If slight hyperinsulinemia were meaningful, wouldn't you expect to see evidence of an increase in cardiovascular disease in past users who took oral contraceptives when doses were higher? As we have emphasized before, there is no such evidence. The data strongly indicate that the changes in lipids and carbohydrate metabolism that have been measured are not clinically meaningful.

It can be stated definitively that oral contraceptive use does not produce an increase in diabetes mellitus.<sup>282,283,284,285</sup> The minor hyperglycemia associated with oral contraception is not deleterious and is completely reversible. Even women who have risk factors for diabetes in their history are not affected. In women with recent gestational diabetes, no significant impact on glucose tolerance could be demonstrated over 6–13 months comparing the use of low-dose monophasic and multiphasic oral

contraceptives with a control group, and no increase in the risk of overt diabetes mellitus could be detected with long-term follow-up.<sup>286,287</sup> A high percentage of women with previous gestational diabetes develop overt diabetes and associated vascular complications. Until overt diabetes develops, it is appropriate for these patients to use low-dose oral contraception.

In clinical practice, it may, at times, be necessary to prescribe oral contraception for the overt diabetic. No effect on insulin requirement is expected with low-dose pills.<sup>288</sup> Older epidemiologic data suggest oral contraceptives increased the risk of thrombosis in women with insulin-dependent diabetes mellitus; historically, women with diabetes had been encouraged to use other forms of contraception. However, a case-control study could find no evidence that oral contraceptive use by young women with insulin-dependent diabetes mellitus increased the development of retinopathy or nephropathy.<sup>289</sup> In a 1-year study of women with insulin-dependent diabetes mellitus who were using a low-dose oral contraceptive, no deterioration could be documented in lipoprotein or hemostatic biochemical markers for cardiovascular risk.<sup>290</sup> And finally, no effect of oral contraceptives on cardiovascular mortality could be detected in a group of women with diabetes mellitus.<sup>291</sup>

These findings can reasonably be assumed to extend to users of transdermal contraception. Users of the NuvaRing with type 1 diabetes were found to have no change in carbohydrate metabolism.<sup>292</sup>

# THE LIVER

---

The liver is affected in more ways and with more regularity and intensity by the sex steroids than any other extragenital organ. Estrogen influences the synthesis of hepatic cell enzymes, serum enzymes formed in the liver, and plasma proteins. Estrogenic hormones also affect hepatic lipid and lipoprotein formation, the intermediary metabolism of carbohydrates, and intracellular enzyme activity. Nevertheless, an extensive analysis of the prospective cohorts of women in the Royal College of General Practitioners' Oral Contraception Study and the Oxford Family Planning Association Contraceptive Study could detect no evidence of an increased incidence or risk of serious liver disease among oral contraceptive users.<sup>293</sup>

The active transport of biliary components is impaired by estrogens as well as some progestins. The mechanism is unclear, but cholestatic jaundice and pruritus were occasional complications of higher-dose oral contraception and are similar to the recurrent jaundice of pregnancy, that is, benign and reversible. The incidence with lower-dose oral contraception is unknown, but it must be a very rare occurrence.

**The only absolute hepatic contraindication to steroid contraceptive use is acute or chronic cholestatic liver disease. Cirrhosis and previous hepatitis are not aggravated. Once recovered from the acute phase of liver disease (normal enzyme levels), a woman can use steroid contraception.**

Data from the Royal College of General Practitioners' prospective study indicated that an increase in the incidence of gallstones occurred in the first years of oral contraceptive use, apparently due to an acceleration of gallbladder disease in women already susceptible.<sup>294</sup> In other words, the overall risk of gallbladder disease was not increased, but in the first years of use, disease was activated or accelerated in women who were vulnerable because of asymptomatic disease or a tendency toward gallbladder disease. The mechanism appears to be induced alterations in the composition of gallbladder bile, specifically a rise in cholesterol saturation that is presumably an estrogen effect.<sup>295</sup> The Nurses' Health Study reported no significant increase in the risk of symptomatic gallstones among ever users but slightly elevated risks among current and long-term users.<sup>296</sup> Although oral contraceptive use has been linked to an increased risk of gallbladder disease, the epidemiologic evidence has been inconsistent. Indeed, an Italian case-control study and a report from the Oxford Family Planning Association cohort found no increase in the risk of gallbladder disease in association with oral contraceptive use and no interaction with increasing age or body weight.<sup>297,298</sup> Keep in mind that even though some studies found a statistically significant modest increase in the relative risk of gallbladder disease, even if the effect were real, it is of little clinical importance because the actual incidence of this problem

is very low.

# Liver Adenomas

Hepatocellular adenomas can be produced by steroids of both the estrogen and androgen families. Actually, there are several different lesions: peliosis, focal nodular hyperplasia, and adenomas. Peliosis is characterized by dilated vascular spaces without endothelial lining and may occur in the absence of adenomatous changes. The adenomas are not malignant; their significance lies in the potential for hemorrhage. The most common presentation is acute right upper quadrant or epigastric pain. The tumors may be asymptomatic, or they may present suddenly with hemoperitoneum. There is some evidence that the tumors and focal nodular hyperplasia regress when oral contraception is stopped.<sup>299,300</sup> Epidemiologic data have not supported the contention that mestranol increased the risk more than ethinyl estradiol.

The risk appears to be related to duration of oral contraceptive use and to the steroid dose in the pills. This is reinforced by the rarity of the condition ever since low-dose oral contraception became available. The ongoing prospective studies have accumulated many woman-years of use and have not identified an increased incidence of such tumors.<sup>293</sup> In a collaborative study of 15 German liver centers, no increase in risk for liver adenomas in contemporary oral contraceptive users could be detected.<sup>301</sup> An Italian case-control study found an increase in risk for focal nodular hyperplasia associated with low-dose oral contraceptives, a risk that reached statistical significance only with 3 or more years of use (with a very wide confidence interval because of only 13 cases).<sup>302</sup> In our view, it is not necessary to discuss liver problems during the informed consent process.

No reliable screening test or procedure is currently available for the detection of liver adenomas. Routine liver function tests are normal. Computed tomography (CT) scanning or magnetic resonance imaging (MRI) is the best means of diagnosis; angiography and ultrasonography are not reliable. Palpation of the liver should be part of the periodic evaluation in oral contraceptive users. If an enlarged liver is found, oral contraception should be stopped, and regression should be evaluated and followed by imaging.

## OTHER METABOLIC EFFECTS

---

Nausea and breast discomfort continue to be disturbing effects, but their incidence is significantly less with low-dose oral contraception. Fortunately, these effects are most intense in the first few months of use and, in most cases, gradually disappear. In placebo-controlled trials with low-dose oral contraceptives, the incidence of “minor” side effects such as headache, nausea, dysmenorrhea, and breast discomfort actually occurred at the same rate in the treated group and the placebo group!<sup>303,304,305</sup> Weight gain usually responds to dietary restriction, but for some patients, the weight gain is an anabolic response to the sex steroids, and discontinuation of oral contraception is the only way that weight loss can be achieved. This must be rare with low-dose oral contraception because data in published studies, especially in placebo-controlled trials, fail to indicate a difference in body weight between users and nonusers.<sup>305,306,307,308,309,310,311,312,313</sup>

There is no association between oral contraception and peptic ulcer disease or inflammatory bowel disease.<sup>314,315</sup> Oral contraception is not recommended for patients with problems of gastrointestinal malabsorption because of the possibility of contraceptive failure, although vaginal administration would be appropriate.

Chloasma, a patchy increase in facial pigment, was, at one time, found to occur in approximately 10% of oral contraceptive users. It is now a rare problem due to the decrease in estrogen dose. Unfortunately, once chloasma appears, it fades only gradually following discontinuation of the pill and may never disappear completely. Skin-blanching medications may be useful.<sup>316</sup>

Hematologic effects include an increased sedimentation rate, an increased total iron-binding capacity due to the increase in globulins, and a decrease in prothrombin time. The use of hormonal contraceptives results in a decrease in iron deficiency anemia because of a reduction in menstrual bleeding.<sup>317,318</sup> Indeed, in anemic women, an increase in hemoglobin and ferritin levels accompanies the use of oral contraceptives.<sup>319</sup>

The continuous, daily use of oral contraceptives may prevent the appearance of symptoms in porphyria precipitated by menses. Changes in vitamin metabolism have been noted: a small nonharmful increase in vitamin A and decreases in blood levels of pyridoxine (B<sub>6</sub>) and the other B vitamins, folic acid, and ascorbic acid. Despite these changes, routine vitamin supplements are not necessary for women eating adequate, normal diets.<sup>320</sup>

# MENTAL HEALTH AND MOOD

---

The relationship between hormonal contraception and mental health has been debated in the literature. Two recent reviews out of Denmark recently posit a relationship between first-time hormonal contraception use and receiving a prescription for an antidepressant and, more concerning, an increased risk of suicide and suicide attempt in young women.<sup>321,322</sup> These studies use women not on any contraception as the comparator group, and it has been argued that this could introduce selection bias, and women who began nonhormonal contraception would be more accurate. A review in the United States focusing on sexually active women using hormonal contraception, nonhormonal contraception, or no contraception found no differences between the groups for most ages and a decrease in depressive symptoms and reported suicide attempt in the past year with women on hormonal contraception.<sup>323</sup> A cross-sectional study found no evidence for increased symptoms of depression or anxiety among users of the oral contraceptive pills among women aged 18–54.<sup>324</sup> Systematic review articles show mental depression is not associated with progestin-only oral contraceptives and that hormonal contraception does not worsen symptoms of depression and is in fact associated with an improvement in depressive symptoms in the adolescent population.<sup>325,326</sup> A review article on combined hormonal contraception and mood posited that no conclusions could be made due to a lack of prospective data on this subject, but the current literature suggests that most women using combined hormonal contraception have little noticeable effect on mood.<sup>327</sup> A randomized controlled study looking on mood fluctuations within a single menstrual cycle reported that women taking combined hormonal contraceptives actually reported significantly less depression in the intermenstrual phase than women on placebo.<sup>328</sup>

Though infrequent, a reduction in libido is occasionally a problem and may be a cause for seeking an alternative method of contraception.<sup>329</sup> Indeed, most women report an increase or no change in libido during oral contraceptive use.<sup>330,331</sup> Nevertheless, the estrogen-induced increase in SHBG and the resulting decrease in free testosterone may produce an impact on sexuality in some women. An empiric trial of a non-estrogen-containing contraceptive method is warranted.

Adverse androgenic voice changes were occasionally encountered with the use of the first very-high-dose oral contraceptives. Vocal virilization can be a serious and devastating problem for some women, especially when vocal performance is important. Careful study of women on low-dose oral contraceptives indicates that this is no longer a side effect of concern.<sup>332</sup>

# **THE RISK OF CANCER**

---

# Endometrial Cancer

The use of oral contraception protects against endometrial cancer. The use for at least 12 months reduces the risk of developing endometrial cancer by **50%**, with the greatest protective effect gained by use for more than 3 years.<sup>333,334,335,336,337,338</sup> This protection persists for 20 or more years after discontinuation (the actual length of duration of protection is unknown) and is greatest in women at highest risk: nulliparous and low-parity women.<sup>338,339</sup> This protection is equally protective for all three major histologic subtypes of endometrial cancer: adenocarcinoma, adenoacanthoma, and adenosquamous cancers. Finally, protection is seen with all monophasic formulations of oral contraceptives, including pills with less than 50 µg estrogen.<sup>332,335,338,340</sup> There are no data as yet with multiphasic preparations or the new progestin formulations, but because these products are still dominated by their progestational component, there is every reason to believe that they will be protective.

# Ovarian Cancer

Protection against ovarian cancer, the most lethal of female reproductive tract cancers, is one of the most important benefits of oral contraception. Because this cancer is detected late and prognosis is poor, the impact of this protection is very significant. Indeed, a decline in mortality from ovarian cancer has been observed in several countries since the early 1970s, perhaps an effect of oral contraceptive use.<sup>341</sup> Women with increased exposure to oral contraceptives have demonstrated a marked decrease in the incidence of ovarian cancer.<sup>342,343,344,345</sup> The risk of developing epithelial ovarian cancer of all histologic subtypes in users of oral contraception is reduced by **40%** compared with that of nonusers.<sup>335,337,346,347,348,349,350,351,352</sup> This protective effect increases with duration of use and continues for at least 20 years after stopping the medication.<sup>353</sup> This protection is seen in women who use oral contraception for 3 years or more, reaching an 80% reduction in risk with more than 10 years of use, and is a benefit associated with all monophasic formulations, including the low-dose products.<sup>350,351,352,354</sup> The protective effect of oral contraceptives is especially observed in women at high risk of ovarian cancer (nulliparous women and women with a positive family history).<sup>355,356</sup> Continuous use of oral contraception for 10 years by women with a positive family history for ovarian cancer can reduce the risk of epithelial ovarian cancer to a level equal to or less than that experienced by women with a negative family history.<sup>355</sup> Again, the multiphasic and new progestin products have not been in use long enough to yield any data on this issue, but because ovulation is effectively inhibited by these formulations, protection against ovarian cancer should be exerted. **The same magnitude of protection has been observed in women with BRCA1 or BRCA2 mutations.**<sup>357,358,359</sup>

# Cancer of the Cervix

Studies have indicated that the risk for dysplasia and carcinoma in situ of the uterine cervix increases with the use of oral contraception for more than 1 year.<sup>360,361,362,363,364,365</sup> Invasive cervical cancer may be increased after 5 years of use, reaching a twofold increase after 10 years. It is well recognized, however, that the number of partners a woman has had and age at first coitus are important risk factors for cervical neoplasia. Other confounding factors include exposure to human papillomavirus (HPV), receiving the human papillomavirus vaccine (protective), the use of barrier contraception (protective), and smoking.<sup>366</sup> It has been well-demonstrated that oral contraceptive users have more sexual partners, more HPV infections, and more Pap smears. These are difficult factors to control, and, therefore, the conclusions regarding cervical cancer are not definitive. An excellent study from the Centers for Disease Control and Prevention (CDC) concluded there is no increased risk of invasive cervical cancer in users of oral contraception, and an apparent increased risk of carcinoma in situ is due to enhanced detection of disease (because oral contraceptive users have more frequent Pap smears).<sup>363</sup> In the World Health Organization Study of Neoplasia and Steroid Contraceptives, a Pap smear screening bias was identified; nevertheless, the evidence still suggested an increased risk of cervical carcinoma in situ with long-term oral contraceptive use.<sup>364</sup> The UK Royal College of General Practitioners completed a study with 44 years of follow-up and noted that while in the first 5 years of oral contraceptive use there was an increase in detection of cervical cancer, the risk of cervical cancer balanced with nonusers over time.<sup>365</sup>

A case-control study of patients in Panama, Costa Rica, Colombia, and Mexico concluded that there was a significantly increased risk for invasive adenocarcinoma.<sup>367</sup> Similar results were obtained in a case-control study in Los Angeles and in the World Health Organization Collaborative Study.<sup>368,369</sup> In Los Angeles, the relative risk of adenocarcinoma of the cervix increased from 2.1 with ever use to 4.4 with 12 or more years of oral contraceptive use.<sup>368</sup> Oral contraceptives increase cervical ectopia, but whether this increases the risk of cervical adenocarcinoma is unclear.

A large meta-analysis concluded that the relative risk of cervical cancer increased with increasing duration of use (for in situ and invasive cancer and both squamous cancer and adenocarcinoma); however, the risk was confined to the cases who tested positively for HPV.<sup>370</sup> A pooled analysis of case-control studies concluded that the risk of cervical cancer in women with HPV increases about threefold but not until after 5 years of use.<sup>371</sup>

A meta-analysis of 24 epidemiologic studies included 16,573 women with cervical

cancer and 35,509 women without cervical cancer.<sup>372</sup> The risk of cervical cancer in situ and invasive cancer increased about twofold with increasing duration of use of oral contraceptives. After discontinuation of oral contraceptives, the risk steadily declined. There was no increase in risk with duration of use less than 5 years or after 10 or more years since last use. The same relationships were seen comparing women likely to have been screened and those likely not to have been screened. Although the numbers were smaller, women who were positive for HPV demonstrated the same pattern of risk. Additionally, a greater incidence of smoking in oral contraceptive users was noted.

We currently know three important facts about cervical cancer. (1) Cervical cancer is caused by HPV. (2) Cervical cancer is reduced in prevalence by Pap smear screening. (3) HPV vaccination can potentially eliminate most cases of cervical cancer. Oral contraceptive users have behavior patterns that place them at greater risk of HPV infections. In addition, oral contraceptives could increase the ability of HPV to establish itself in the cervix. Once infected with HPV, oral contraceptives could influence the response of a woman to HPV, for example, suppressing the immune response. Therefore, we don't know for certain whether case-control and cohort data reflect an enhancing effect of oral contraceptives on the risk of cervical cancer or whether the results are affected by the confounding problems of HPV infections and the prevalence of Pap smear screening.

These studies reinforce the HPV and Pap smear screening that we already support and provide another argument in favor of HPV vaccination. The liquid-based methods along with HPV DNA testing will provide even better identification of at-risk women. Fortunately, steroid contraception does not mask abnormal cervical changes, and the necessity for prescription renewals offers the opportunity for improved screening for cervical disease. **Pap smear guidelines from the American Society for Colposcopy and Cervical Pathology should be followed.** Oral contraceptive use is appropriate for women with a history of cervical intraepithelial neoplasia (CIN), including those who have been surgically treated.

# Liver Cancer

Oral contraception has been linked to the development of hepatocellular carcinoma.<sup>373,374</sup> However, the very small number of cases, and, thus, the limited statistical power, requires great caution in interpretation. The largest study on this question, the WHO Collaborative Study of Neoplasia and Steroid Contraceptives, found no association between oral contraception and liver cancer.<sup>375</sup> Even case-control analysis of oral contraceptives containing cyproterone acetate (known to be toxic to the liver in high doses) could detect no evidence of an increased risk of liver cancer.<sup>376</sup> In the United States, Japan, Sweden, England, and Wales, the death rates from liver cancer did not change despite introduction and use of oral contraception.<sup>377,378</sup> More recently, there has been an increase in liver cancer incidence and mortality in the United States, but this is believed to be due to infection with hepatitis C and hepatitis B.<sup>379</sup>

# Breast Cancer

Because of breast cancer's prevalence and its long latent phase, concern over the relationship between oral contraception and breast cancer continues to be an issue in the minds of both patients and clinicians. Risk of developing breast cancer with hormonal contraception in the general population and in BRCA gene mutation carriers is discussed in full in [Chapter 16](#). This subject has been studied extensively, and the results of the studies are not clear-cut. Some studies have indicated an overall increased relative risk of early, premenopausal breast cancer,<sup>380,381,382,383,384,385,386,387,388,389,390,391,392,393,394,395,396,397,398,399</sup> while others indicated no increase in overall risk.<sup>400,401,402</sup> The most impressive finding indicates a link in most studies,<sup>393,394,395,396,397,398,399,400,401,402</sup> but not all,<sup>403,404,405,406,407</sup> of early breast cancer before age 40 with women who used oral contraception for long durations of time. The evidence seems stronger for a relationship with time since last use, an elevated risk being significant for current users and in women who had stopped use 1–4 years before (recent use).

Overall, this massive statistical exercise yielded good news. No major adverse impact of oral contraceptives emerged. **Even though the data indicated that young women who begin use before age 20 have higher relative risks of breast cancer during current use and in the 5 years after stopping, this is a time period when breast cancer is very rare, and, thus, there would be little impact on the actual number of breast cancers.** The difference between localized disease and metastatic disease was statistically greater and should be observable. Thus, many years after stopping oral contraceptive use, the main effect may be protection against metastatic disease. Breast cancer is more common in older years, and 10 or more years after stopping, the risk was not increased.

What explanation could account for an increased risk associated only with current or recent use, no increase with duration of use, and a return to normal 10 years after exposure? The slightly increased risk could be influenced by detection/surveillance bias (more interaction with the health care system by oral contraceptive users). It is also possible that this situation is analogous to that of pregnancy. Studies indicate that pregnancy transiently increases the risk of breast cancer (for a period of several years) after a woman's first childbirth, and this is followed by a lifetime reduction in risk.<sup>408</sup> And some have found that a concurrent or recent pregnancy adversely affects survival.<sup>409,410</sup> It is argued that breast cells that have already begun malignant transformation are adversely affected by the hormones of pregnancy, while normal stem cells become more resistant because of a pregnancy. It is possible that early and recent use of oral contraceptives also affects the growth of a preexisting malignancy,

explaining the limitation of the finding to current and recent use and the increase in localized disease.

For women who are BRCA positive, the research results are similarly confusing. A case-control study concluded that BRCA1 mutation carriers had small increases in the risk of breast cancer in users for at least 5 years, in users before age 30, and in those who developed breast cancer before age 40.<sup>411</sup> In contrast, another case-control study concluded that oral contraceptive use for at least 5 years doubled the risk of breast cancer before age 50 in BRCA2 carriers, but not in BRCA1 carriers.<sup>412</sup> A retrospective analysis of an international cohort of BRCA carriers indicated that an increased risk of breast cancer with both BRCA1 and BRCA2 carriers was present only with 4 or more years of use before a first full-term pregnancy.<sup>413</sup> A study that focused on low-dose oral contraceptives could detect no association with breast cancer risk in BRCA mutation carriers.<sup>414</sup> Another case-control study found no increase in the risk of breast cancer diagnosed before age 40 in either BRCA1 or BRCA2 carriers.<sup>415</sup> And finally, a case-control study could detect no significant increase in the risk of contralateral breast cancer among BRCA1 and BRCA2 carriers or in noncarriers.<sup>416</sup> The data with oral contraceptives in BRCA mutation carriers (also discussed in [Chapter 16](#)) are all observational and not robust. **Until better information is forthcoming, it seems reasonable to inform carriers of BRCA mutations that the use of oral contraceptives is likely to reduce the risk of ovarian cancer, but the effect on breast cancer risk is uncertain.**

A team of epidemiologists from several institutions in the United States performed a case-control study of the association between oral contraceptive use and lobular and ductal breast cancer occurring in young women (under age 44) and found that use of oral contraceptives has no effect on breast cancer histologic subtype.<sup>416</sup>

Even if there is a small increase in premenopausal breast cancer associated with oral contraceptives, this would be a very small number of cases because most cases of breast cancer occur after age 40. Well-done and large case-control studies of modern low-dose oral contraceptives have been consistently negative and reassuring.

# Colorectal Cancer

The Nurses' Health Study reported about a 40% reduced risk of colorectal cancer associated with 8 years of previous use of oral contraceptives.<sup>417</sup> A meta-analysis of published studies concluded that there is an 18% reduction in risk of colorectal cancer in ever users of oral contraception, with a stronger effect in recent users.<sup>418</sup> Both case-control and cohort studies have reported reductions in the risk of colorectal cancer associated with the ever use of oral contraceptives.<sup>419,420,421</sup> **Steroid contraception should be offered to women with a strong family history of colorectal cancer.**

## Other Cancers

The major risk factor for melanoma is exposure to sunlight, but there are previous reports of an association with hormonal contraception use. More accurate evaluation utilizing both the Royal College General Practitioners and Oxford Family Planning Association prospective cohorts and accounting for exposure to sunlight did not indicate a significant difference in the risk of melanoma comparing users to nonusers.<sup>422,423,424</sup> There is no evidence linking oral contraceptive use to kidney cancer, gallbladder cancer, or pituitary tumors.<sup>425</sup> Long-term oral contraceptive use may slightly increase the risk of molar pregnancy.<sup>426,427,428</sup> A case-control study concluded that oral contraceptives reduce the risk of salivary gland cancer.<sup>429</sup>

# Summary: Oral Contraceptives and the Risk of Breast Cancer

- Current and recent use of oral contraceptives may be associated with a slightly increased risk of early premenopausal breast cancer. This finding may be due to detection/surveillance bias and accelerated growth of already-present malignancies, a situation similar to the effects of pregnancy and postmenopausal hormone therapy on the risk of breast cancer (as reviewed in [Chapter 18](#)).
- There is no effect of past use or duration of oral contraceptive use (up to 15 years of continuous use) on the risk of breast cancer, and there is no evidence indicating that higher-dose oral contraceptives increased the risk of breast cancer.
- Previous oral contraceptive use may be associated with a reduced risk of metastatic breast cancer later in life and possibly with a reduced risk of postmenopausal breast cancer.
- Oral contraceptive use does not further increase the risk of breast cancer in women with positive family histories of breast cancer or in women with proven benign breast disease.
- The clinician should not fail to take every opportunity to direct attention to all factors that affect breast cancer. Breast-feeding and control of alcohol intake are good examples and are also components of preventive health care. Especially important is this added motivation to encourage breast-feeding. The protective effect of breast-feeding is exerted (although it is probably a small one, see [Chapter 16](#)) mainly on premenopausal breast cancer, the cancer of concern to younger women using oral contraception.

# **ENDOCRINE EFFECTS**

---

# Adrenal Gland

Estrogen increases the cortisol-binding globulin (CBG). It had been thought that the increase in plasma cortisol while on oral contraception was due to increased binding by this globulin and not an increase in free active cortisol. Now it is apparent that free and active cortisol levels are also elevated, but only slightly.<sup>430</sup> Estrogen decreases the ability of the liver to metabolize cortisol, and in addition, progesterone and related compounds can displace cortisol from transcortin and thus contribute to the elevation of unbound cortisol. The effects of these elevated levels over prolonged periods of time are unknown, but no obvious impact has become apparent. To put this into perspective, the increase is not as great as that which occurs in pregnancy, and, in fact, it is within the normal range for nonpregnant women.

The adrenal gland responds to adrenocorticotrophic hormone (ACTH) normally in women on oral contraceptives; therefore, there is no suppression of the adrenal gland itself. Initial studies indicated that the response to metyrapone (an  $11\beta$ -hydroxylase blocker) was abnormal, suggesting that the pituitary was suppressed. However, estrogen accelerates the conjugation of metyrapone by the liver, and, therefore, the drug has less effect, thus explaining the subnormal responses initially reported. The pituitary-adrenal reaction to stress is normal in women on oral contraceptive pills.

# Thyroid

Estrogen increases the synthesis and circulating levels of thyroxine-binding globulin. Prior to the introduction of methods for measuring free thyroxine levels, evaluation of thyroid function was a problem. Measurement of TSH (thyroid-stimulating hormone) and the free thyroxine level in a woman on oral contraception provide an accurate assessment of a patient's thyroid state. Oral contraception affects the total thyroxine level in the blood as well as the amount of binding globulin, but the free thyroxine level is unchanged.<sup>430</sup>

# **ORAL                      CONTRACEPTION                      AND REPRODUCTION**

---

The impact of oral contraceptives on the reproductive system is less than initially thought. Early studies that indicated adverse effects have not stood the test of time and the scrutiny of multiple, careful studies. There are two major areas that warrant review: (1) inadvertent use of oral contraceptives during the cycle of conception and during early pregnancy and (2) reproduction after discontinuing oral contraception.

# Inadvertent Use During the Cycle of Conception and During Early Pregnancy

One of the reasons, if not the major reason, why a lack of withdrawal bleeding while using oral contraceptives is such a problem is the anxiety produced in both patient and clinician. The patient is anxious because of the uncertainty regarding pregnancy, and the clinician is anxious because of the concerns stemming from the retrospective studies that indicated an increased risk of congenital malformations among the offspring of women who were pregnant and using oral contraception. Organogenesis does not occur in the first 2 embryonic weeks (first 4 weeks since last menstrual period); however, teratogenic effects are possible between the 3rd and 8th embryonic weeks (5–10 weeks since the last menstrual period).

Initial positive reports linking the use of contraceptive steroids to congenital malformations have not been substantiated. Many suspect a strong component of recall bias in the few positive studies due to a tendency of patients with malformed infants to recall details better than those with normal children. Other confounding problems have included a failure to consider the reasons for the administration of hormones (e.g., bleeding in an already abnormal pregnancy) and a failure to delineate the exact timing of the treatment (e.g., treatment was sometimes confined to a period of time during which the heart could not have been affected).

An association with cardiac anomalies was first claimed in the 1970s.<sup>431,432</sup> This link received considerable support with a report from the U.S. Collaborative Perinatal Project; however, subsequent analysis of these data uncovered several methodologic shortcomings.<sup>433</sup> A very thorough and critical review concluded that there was no reliable evidence implicating sex steroids as cardiac teratogens.<sup>434</sup> In fact, no relationship was found between oral contraception and the following problems: hypospadias, limb reduction anomalies, neural tube defects, and mutagenic effects that would be responsible for chromosomally abnormal fetuses. Even virilization is not a practical consideration because the doses required (e.g., 20–40 mg norethindrone per day) are in excess of anything currently used. These conclusions reflect the use of combined oral contraceptives as well as progestins alone.

In the past, there was a concern regarding the VACTERL complex. VACTERL refers to a complex of vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies. While case-control studies indicated a relationship with oral contraception, prospective studies have failed to observe any connection between sex steroids and the VACTERL complex.<sup>435</sup> Meta-analyses of the studies of the risk of birth defects with oral contraceptive ingestion during pregnancy concluded that there was no increase in risk for major malformations, congenital heart defects, or limb reduction defects.<sup>436,437</sup>

Women who become pregnant while taking oral contraceptives or women who inadvertently take birth control pills early in pregnancy should be advised that the risk of a significant congenital anomaly is no greater than the general rate of 2–3%. This recommendation can be extended to those pregnant women who have been exposed to a progestational agent such as medroxyprogesterone acetate or 17-hydroxyprogesterone caproate.<sup>438,439</sup>

# Reproduction After Discontinuing Oral Contraception

## Fertility

There may be a mild delay in return to fertility after taking hormonal contraceptives. Initial analysis indicated that a delay was concentrated in women aged 30–34 who had never given birth.<sup>440</sup> At 48 months, 82% of these women had given birth compared with a similar 89% of users of other contraceptive methods. No effect was observed in women younger than 30 or in women who had previously given birth. Childless women aged 25–29 experienced some delay in return to fertility, but by 48 months, 91% had given birth compared with 92% in users of other methods.

This delay was observed in the United States as well. In the Boston area, the interval from cessation of contraception to conception was 13 months or greater for 24.8% of prior oral contraceptive users compared with 10.6% for former users of all other methods (12.4% for intrauterine device, IUD, users, 8.5% for diaphragm uses, and 11.9% for other methods).<sup>441</sup> Oral contraceptive users had a lower monthly percentage of conceptions for the first 3 months and somewhat lower percentage from 4 to 10 months. It took 24 months for 90% of previous oral contraceptive users to become pregnant, 14 months for IUD users, and 10 months for diaphragm users. Similar findings in Connecticut indicated that this delay lasted at least a year, and the effect was greater with higher-dose preparations.<sup>442</sup> Despite the possibility of a delay, there is no evidence that infertility is increased by the use of oral contraception. In fact, in young women, previous oral contraceptive use is associated with a lower risk of primary infertility.<sup>443</sup> Furthermore, the studies indicating a delay in conception are influenced by older, higher-dose products. In a prospective study from the United Kingdom reflecting modern, low-dose oral contraceptives, no delay to conception was found, and long-term use was actually associated with greater fertility.<sup>444</sup> The European Active Surveillance Study on Oral Contraceptives was a prospective cohort study of 59,510 users of low-dose oral contraception. The early and 1-year pregnancy rates after discontinuation of oral contraceptives were not negatively affected, regardless of progestin type, duration of use, or parity.<sup>445</sup> After 2 years, the pregnancy rate was 88.3% and the average time to pregnancy was 5.5 cycles. The previous reports indicating a delay in achieving pregnancy may have been influenced not only by higher-dose products but also by a failure to account for declining fertility with aging and the prescribing of oral contraceptives to women with anovulatory, irregular menstrual periods. **It is unlikely that women discontinuing low-dose steroid contraception experience any significant delay in achieving pregnancy compared with the experience in a general**

**population.**

# Spontaneous Miscarriage

There is no increase in the incidence of spontaneous miscarriage in pregnancies after the cessation of oral contraception. Indeed, the rate of spontaneous miscarriages and stillbirths is slightly less in former pill users, about 1% less for spontaneous miscarriages and 0.3% less for stillbirths.<sup>446</sup> A protective effect of previous oral contraceptive use against spontaneous miscarriage has been observed to be more apparent in women who become pregnant after age 30.<sup>447</sup>

# Pregnancy Outcome

There is no evidence that oral contraceptives cause changes in germ cells that would yield an abnormal child at a later time.<sup>436</sup> There is no increase in the number of abnormal children born to former oral contraceptive users, and there is no change in the sex ratio (a sign of sex-linked recessive mutations).<sup>446,448</sup> These observations are not altered when analyzed for duration of use. Initial observations that women who had previously used oral contraception had an increase in chromosomally abnormal fetuses have not been confirmed. Furthermore, as noted above, there is no increase in the miscarriage rate after discontinuation, something one would expect if oral contraceptives induce chromosomal abnormalities because these are the principal cause of spontaneous miscarriage.

In a 3-year follow-up of children whose mothers used oral contraceptives prior to conception, no differences could be detected in weight, anemia, intelligence, or development.<sup>449</sup> Former pill users have no increased risks for the following: perinatal morbidity or mortality, prematurity, and low birth weight.<sup>450,451</sup> Dizygous twinning has been observed to be nearly twofold (1.6% vs. 1.0%), increased in women who conceive soon after cessation of oral contraception.<sup>446</sup> This effect was greater with longer duration of use.

The only reason (and it is a good one) to recommend that women defer attempts to conceive for a month or two after stopping the pill is to improve the accuracy of gestational dating by allowing accurate identification of the last menstrual period.

# INITIATION OF ORAL CONTRACEPTION IN THE POSTPARTUM PERIOD

---

The 6-week postpartum visit is an anachronism. It is rooted in old texts and teachings from a time when infection was prevalent and before modern methods of contraception were available. The 6-week visit and pelvic examination were based on the understanding that a 6-week period of time would result in sufficient involution of the changes of pregnancy to allow an effective examination that would establish the return of normal pelvic anatomy. These concepts are antiquated. Many women resume sexual activity before the 6th postpartum week, and because ovulation frequently returns before 6 weeks, the obstetrical tradition of scheduling the postpartum visit at 6 weeks should be changed. A 3-week visit would be more effective in avoiding postpartum surprises, preventing postpartum conception by earlier initiation of effective contraception. There is no reason why a complete physical examination cannot be deferred in an asymptomatic woman until the 3-month follow-up visit that is part of good contraceptive care.

# Postpartum Return of Ovulation in Non–Breast-Feeding Women

In non–breast-feeding women, gonadotropin levels remain low during the early puerperium and return to normal concentrations during the 3rd to 5th week when prolactin levels have returned to baseline. In a careful study of 22 women, not one woman ovulated before 25 days after delivery, but 11 ovulated before the 6th postpartum week.<sup>452,453</sup> In addition, two-thirds of the women ovulated before their first menses. **Non–breast-feeding women, therefore, begin to ovulate after 3 postpartum weeks, and the return of menses cannot be used as an indicator.**

# The Contraceptive Effect of Lactation

In primitive human societies, the duration of the birth interval was very important for the survival of the young. Throughout human history, no preliterate society achieved a fertility rate at the maximal level possible. The hunter-gatherer, nomadic Kung women had a high suckling frequency and gave birth about every 4 years.<sup>454</sup> Lactational amenorrhea, lasting up to 2 years, has been nature's most effective form of contraception.<sup>455</sup> Indeed, lactation is the mechanism that maintains a reasonable interval between pregnancies in all nonseasonally breeding animals. In Africa and Asia, breast-feeding reduces the fertility rate by an average of about 30%.<sup>456</sup> Birth intervals of less than 2 years are associated with a greater incidence of low birth weight, preterm birth, and neonatal death for the new infant and malnutrition, infection, and increased 2nd-year mortality for the previous child.<sup>457</sup>

The contraceptive effectiveness of lactation, that is, the length of the interval between births, depends on the level of nutrition of the mother, the intensity of suckling, and the extent to which supplemental food is added to the infant diet. Well-nourished and undernourished women resume ovulating at the same time postpartum.<sup>458</sup>

Amenorrheic women who exclusively breast-feed (full breast-feeding) at regular intervals, including nighttime, during the first 6 months postpartum have the contraceptive protection equivalent to that provided by oral contraception (98% efficacy), but with menstruation or after 6 months, the chance of ovulation increases.<sup>453,459</sup> With full or nearly full breast-feeding, approximately 70% of women remain amenorrheic through 6 months and only 37% through 1 year; nevertheless, with exclusive breast-feeding, the contraceptive efficacy at 1 year is high, about 92%.<sup>460</sup> Fully breast-feeding women commonly have some vaginal bleeding or spotting in the first 8 postpartum weeks, but this bleeding is not due to ovulation.<sup>461</sup> Half of women studied who are not fully breast-feeding ovulate before the 6th week. Lactation, therefore, provides a contraceptive effect, but it is variable and not reliable for every woman.

Prolactin concentrations are increased in response to the repeated suckling stimulus of breast-feeding. Given sufficient intensity and frequency, prolactin levels will remain elevated. Under these conditions, FSH concentrations are in the low-normal range (having risen from extremely low concentrations at delivery to follicular range in the 3 weeks postpartum), and LH values are also in the low-normal range. These low levels of gonadotropins do not allow the ovary during lactational hyperprolactinemia to display follicular development and secrete estrogen. Therefore, vaginal dryness and dyspareunia are commonly reported by breast-feeding women. **The use of vaginal estrogen preparations is discouraged because absorption of the estrogen can lead**

**to inhibition of milk production. Vaginal lubricants should be used until ovarian function and estrogen production return.**

# The Return of Ovulation in Breast-Feeding Women

The return of ovulation in breast-feeding women has been documented in women from all parts of the world. In Chile, 14% of women ovulated during full breast-feeding, although full nursing provided effective contraception up to 3 months postpartum.<sup>461,462</sup> It has been argued that the threshold for suppression of ovulation is at least five feedings for a total of at least 65 min/day suckling duration.<sup>463</sup> However, in the studies from Chile, the frequency of nursing was the same in breast-feeders who ovulated and those who did not.

In Mexico, a study of 29 breast-feeding mothers and 10 non-breast-feeders observed that in the absence of bleeding and supplementary feedings, 100% of the breast-feeders remained anovulatory for 3 months postpartum and 96% up to 6 months.<sup>464</sup> The median time from delivery to first ovulation was 259 days for breast-feeders compared to 119 days for non-breast-feeders. However, by the 3rd postpartum month, 18% of the breast-feeders had ovulated.

In a well-nourished population in Australia, less than 20% of breast-feeding women ovulated by the 6th postpartum month, and less than 25% menstruated.<sup>465</sup> Neither time of first supplement nor the amount of supplement predicted the return of ovulation or menstruation. In other words, even in women giving their infants supplemental feedings, there is effective inhibition of ovulation during the first 6 months of breast-feeding.

# THE POSTPARTUM RISK OF PREGNANCY

---

All too often, writers have emphasized that many couples do not resume sexual intercourse before the 6th postpartum week. What should be emphasized is that longitudinal surveys indicate that impressive numbers do. In England, about one-third of primiparous women resumed intercourse by 6 weeks, and nearly everyone by 3 months.<sup>466</sup> A random survey of all women who delivered in the Grampian region of Scotland in 1990–1991 revealed that 71% had experienced intercourse by 8 weeks postpartum, most by 5 weeks.<sup>467</sup> In another longitudinal follow-up study, nearly 60% of women had resumed intercourse **within** 6 weeks after birth.<sup>468</sup> In North Carolina, 57% of women resumed intercourse by the 6th postpartum week.<sup>469</sup> In Thailand, 35% of women reported resumption of sexual activity before the 6th postpartum week, and no differences were noted comparing vaginal or cesarean deliveries or with and without episiotomies.<sup>470</sup> Breast-feeding in a Canadian study was found to be associated with earlier, not later, resumption of intercourse.<sup>471</sup> In an English study, 166 of 328 women had resumed sexual intercourse, most before the 6th postpartum week, and only 55 of the 166 sexually active women recalled medical and nursing advice regarding resumption of sexual activity.<sup>472</sup> In Nigeria, 32% of breast-feeding mothers resumed sexual activity by 6 weeks postpartum, but only 5% began a method of contraception.<sup>473</sup>

In Australia among women who have unprotected intercourse during lactation amenorrhea and use contraception when menses resume, 1.7% become pregnant in the first 6 months of breast-feeding, 7% after 12 months, and 13% after 24 months.<sup>474</sup> In a study of 422 middle-class women in Santiago, Chile, there was only one pregnancy (in month 6) when lactational amenorrhea was consciously relied upon for contraception.<sup>475</sup> This was equal to a cumulative 6-month life-table pregnancy rate of 0.45%. However, this accomplishment required an extensive program of education and support. In this study, 9% of exclusively breast-feeding women had resumption of menses by the end of 3 months and 19% by the end of 6 months. This increased suppression of fertility undoubtedly reflected the intensity of the breast-feeding program and the motivation of the participants. In Chile, the probability of pregnancy in breast-feeding women who are amenorrheic was reported as 0.9% at 6 months and 17% at 112 months, and in menstruating women, 36% at 6 months and 55% at 12 months.<sup>476</sup> In Pakistan, women who deliberately chose lactational amenorrhea as a method of contraception experienced a pregnancy rate of only 1.1% at 12 months if they remained amenorrheic.<sup>477</sup>

An international group of researchers in the area of lactational infertility reached the following consensus in 1989, called the Bellagio Consensus (after the site of the

conference at Bellagio, Italy)<sup>478</sup>:

**The maximum birth spacing effect of breast-feeding is achieved when a mother “fully” or nearly fully breast-feeds and remains amenorrheic. When these two conditions are fulfilled, breast-feeding provides more than 98% protection from pregnancy in the first 6 months.**

Full breast-feeding means that the infant’s total suckling stimulus is directed to the mother. There is no diminution of suckling by supplementation or the use of a pacifier. The Bellagio degree of protection in the first 6 months of full or nearly full breast-feeding has been confirmed in clinical studies.<sup>459,479</sup>

The World Health Organization conducted a large prospective study examining the relationship between infant feeding and amenorrhea, as well as the rate of pregnancy during lactational amenorrhea.<sup>480,481,482,483</sup> Women who were still breast-feeding and remained amenorrheic had pregnancy rates of 0.8% at 6 months and 4.4% at 12 months, again confirming the Bellagio Consensus.

The duration of postpartum lochia is variable and can make it difficult to detect the onset of menstrual bleeding. In the World Health Organization study, postpartum lochia was present from a minimum of 2 days to a maximum of 90 days, with an average duration of 27 days.<sup>483</sup> Most women with lactational amenorrhea will not experience true menstrual bleeding before postpartum day 56 (8 weeks). Breast-feeding frequency has no effect on the duration of postpartum lochia.

**Therefore, only amenorrheic women who exclusively breast-feed at regular intervals, including nighttime, during the first 6 months have the contraceptive protection equivalent to that provided by oral contraception; with menstruation or after 6 months postpartum, the risk of ovulation increases.<sup>453,460,484</sup> Supplemental feeding increases the risk of ovulation (and pregnancy) even in amenorrheic women.<sup>476</sup> Total protection against pregnancy is achieved by the exclusively breast-feeding woman for a duration of only 10 weeks.<sup>460</sup>**

Women skilled in the cervical mucus method can detect evidence of fertile-type mucus prior to the first menses in the postpartum period. However, there are many false-positive and false-negative interpretations.<sup>485</sup> This method cannot be used with a great deal of confidence until regular menses are resumed.

# POSTPARTUM CONTRACEPTION

---

A recent pregnancy and a new infant provide strong motivation for the mother to consider contraception. In non–breast-feeding women, ovulation can occur during the 4th postpartum week. We urge clinicians and patients to start a new tradition: schedule the first postpartum visit during the **3rd week after delivery**. Even breast-feeding women should be evaluated at this time, to consider whether breast-feeding is full and exclusive or whether an additional contraceptive method is necessary.

Additional contraception is necessary during lactation for most women. That is not to say that full breast-feeding should not be encouraged and that the protection obtained in the first 6 months of breast-feeding shouldn't be emphasized. But after 3 months, the first ovulation can precede the first menstrual bleed. Half of women studied who are not fully breast-feeding ovulate before the 6th week, the time of the traditional postpartum visit; a visit during the 3rd postpartum week for both breast-feeding and non–breast-feeding mothers is strongly recommended for contraceptive counseling.

**In the presence of FULL breast-feeding, a contraceptive method should be used beginning in the 3rd postpartum month.**

**With PARTIAL breast-feeding or NO breast-feeding, a contraceptive method should begin during the 3rd postpartum week.**

**After the spontaneous or elective termination of a pregnancy of less than 12 weeks, steroid contraception can be started immediately. After a pregnancy of 12 or more weeks, the 3rd-postpartum-week rule should be followed if the pregnancy is term or near term to avoid the postpartum risk of venous thromboembolism (discussed later).**

The suppression of prolactin secretion with a dopamine agonist (e.g., bromocriptine), not surprisingly, is associated with the return of gonadotropin secretion in the 2nd postpartum week and an earlier return to ovulation and menses.<sup>486</sup> In women who receive dopamine agonist treatment at or immediately after delivery, contraception is required a week earlier, in the 2nd week postpartum.<sup>487</sup>

Oral contraception even in low-dose formulations has been demonstrated to diminish the quantity and quality of lactation in postpartum women. Although there has been concern regarding the potential hazard of transfer of contraceptive steroids to the infant (a significant amount of the progestational component is secreted into breast milk),<sup>488,489</sup> no adverse effects have thus far been identified. Because iron is an important factor in the bacteriostatic activity of breast milk, it is good to know that iron and copper concentrations in breast milk are not affected by the use of oral contraceptives.<sup>490</sup>

Women who use oral contraception have a lower incidence of breast-feeding after the 6th postpartum month, regardless of whether oral contraception is started at the first, second, or third postpartum month.<sup>491,492,493</sup> In adequately nourished women, no impairment of infant growth and development can be detected; presumably, compensation is achieved through either supplementary feedings or increased suckling.<sup>494,495,496</sup> In an 8-year follow-up study of children breast-fed by mothers using oral contraceptives, no effect could be detected on diseases, intelligence, or psychological behavior.<sup>497</sup> This study also found that mothers on oral contraceptives lactated a significantly shorter period of time than controls, a mean of 3.7 months versus 4.6 months in controls.

Because of the concern regarding the impact of oral contraceptives on breast-feeding, a useful alternative is to combine the contraceptive effect of lactation with the progestin-only minipill; there is no evidence for any adverse effect on breast-feeding as measured by milk volume and infant growth and development.<sup>494,495,496</sup>

In contrast to the combined oral contraceptive, the progestin-only minipill even provides a modest boost to milk production, and women using the minipill breast-feed longer and add supplementary feeding at a later time.<sup>494,498,499</sup> The combination of lactation and the progestin-only minipill is associated with near-total contraceptive efficacy. In addition, the minipill can protect against the bone loss associated with lactation, a potential advantage in undernourished women.<sup>500</sup> Because of the slight positive impact on lactation, the minipill can be started immediately after delivery.<sup>501</sup> Progestins alone do not increase the risk of venous thrombosis.<sup>502,503</sup>

# The Risk of Postpartum Venous Thromboembolism

Although venous thromboembolism is a rare event, the potential for a catastrophic consequence makes this an important consideration. In the past, the risk of venous thromboembolism was believed to be concentrated in the postpartum period. It is now apparent that the postpartum incidence of this problem has decreased and antepartum diagnosis is now more common. Undoubtedly a contributing factor to this change is the now common practice of early ambulation after delivery. Over a 30-year period in Minnesota, the incidence of antepartum venous thromboembolism remained constant, but postpartum cases decreased more than twofold; nevertheless, the number of cases was still 5 times higher among postpartum women compared with pregnant women.<sup>504</sup> In a large American surveillance study, half of the events occurred during pregnancy and half postpartum.<sup>505</sup> In Spain, however, cases were slightly more frequent during pregnancy compared with the postpartum period.<sup>506</sup> In a large multicenter American registry, there were almost twice as many antepartum cases than postpartum cases.<sup>507</sup>

In Sweden over a 10-year period, the venous thromboembolism mortality rate was similar comparing pregnancy with oral contraceptive users; the incidence rate was about 9 cases per 1,000,000 women-years.<sup>508,509</sup> Most cases of venous thromboembolism occur in individuals with well-recognized risk factors, including older age, obesity, severe varicose veins, cancer, fractures, surgery, and inflammatory bowel disease.<sup>510</sup> Pregnancy and combined estrogen-progestin contraception must be added to this list.

The increase of venous thromboembolism begins shortly after conception, is maintained throughout pregnancy and the first week postpartum, and then gradually declines, reaching baseline levels about 4–6 weeks postpartum.<sup>504</sup> Venous thromboembolism more than 6 weeks postpartum is very uncommon. To minimize the risk of postpartum venous thromboembolism, good contraceptive practice has for decades emphasized the avoidance of exposure to pharmacologic levels of estrogen immediately after delivery. **Therefore, we recommend that non-breast-feeding mothers use a progestin-only contraceptive method beginning in the 3rd postpartum week; a change to a combination estrogen-progestin method can be initiated in the 7th postpartum week. This recommendation also applies to the vaginal and transdermal methods of estrogen-progestin contraception.**

# **OTHER CONSIDERATIONS**

---

# Prolactin-Secreting Adenomas

Because estrogen is known to stimulate prolactin secretion and to cause hypertrophy of the pituitary lactotrophs, it is appropriate to be concerned over a possible relationship between oral contraception and prolactin-secreting adenomas. Case-control studies have uniformly concluded that no such relationship exists.<sup>511,512</sup> Data from both the Royal College of General Practitioners and the Oxford Family Planning Association studies indicated no increase in the incidence of pituitary adenomas.<sup>513</sup> Previous use of oral contraceptives is not related to the size of prolactinomas at presentation and diagnosis.<sup>513,514</sup> Oral contraception can be prescribed to patients with pituitary microadenomas without fear of subsequent tumor growth.<sup>515,516</sup> **We have routinely prescribed oral contraception to patients with pituitary microadenomas and have never observed evidence of tumor growth.**

## Postpill Amenorrhea

The approximate incidence of “postpill amenorrhea” is 0.7–0.8%, which is equal to the incidence of spontaneous secondary amenorrhea,<sup>451,517,518</sup> and there is no evidence to support the idea that oral contraception causes secondary amenorrhea. If a cause-and-effect relationship exists between oral contraception and subsequent amenorrhea, one would expect the incidence of infertility to be increased after a given population discontinues the use of oral contraception. In those women who discontinue oral contraception in order to get pregnant, 50% conceive by 3 months, and after 2 years, a maximum of 15% of nulliparous women and 7% of parous women fail to conceive,<sup>451</sup> rates comparable with those quoted for the prevalence of spontaneous infertility. Attempts to document a cause-and-effect relationship between oral contraceptive use and secondary amenorrhea have failed.<sup>519</sup> Although patients with this problem come more quickly to our attention because of previous oral contraceptive use and follow-up, there is no cause-and-effect relationship. Women who have not resumed menstrual function within 12 months should be evaluated as any other patient with secondary amenorrhea.

## Use During Puberty

Should oral contraception be advised for a young woman with irregular menses and oligo-ovulation or anovulation? The fear of subsequent infertility should not be a deterrent to providing appropriate contraception. Women who have irregular menstrual periods are more likely to develop secondary amenorrhea whether they use oral contraception or not. The possibility of subsequent secondary amenorrhea is less of a risk and a less urgent problem for a young woman than leaving her unprotected. The need for contraception takes precedence.

There is no evidence that the use of oral contraceptives in the pubertal, sexually active girl impairs growth and development of the reproductive system.<sup>443</sup> Again, the most important concern is and should be the prevention of an unwanted pregnancy. For most teenagers, oral contraception, dispensed in a 28-day package for better compliance, is the contraceptive method of choice. However, even better continuation can be achieved with the vaginal and transdermal methods of estrogen-progestin contraception.

# Eye and Ear Diseases

In the 1960s and 1970s, there were numerous anecdotal reports of eye disorders in women using oral contraception. An analysis of the two large British cohort studies (the Royal College of General Practitioners' study and the Oxford Family Planning Association Study) could find no increase in risk for the following conditions: conjunctivitis, keratitis, iritis, lacrimal disease, strabismus, cataract, glaucoma, and retinal detachment.<sup>520</sup> Retinal vascular lesions were slightly more common in recent users of oral contraception, but this finding did not reach statistical significance. Contact lens may be less well tolerated, requiring more frequent use of wetting solutions.

The Oxford Family Planning Association Study could detect no evidence of any adverse effects of oral contraception on ear disorders.<sup>521</sup>

# Multiple Sclerosis

There is no evidence in third cohort studies (the Royal College of General Practitioners' study, the Oxford Family Planning Association Study, and the Nurses' Health Study) that there is any effect of oral contraceptive use on the risk or course of multiple sclerosis.<sup>522,523,524</sup> A case-control study suggested that recent users of oral contraceptives had a substantial reduction in the incidence of multiple sclerosis, perhaps delaying the onset of the disease.<sup>525</sup> A small (seven women on oral contraceptives) prospective study indicated that symptoms increased during the pill-free interval.<sup>526</sup> Patients with multiple sclerosis should consider using the regimen of daily, continuous administration.

# **INFECTIONS AND ORAL CONTRACEPTION**

---

# Viral Sexually Transmitted Infections

The viral sexually transmitted infections (STIs) include human immunodeficiency virus (HIV), human papillomavirus (HPV), herpes simplex virus (HSV), and hepatitis B virus (HBV). At the present time, no known associations exist between oral contraception and the viral STIs. Of course, significant prevention includes barrier methods of contraception.

Thus far, most studies have found no association between oral contraceptive use and HIV seropositivity, and some have indicated a protective effect.<sup>527,528,529</sup> Steroid contraception used by HIV-positive women does not affect the progress of the disease.<sup>530,531</sup>

Antiretroviral drugs may decrease oral contraceptive efficacy by affecting drug metabolism or causing diarrhea and vomiting. Treatment usually consists of a combination of three or four drugs, and the available studies often reflect drugs and doses not currently used. Therefore, the degree of clinical impact on hormonal contraception, if any, is not well studied.<sup>532</sup> Nevertheless, the studies suggest that some of the antiretroviral drugs are associated with a decrease in steroid levels during oral contraceptive use.

**A dual approach is recommended, combining the contraceptive efficacy and protection against PID offered by steroid contraception with the use of a barrier method for prevention of viral STIs and added contraception.**

# Bacterial STIs

STIs are one of the most common public health problems in the United States. Pelvic inflammatory disease (PID) is usually a consequence of STIs. The best estimate of subsequent tubal infertility is derived from an excellent Swedish report: approximately 12% after one episode of PID, 23% after two episodes, and 54% after three episodes.<sup>533</sup> Because pelvic infection is the single greatest threat to the reproductive future of a young woman, the now recognized protection offered by oral contraception against PID is highly important.<sup>534,535,536</sup> **The risk of hospitalization for PID is reduced by approximately 50–60%, but at least 12 months of use is necessary, and the protection is limited to current users.**<sup>534,537</sup> Furthermore, if a patient does get a pelvic infection, the severity of the salpingitis found at laparoscopy is decreased.<sup>538,539</sup> The mechanism of this protection remains unknown. Speculation includes thickening of the cervical mucus to prevent movement of pathogens and bacteria-laden sperm into the uterus and tubes and decreased menstrual bleeding, reducing movement of pathogens into the tubes, as well as a reduction in “culture medium.” This protection probably accounts for the greater fertility rate observed in previous users of oral contraception.<sup>443,444</sup>

The argument has been made that this protection is limited to gonococcal disease, and chlamydial infections may even be enhanced. Most published studies have reported a positive association of oral contraceptives with lower genital tract chlamydial cervicitis.<sup>540,541</sup> Because lower genital tract infections caused by chlamydia are on the rise (now the most prevalent bacterial STI in the United States) and the rate of hospitalization for PID is also increased, it is worthwhile for both patients and clinicians to be alert for symptoms of cervicitis or salpingitis in women on oral contraception who are at high risk of STIs (multiple sexual partners, a history of STI, or cervical discharge). The mechanism for the association between chlamydial cervicitis and oral contraceptives may be the well-recognized extension of the columnar epithelium from the endocervix out over the cervix (ectopia) that occurs with oral contraceptive use.<sup>542</sup> This ectropion may allow a more effective collection of cervical specimens for culture, thus introducing detection bias into the epidemiologic studies.

Despite this potential relationship between oral contraception and chlamydial infections, it should be emphasized that there is no evidence for an impact of oral contraceptives increasing the incidence of tubal infertility.<sup>543</sup> In fact, case-control studies indicated that oral contraceptive users with chlamydia infection are protected against symptomatic PID.<sup>544,545</sup> A case-control study suggested that oral contraceptive users are more likely to harbor unrecognized endometritis and that this would explain the discrepancy between the observed rates between lower and upper tract infection.<sup>546</sup>

However, this would not explain the lack of an association between oral contraceptive use and tubal infertility. Thus, the influence of oral contraception on the upper reproductive tract may be different than on the lower tract. These observations on fertility are derived mostly, if not totally, from women using oral contraceptives containing 50 µg of estrogen. The continued progestin dominance of the lower-dose formulations, however, should produce the same protective impact. Early evidence indicated protection with low-dose oral contraceptives, but a later study failed to find a reduction in upper genital tract disease associated with oral contraceptives or barrier methods.<sup>537,547</sup>

## Other Infections

In the British prospective studies of high-dose oral contraceptives, urinary tract infections were increased in users of oral contraception by 20%, and a correlation was noted with estrogen dose. An increased incidence of cervicitis was also reported, an effect related to the progestin dose. The incidence of cervicitis increased with the length of time the pill was used, from no higher after 6 months to 3 times higher by the 6th year of use. A significant increase in a variety of viral diseases, for example, chickenpox, was observed, suggesting steroid effects on the immune system. The prevalence of these effects with low-dose oral contraception is unknown.

Oral contraception appears to protect against bacterial vaginosis and infections with *Trichomonas*.<sup>548,549,550,551</sup> Evidence is lacking to convincingly implicate oral contraception with vaginal infections with *Candida* species<sup>548</sup>; however, clinical experience is sometimes impressive when recurrence and cure repeatedly follow use and discontinuation of oral contraception.

Vaginal flora are not affected by the presence of vaginal ring contraception.<sup>552,553</sup> Despite no change in inflammatory vaginal flora, one well-done study reported that ring users have slightly more vaginal wetness (not sufficient to cause discontinuation), perhaps due to an increase in lactobacilli.<sup>554</sup>

# **PATIENT MANAGEMENT**

---

# Absolute Contraindications to the Use of Oral Contraception

1. Thrombophlebitis, thromboembolic disorders (including a close family history, parent or sibling, suggestive of an inherited susceptibility for venous thrombosis), cerebral vascular disease, coronary occlusion, or a past history of these conditions, or conditions predisposing to these problems.
2. Markedly impaired liver function or liver cancer. Steroid hormones are contraindicated in patients with hepatitis until liver function tests return to normal.
3. History of coronary heart disease or cerebrovascular disease.
4. Migraine headaches with aura.
5. Diabetes mellitus with vascular disease.
6. Known or suspected breast cancer.
7. Undiagnosed abnormal vaginal bleeding.
8. Known or suspected pregnancy.
9. Smokers over the age of 35.
10. Severe hypercholesterolemia or hypertriglyceridemia.
11. Uncontrolled hypertension.
12. Breast-feeding and less than 21 days postpartum.
13. Surgery with prolonged nonmobility.
14. History of peripartum cardiomyopathy.

# **Relative Contraindications Requiring Clinical Judgment and Informed Consent**

1. Migraine headaches without aura
2. Controlled hypertension
3. Gestational diabetes
4. Diabetes mellitus
5. Seizure disorders
6. Obstructive jaundice in pregnancy
7. Sickle cell disease or sickle C disease
8. Gallbladder disease
9. Mitral valve prolapse
10. Systemic lupus erythematosus
11. Hyperlipidemia
12. Smoking younger than 35
13. Hepatic disease

# CLINICAL DECISIONS

---

# Surveillance

Many women can be prescribed hormonal contraception without a clinical breast and pelvic examination.<sup>555</sup> Problems requiring further evaluation can be identified with a careful medical history and measurement of blood pressure. Subsequently, in view of the increased safety of low-dose preparations for healthy young women with no risk factors, patients need be seen only every 12 months for exclusion of problems by history, measurement of the blood pressure, urinalysis, breast examination, palpation of the liver, and pelvic examination with Pap smear if indicated. Women with risk factors should be seen every 6 months by appropriately trained personnel for screening of problems by history and blood pressure measurement. Breast and pelvic examinations are necessary only yearly. It is worth emphasizing that better continuation is achieved by reassessing new users within 1–2 months. It is at this time that subtle fears and unvoiced concerns need to be confronted and resolved.

Oral contraception is safer than most people think it is, and the low-dose preparations are extremely safe. Health care providers should make a significant effort to get this message to our patients (and our colleagues). We must make sure our patients receive adequate counseling, either from ourselves or from our professional staff. The major reason why patients discontinue oral contraception is fear of side effects.<sup>556</sup> Let's take time to put the risks into proper perspective and to emphasize the benefits as well as the risks.

Laboratory surveillance should be used only when indicated. Routine biochemical measurements fail to yield sufficient information to warrant the expense. Assessing the cholesterol-lipoprotein profile and carbohydrate metabolism should follow the same guidelines applied to all patients, users and nonusers of contraception. The following is a useful guide as to who should be monitored with blood screening tests for glucose, lipids, and lipoproteins:

Women 35 years or older—then every 3 years if screening tests are normal

Women with a strong family history of heart disease, diabetes mellitus, or hypertension

Women with gestational diabetes mellitus

Women with xanthomatosis

Obese women

Diabetic women

# Choice of Pill

The therapeutic principle remains: utilize the formulations that give effective contraception and the greatest margin of safety. Use only low-dose preparations containing less than 50  $\mu\text{g}$  of estrogen, combined with low doses of new or old progestins. Current data support the view that there is greater safety with preparations containing less than 50  $\mu\text{g}$  of estrogen. The arguments in this chapter indicate that all patients should begin oral contraception with low-dose products and that patients on higher-dose oral contraception should be changed to the low-dose preparations. Stepping down to a lower dose can be accomplished immediately with no adverse reactions such as increased bleeding or failure of contraception.

**An extended regimen or continuous dosing deserves consideration. Breakthrough and withdrawal bleeding is reduced with these schedules, and because of greater suppression of FSH and follicular growth, it is very likely that the failure rates with typical use will be less.**

The multiphasic preparations do have a reduced progestin dosage compared with some of the existing monophasic products; however, based on currently available information, there is little difference between the low-dose monophasics and the multiphasics.

The pharmacologic effects in animals of various formulations have been used as a basis for therapeutic recommendations in selecting the optimal oral contraceptive pill. **These recommendations (personalized medicine approach) have not been supported by appropriately controlled clinical trials. All too often this leads to the prescribing of a pill of excessive dosage with its attendant increased risk of serious side effects.** It is worth repeating our earlier comments on potency. Oral contraceptive potency (specifically progestin potency) is no longer a consideration when it comes to prescribing birth control pills. The potency of the various progestins has been accounted for by appropriate adjustments of dose. The biologic effect of the various progestational components in current low-dose oral contraceptives is approximately the same. Our progress in lowering the doses of the steroids contained in oral contraceptives has yielded products with little serious differences.

# Pill Taking

Effective contraception is present during the first cycle of pill, transdermal, or vaginal ring use, provided the hormones are started no later than the 5th day of the cycle and no pills are missed. Thus, starting oral contraception on the first day of menses ensures immediate protection. The Sunday start packages, beginning on the first Sunday following the onset of menstruation, can be easier to remember, and it usually avoids menstrual bleeding on weekends. It is probable, **but not totally certain**, that even if a dominant follicle should emerge in occasional patients after a Sunday start, an LH surge and ovulation would still be prevented.<sup>557</sup> **We prefer the first-day start and no longer recommend the Sunday start. If the Sunday start is used, it is prudent to advise patients to use added protection in the first week of use.**

The conventional approach to starting oral contraceptives, either with menses or on Sunday, carries with it a delay in achieving contraception for many women. Many clinicians advocate the Quick-Start method, an **immediate or same-day start**, on the day the patient receives her prescription, regardless of the patient's day in her cycle.<sup>558</sup> Combined with a backup method for the first week, preferably condoms, an immediate start may avoid unwanted pregnancies occurring during the delay before initiating oral contraception with the conventional methods. In some instances of appropriate coital history, a sensitive pregnancy test would be a wise precaution before starting treatment. Women who use the immediate start method have better continuation rates and do not experience an increase in breakthrough bleeding.<sup>63,559</sup>

## Starting Choices for Steroid Contraception

### 1. Start on first day of menses

**Advantage:** assured immediate protection

### 2. Start on first Sunday after onset of menses

**Advantage:** avoids weekend menses

**Disadvantage:** backup protection advisable during first week

### 3. Quick-Start (immediate, same-day start)

**Advantage:** better compliance.

**Disadvantage:** backup protection necessary during first week; rule out pregnancy before beginning.

**There is no scientific rationale for recommending a pill-free interval. The serious side effects are not eliminated by pill-free intervals. This practice all too often results in unwanted pregnancies.**

How important is it to take the oral contraceptive at the same time every day? Although not well studied, there is reason to believe precise pill taking minimizes breakthrough bleeding. In addition, compliance is improved by a fixed schedule that is habit-forming.

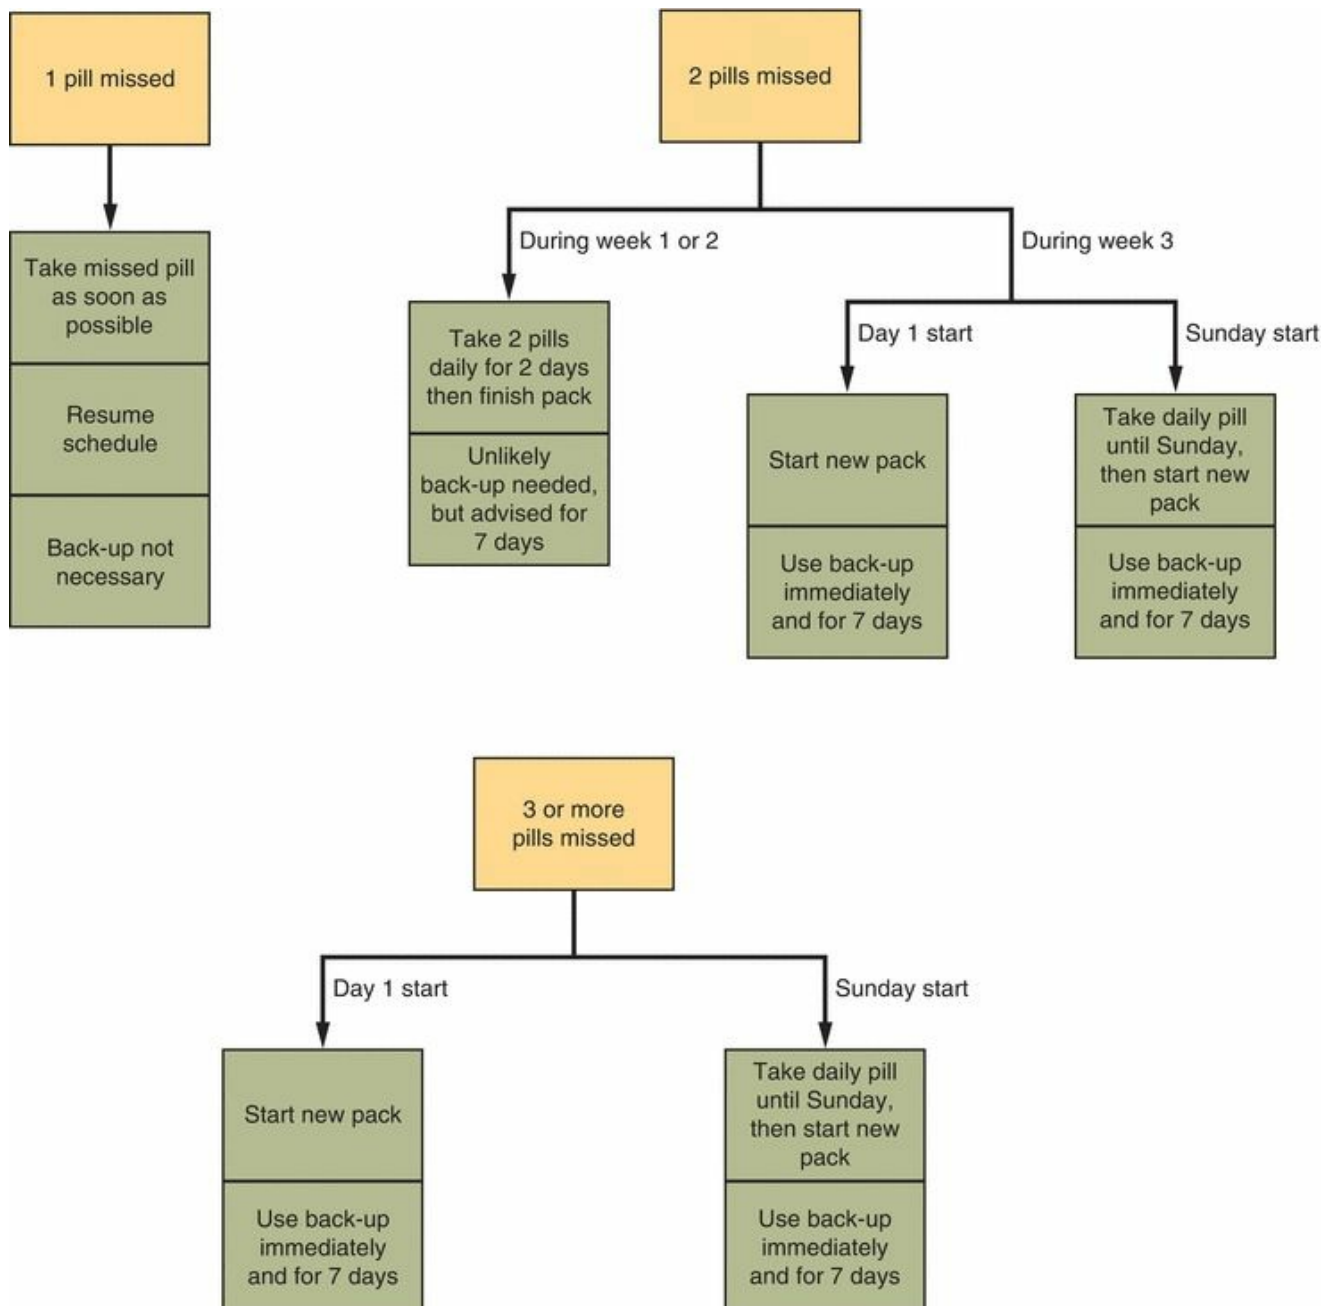

# Avoiding Menstrual Bleeding

Clinicians for years have prescribed unlimited daily oral contraceptives to treat conditions such as endometriosis, bleeding disorders, menstrual seizures, and menstrual migraine headaches, even to avoid bleeding in athletes and busy individuals. Withdrawal bleeding is not a desired experience for many women, and today, monthly bleeding, periodic bleeding, and no bleeding are choices available for women. Any combination oral contraceptive can be used on a daily continuous dosing basis; even the lowest-estrogen dose formulations provide excellent bleeding and side effect profiles in a continuous regimen.<sup>77,86</sup> A further benefit of continuous dosing is simplification of the pill-taking schedule with the potential of better compliance and a lower failure rate.

Occasionally patients would like to postpone a menstrual period, for example, for a wedding, holiday, or vacation. This can be easily achieved by omitting the hormone-free interval. Simply start a new package of pills the next day after finishing the series of **active** pills in the previous package.

# What to Do When Pills Are Missed

Irregular pill taking is a common occurrence. Using an electronic monitoring device to measure compliance, it was apparent that consistency of pill taking is even worse than what patients report; only 33% of women were documented to have missed no pills in cycle 1, and by cycle 3, about one-third of the women missed 3 or more pills with many episodes of consecutive days of missed pills.<sup>560</sup> These data indicate that women become less careful over time, emphasizing the importance of repeatedly reviewing with patients what to do when pills are missed (Figure 22.14).

## FIGURE 22.14

**If a woman misses 1 pill**, she should take that pill as soon as she remembers and take the next pill as usual. No backup method is needed.

**If she misses 2 pills in the first 2 weeks**, she should take two pills on each of the next 2 days; it is unlikely that a backup method is needed, but the official consensus is to recommend backup for the next 7 days, especially if the missed pills occurred in the first week. **If the patient is using an oral contraceptive with 20 µg or less of estrogen and the missed pills occur in the first week, consider the use of emergency contraception.**

**If 2 pills are missed in the 3rd week or if more than 2 active pills are missed at any time**, another form of contraception should be used as backup immediately and for 7 days; if a Sunday starter, keep taking a pill every day until Sunday, and on Sunday, start a new package; if a non-Sunday starter, start a new package the same day.

Studies have questioned whether missing pills has an impact on contraception. One study demonstrated that skipping 4 consecutive pills at varying times in the cycle did not result in ovulation.<sup>560</sup> Studies in which women deliberately lengthen their pill-free interval up to 11 days have failed to show signs of ovulation.<sup>78,561</sup> So far there is no evidence that moving to lower doses has had an impact on the margin of error. Despite greater follicular activity with the lowest-dose oral contraceptives, ovulation is still effectively prevented.<sup>52</sup> However, the studies have involved small numbers of women, and given the large individual variation, it is possible that some women might be at risk with a small increase in the pill-free interval. Although the progestational effects on endometrium and cervical mucus serve to ensure good contraceptive efficacy,<sup>94</sup> conservative advice regarding missing pills is the safest message to convey.

The most prevalent problems that can be identified associated with apparent oral contraceptive failures are vomiting and diarrhea.<sup>93</sup> **Even if no pills have been missed, patients should be instructed to use a backup method for at least 7 days after an episode of gastroenteritis.**

# CLINICAL PROBLEMS

---

# Breakthrough Bleeding

A major continuation problem is breakthrough bleeding. Breakthrough bleeding gives rise to fears and concerns; it is aggravating and even embarrassing. Therefore, on starting oral contraception, patients need to be fully informed about breakthrough bleeding.

There are two characteristic breakthrough bleeding problems: irregular bleeding in the first few months after starting oral contraception and unexpected bleeding after many months of use. Effort should be made to manage the bleeding problem in a way that allows the patient to remain on low-dose oral contraception. **There is no evidence that the onset of bleeding is associated with decreased efficacy, no matter what oral contraceptive formulation is used, even the lowest-dose products.** Indeed, in a careful study, breakthrough bleeding did not correlate with changes in the blood levels of the contraceptive steroids.<sup>59</sup>

The most frequently encountered breakthrough bleeding occurs in the first few months of use. The incidence is greatest in the first 3 months, ranging from 10% to 30% in the first month to less than 10% in the third. Breakthrough bleeding rates are higher with the lowest-dose oral contraceptives, but not dramatically.<sup>54,55</sup> Breakthrough bleeding is higher in women who smoke and in smokers who use formulations with 20 µg ethinyl estradiol.<sup>57</sup> However, the differences among the various formulations currently available are of minimal clinical significance. The basic pattern is the same, highest in the first month and a greater prevalence in smokers, especially in later cycles.

Breakthrough bleeding is best managed by good educational anticipatory preparation of the patient at initiation of treatment, with encouragement and reassurance when bleeding occurs. This bleeding usually disappears by the third cycle in the majority of women. Women should be strongly advised to call the clinician before discontinuing contraception. If necessary, even this early pattern of breakthrough bleeding can be treated as outlined below. It is helpful to explain to the patient that this bleeding represents tissue breakdown as the endometrium adjusts from its usual thick state to the relatively thin state allowed by the hormones in oral contraceptives.

Breakthrough bleeding that occurs after many months of oral contraceptive use is a consequence of the progestin-induced decidualization. This endometrium and the blood vessels within the endometrium tend to be fragile and prone to breakdown and asynchronous bleeding.

There are two recognized factors (both preventable) that are associated with a greater incidence of breakthrough bleeding. Consistency of use and smoking increase spotting and bleeding, but inconsistency of pill taking is more important and has a greater effect in later cycles, whereas smoking exerts a general effect at any time.<sup>562</sup>

Reinforcement of consistent pill taking can help minimize breakthrough bleeding. Young women who smoke are more likely to discontinue oral contraception,<sup>563</sup> and this may be partly due to irregular bleeding.

Cervical infection can be another cause of breakthrough bleeding; the prevalence of cervical chlamydial infections is higher among oral contraceptive users who report breakthrough bleeding.<sup>564</sup>

If bleeding occurs just before the end of the pill cycle, it can be managed by having the patient stop the pills, wait 7 days, and start a new cycle. If breakthrough bleeding is prolonged or if it is aggravating for the patient, regardless of the point in the pill cycle, control of the bleeding can be achieved with a short course of exogenous estrogen. Conjugated estrogen, 1.25 mg, or estradiol, 2 mg, is administered daily for 7 days when the bleeding is present, no matter where the patient is in her pill cycle. The patient continues to adhere to the schedule of pill taking. Usually, one course of estrogen solves the problem, and recurrence of bleeding is unusual (but if it does recur, another 7-day course of estrogen is effective).

Remember that there is a significant reduction in the number of bleeding and spotting days, as well as the amount of withdrawal bleeding, in women using a 24-day regimen. Studies comparing 24- and 21-day regimens have indicated that some of the breakthrough bleeding experienced by women on 21-day regimens is due to follicular growth, a rise in endogenous estrogen levels, followed by demise of the follicle and estrogen withdrawal bleeding. There are two operative mechanisms, therefore, in breakthrough bleeding: progestin-induced atrophic endometrium with vascular fragility and withdrawal bleeding in response to the rise and fall of endogenous estrogen levels associated with follicular growth and demise. Greater suppression of follicular growth with 24-day regimens results in less bleeding.

**Breakthrough bleeding in women using steroid contraception without a break, daily continuous dosing of oral contraceptives, is best treated by discontinuing medication for 3 or 4 days (no more than once every 3 weeks), allowing a withdrawal menstrual sloughing.**<sup>102,565</sup>

Responding to irregular bleeding by having the patient take 2 or 3 pills is not effective. The progestin component of the pill will always dominate; hence, doubling the number of pills will also double the progestational impact and its decidualizing, atrophic effect on the endometrium and its destabilizing effect on endometrial blood vessels. The addition of extra estrogen while keeping the progestin dose unchanged is logical and effective. This allows the patient to remain on the low-dose formulation with its advantage of greater safety. Breakthrough bleeding, in our view, is not sufficient reason to expose patients to the increased risks associated with higher-dose oral contraceptives. Any bleeding that is not handled by this routine requires investigation

for the presence of pathology.

There is no evidence that any oral contraceptive formulations that are approximately equivalent in estrogen and progestin dosage are significantly different in the rates of breakthrough bleeding. Clinicians often become impressed that switching to another product effectively stops the breakthrough bleeding. It is more likely that the passage of time is the responsible factor, and bleeding would have stopped regardless of switching and regardless of product.

# Amenorrhea

With low-dose pills, the estrogen content is not sufficient in some women to stimulate endometrial growth. The progestational effect dominates to such a degree that a shallow atrophic endometrium is produced, lacking sufficient tissue to yield withdrawal bleeding. It should be emphasized that permanent atrophy of the endometrium does not occur and resumption of normal ovarian function will restore endometrial growth and development. Indeed, there is no harmful, permanent consequence of amenorrhea while on oral contraception.

The major problem with amenorrhea while on oral contraception is the anxiety produced in both patient and clinician because the lack of bleeding may be a sign of pregnancy. The patient is anxious because of the uncertainty regarding pregnancy, and the clinician is anxious because of the medicolegal concerns stemming from the old studies, which indicated an increased risk of congenital abnormalities among the offspring of women who inadvertently used oral contraception in early pregnancy. There is no association between oral contraception and an increased risk of congenital malformation, and there is no increased risk of having abnormal children.

The incidence of amenorrhea in the first year of use with low-dose oral contraception is less than 2%. This incidence increases with duration, reaching perhaps 5% after several years of use. It is important to alert patients upon starting oral contraception that diminished bleeding and possibly no bleeding may ensue.

Amenorrhea is a difficult management problem. A pregnancy test will allow reliable assessment for the presence of pregnancy even at this early stage.

Many women are reassured with an understanding of why there is no bleeding and are able to continue on the pill despite the amenorrhea. Some women cannot reconcile themselves to a lack of bleeding, and this is an indication for trying other formulations (a practice unsupported by any clinical trials, and, therefore, the expectations are uncertain). But again, this problem does not warrant exposing patients to the greater risks of major side effects associated with higher-dose products.

Some clinicians have observed that the addition of extra estrogen for 1 month (1.25 mg conjugated estrogens or 2 mg estradiol daily throughout the 21 days while taking the oral contraceptive) will rejuvenate the endometrium and withdrawal bleeding will resume, persisting for many months.

# Weight Gain

The complaint of weight gain is frequently cited as a major problem with compliance. Yet, studies of the low-dose preparations fail to demonstrate a significant weight gain with oral contraception and no major differences among the various products.<sup>306,307,308,309,310,311,313</sup> There is also no association between transdermal contraception and weight gain.<sup>249</sup> This is obviously a problem of perception, a conclusion supported by finding the weight gain identical in treated and placebo groups. The clinician has to carefully reinforce the lack of association between low-dose oral contraceptives and weight gain and focus the patient on the real culprit: diet and level of exercise. Most women gain a moderate amount of weight as they age, whether they take oral contraceptives or not.

# Acne

Low-dose oral contraceptives improve acne regardless of which product is used.<sup>303,304,312,566,567,568,569,570,571</sup> The low progestin doses (including levonorgestrel formulations) currently used are insufficient to stimulate an androgenic response, and they provide effective treatment for acne and hirsutism. In addition to the inhibitory action of the progestational component on LH and the subsequent reduction in ovarian androgen production, estrogen-progestin contraceptives provide a further benefit because of the increase in SHBG levels induced by the estrogen component. The increase in SHBG results in a greater androgen-binding capacity with a decrease in free testosterone levels. The progestins in estrogen-progestin contraceptives also inhibit 5-reductase activity in the skin, further contributing to the clinical impact of oral contraceptives on hirsutism.<sup>572</sup>

# Ovarian Cysts

Anecdotal reports suggested that functional ovarian cysts are encountered more frequently and suppress less easily with multiphasic formulations. This observation failed to withstand careful scrutiny.<sup>573,574</sup> Functional ovarian cysts occurred less frequently in women on higher-dose oral contraception.<sup>575</sup> This protection is reduced with the current lower-dose products to the point where little effect can be measured.<sup>574,576,577,578,579</sup> Thus, the risk of such cysts is not eliminated, and, therefore, clinicians can encounter such cysts in patients taking any of the oral contraceptive formulations.

# Drugs that Affect Efficacy

There are many anecdotal reports of patients who conceived on oral contraceptives while taking antibiotics. There is little evidence, however, that antibiotics such as ampicillin, metronidazole, quinolone, and tetracycline, which reduce the bacterial flora of the gastrointestinal tract, affect hormonal contraceptive efficacy. Studies indicate that while antibiotics can alter the excretion of contraceptive steroids, plasma levels are unchanged, and there is no evidence of ovulation.<sup>580,581,582,583,584</sup> A review of a large number of patients derived from dermatology practices failed to find an increased rate of pregnancy in women on oral contraceptives and being treated with antibiotics (tetracyclines, penicillins, cephalosporins).<sup>585</sup> The anti-HIV drug, etravirine, does not produce important changes in the pharmacodynamics of ethinyl estradiol and norethindrone.<sup>586</sup>

There is good reason to believe that drugs that stimulate the liver's metabolic capacity can affect oral contraceptive efficacy. St. John's wort must be added to this list.<sup>587</sup> On the other hand, a search of a large database failed to discover any evidence that lower-dose oral contraceptives are more likely to fail or to have more drug interaction problems when other drugs are used.<sup>588</sup>

To be cautious, patients on medications that affect liver metabolism should choose an alternative contraceptive. A list, which may not be complete, includes the following:

Carbamazepine (Tegretol)

Felbamate

Lamotrigine

Nevirapine

Oxcarbazepine

Phenobarbital

Phenytoin (Dilantin)

Primidone (Mysoline)

Rifabutin

Rifampicin (Rifampin)

St. John's wort

Topiramate

Vigabatrin

**Possibly** valproic acid, ethosuximide, griseofulvin, and troglitazone

## Other Drug Interactions

Although not extensively documented, there is reason to believe that oral contraceptives potentiate the action of diazepam (Valium), chlordiazepoxide (Librium), tricyclic antidepressants, and theophylline.<sup>589</sup> Thus, lower doses of these agents may be effective in oral contraceptive users. Because of an influence on clearance rates, oral contraceptive users may require larger doses of acetaminophen and aspirin.<sup>590</sup>

# Migraine Headaches

True migraine headaches are more common in women, while tension headaches (90% of all headaches) occur equally in men and women.<sup>591</sup> There have been no well-done studies to determine the impact of oral contraception on the severity of migraine headaches. Patients may report that their headaches are worse or better.

There are two categories of migraine headaches: common migraine, which is migraine without aura, and classic migraine, which is migraine with aura (essentially migraine headaches with visual aura or other neurologic symptoms, occurring in 30% of migraine sufferers). These symptoms begin **before** the headache and resolve with the onset of the headache. Symptoms that occur during headaches, especially photophobia, are not signs of aura. Symptoms that indicate a premonition of a headache, such as light or sound sensitivity, poor concentration, and fatigue occurring 1–2 days before a headache, are also not considered signs of aura.

## Symptoms of migraine with aura:

- Scotomata (blind spots) or blurred vision
- Visualization of bright ragged lines or spots
- Episodes of blindness
- Numbness, paresthesias
- Speech difficulties
- Unilateral symptoms, such as weakness

Because of the seriousness of this potential complication, the onset of visual symptoms or severe headaches requires a response. If the patient is at a higher dose, a move to a low-dose formulation may relieve the headaches; however, this practice has not been studied. True vascular headaches (migraine with aura) are an indication to avoid or discontinue oral contraception. Oral contraceptives should be avoided in women who have migraine with complex or prolonged aura or if additional stroke factors are present (older age, smoking, hypertension, diabetes mellitus, obesity, family history of arterial disease at a young age).<sup>592</sup> Oral contraceptives can be considered in women under age 35, who have migraine **without** aura, and who are otherwise healthy and not smokers.

Migraine headaches, especially with aura, are a risk factor for stroke.<sup>593</sup> The risk is greater in women with hypertension, in smokers, in women with a family history of migraine, and in women with a long history of migraine or with more than 12 attacks per year of migraine with aura.<sup>594,595</sup> Studies with high-dose pills indicated that migraine headaches were linked to a risk of stroke. More recent studies reflecting the use of low-

dose formulations yield mixed results. One failed to find a further increase in stroke in patients with migraine who use oral contraception; another concluded that the use of oral contraception by migraineurs was associated with a fourfold increase of the already increased risk of ischemic stroke.<sup>596,597</sup> The World Health Organization case-control study indicated an increased risk in migraine oral contraceptive users who smoked.<sup>598</sup> Because 20–30% of women experience migraine headaches, one would expect the study populations in the most recent studies of thrombosis to have included substantial numbers of migraineurs. An adverse effect of low-dose oral contraceptives on stroke risk in migraineurs should have manifested itself in the data. The lack of an increased risk of stroke in these studies is reassuring. Nevertheless, it is believed that migraineurs on oral contraceptives have an increased risk of stroke; the absolute risk in a 20-year-old woman is estimated to be 10 per 100,000 and for a 40-year-old woman, 100 per 100,000.<sup>593</sup> Because of the small numbers of young women who have strokes, most studies could not differentiate between migraine with and without aura. However in the American Stroke Prevention in Young Women Study, oral contraceptive use in smokers was associated with an increased risk of stroke in migraineurs with aura.<sup>598</sup>

In some women, a relationship exists between their fluctuating hormone levels during a menstrual cycle and migraine headaches, with the onset of headaches characteristically coinciding with menses (also seen during the pill-free week of oral contraception). We have had personal success (anecdotal to be sure) alleviating headaches by eliminating the menstrual cycle, either with the use of **daily** continuous dosing oral contraceptives or with the daily administration of a progestational agent (such as 10 mg medroxyprogesterone acetate) or the use of depot medroxyprogesterone acetate. An extended regimen, rather than continuous dosing, may also improve menstrual migraine headaches. Some women with migraine headaches have extremely gratifying responses. Women who experience an exacerbation of their headaches with estrogen-progestin contraception should consider one of the progestin-only methods or intrauterine contraception.

**In summary, estrogen-progestin contraception should not be used by women who have migraine with aura. Women who have migraine without aura and who are less than 35 years of age (the risk of stroke increases with age), healthy, and nonsmoking can use combined steroid contraception. Migraineurs without aura over the age of 35 should avoid the pharmacologic use of estrogen.**

# **SUMMARY: ORAL CONTRACEPTIVE USE AND MEDICAL PROBLEMS**

---

# Hypertension

Low-dose oral contraception can be used in women less than age 35 years old with hypertension well controlled by medication and who are otherwise healthy and do not smoke. We recommend the lowest-estrogen dose formulations.

# **Pregnancy-Induced Hypertension**

Women with pregnancy-induced hypertension can use oral contraception as soon as the blood pressure is normal in the postpartum period.

# Uterine Leiomyoma

This is not a contraindication for low-dose oral contraceptives. The administration of low-dose oral contraceptives to women with leiomyomas does not stimulate fibroid growth and is associated with a reduction in menstrual bleeding.<sup>599</sup>

# **Gestational Diabetes**

Low-dose formulations do not produce a diabetic glucose tolerance response in women with previous gestational diabetes, and there is no evidence that combined oral contraceptives increase the incidence of overt diabetes mellitus. We believe that women with previous gestational diabetes can use oral contraception with annual assessment of the fasting glucose level.

# Diabetes Mellitus

Oral contraception can be used by diabetic women who do not smoke and are otherwise healthy (especially an absence of diabetic vascular complications). Women with diabetes and vascular disease or major cardiovascular risk factors should avoid pharmacologic doses of exogenous estrogen.

# **Elective Surgery**

With major surgery and immobilization, including arthroscopy, especially if the patient is overweight, prophylactic treatment should be considered for a current or recent user of oral contraceptives. It is prudent to maintain contraception right up to the performance of a sterilization procedure or any short, outpatient operation.

# Seizure Disorders

Oral contraceptives do not exacerbate epilepsy, and in some women, improvement in seizure control has occurred.<sup>600,601</sup> A potential problem is repeatedly raised regarding antiepileptic drugs that affect liver metabolism, and that is that they may decrease the effectiveness of oral contraception. Some clinicians advocate the use of higher-dose (50 µg estrogen) products; however, no studies have been performed to demonstrate that this higher dose is necessary. Another concern is that moving to a higher-dose product increases the estrogen dose and the risk of side effects. Most importantly, even though studies indicate that some antiepileptic drugs lower steroid levels in oral contraceptive users, ovulation or pregnancies could not be detected in these studies.<sup>602,603,604,605</sup> The efficacy of most antiepileptic drugs is not affected by steroid contraception; however, there is evidence that lamotrigine and valproic acid may need dosage adjustments because of estrogen-induced metabolism.<sup>606,607,608</sup> Consideration should be given to methods that neither affect antiepileptic drug metabolism nor the method affected by the drugs. These include intrauterine contraception with a copper IUD or the levonorgestrel-releasing IUS,<sup>609</sup> long-acting progestin-only methods, barrier methods, and sterilization.

# **Obstructive Jaundice in Pregnancy**

Not all patients with this history will develop jaundice on oral contraception, especially with the low-dose formulations.

# Sickle Cell Disease

Patients with sickle cell trait can use oral contraception. The risk of thrombosis in women with sickle cell disease or sickle C diseases is theoretical (and a medicolegal) concern. We believe effective protection against pregnancy in these patients warrants the use of low-dose oral contraception. In the only long-term (10 years) follow-up report of women with sickle cell disease and using oral contraceptives, no apparent adverse effects were observed (at a time when higher-dose products were prevalent).<sup>610</sup> A study of erythrocyte deformability in women with sickle cell anemia could detect no adverse effects of contraceptive steroids.<sup>611</sup> Keep in mind that depot medroxyprogesterone acetate used for contraception is associated with inhibition of sickling and improvement in anemia in patients with sickle cell disease.<sup>612</sup>

# Gallbladder Disease

Oral contraception use may precipitate a symptomatic attack in women known to have stones or a positive history for gallbladder disease and, therefore, should be done either very cautiously or not at all.

# Mitral Valve Prolapse

Oral contraception use is limited to nonsmoking patients who are asymptomatic (no clinical evidence of regurgitation). There is a small subset of patients with mitral valve prolapse who are at increased risk of thromboembolism. Patients with atrial fibrillation, migraine headaches, or clotting factor abnormalities should consider progestin-only methods or the IUD (prophylactic antibiotics should cover IUD insertion if mitral regurgitation is present).

# Systemic Lupus Erythematosus

Oral contraceptive use can exacerbate systemic lupus erythematosus, and the vascular disease associated with lupus, when present, represents a contraindication to estrogen-containing oral contraceptives.<sup>613</sup> A large case-control study using the General Practice Research Database in the United Kingdom indicated an increased risk of this autoimmune disease in current and recent users of oral contraceptives; however, the only significant increase was in users of 50- $\mu$ g high-dose formulations.<sup>614</sup> The progestin-only methods are a good choice for women with systemic lupus erythematosus. However, in patients with stable or inactive disease, without renal involvement and high antiphospholipid antibodies, low-dose oral contraception can be considered.<sup>615</sup>

In a clinical trial conducted in Mexico City, 162 women with systemic lupus erythematosus were randomized to treatment with one of three contraceptive methods: estrogen-progestin oral contraceptives, oral progestin-only pills, or a copper IUD.<sup>616</sup> Disease activity remained equally mild and stable over 1 year in all three groups. There were no differences in the use of anti-inflammatory drugs. There were four cases of lower-limb thromboses, two in the group receiving oral contraceptives and two with progestin-only pills. All four had low titers of antiphospholipid antibodies. Estrogen-containing contraceptives did not exacerbate systemic lupus erythematosus.

The NIH-supported OC-SELENA (Safety of Estrogens in Lupus Erythematosus National Assessment) trial was a double-blind, randomized trial of 183 women with stable systemic lupus erythematosus treated with either a 35- $\mu$ g ethinyl estradiol oral contraceptive or placebo and followed for 1 year.<sup>617</sup> Lupus flares, the primary endpoint, occurred equally in the two groups. Venous thrombosis did not occur more frequently in the oral contraceptive group. The results indicated that low-dose, estrogen-progestin oral contraceptives can be used by patients with inactive or stable, moderate systemic lupus erythematosus who are at low risk for thrombosis. Patients with high-titer anticardiolipin antibodies, lupus anticoagulant, or previous thrombosis were excluded from the SELENA study. If hormone therapy is to be provided to these patients, some form of chronic anticoagulation should be considered (such as low-dose aspirin).

These studies are important for at least two good reasons. First, there has been a general clinical impression that exogenously administered estrogens would increase lupus disease activity. Second, there are important effects of oral contraceptives that would be beneficial for patients with lupus. These beneficial effects include the following. (1) Contraception is a chief component of care for lupus patients because pregnancy outcome is adversely affected by unstable, active disease. (2) Patients with lupus experience major bone loss and an increase in fractures as an unwanted side

effect of their medical treatment. (3) Estrogen-progestin contraceptives may moderate the intensity of lupus.

# Hyperlipidemia

Because low-dose oral contraceptives have negligible impact on the lipoprotein profile, hyperlipidemia is not an absolute contraindication, with the exception of very high levels of triglycerides (which can be made worse by estrogen). In women with triglyceride levels greater than 250 mg/dL, estrogen should be provided with great caution. If vascular disease is already present, oral contraception should be avoided. If other risk factors are present, especially smoking, oral contraception is not recommended. Dyslipidemic patients who begin oral contraception should have their lipoprotein profiles monitored monthly for a few visits to ensure no adverse impact. If the lipid abnormality cannot be held in control, an alternative method of contraception should be used.<sup>618</sup> If hypertriglyceridemia is the only concern, keep in mind that the triglyceride response to estrogen is rapid. A repeat level should be obtained in 2–4 weeks. **A triglyceride level greater than 750 mg/dL represents an absolute contraindication to estrogen treatment because of the risk of pancreatitis.**

# Smoking

Oral contraception is absolutely contraindicated in smokers over the age of 35. In patients 35 years old and younger, heavy smoking (15 or more cigarettes per day) is a relative contraindication. The relative risk of cardiovascular events is increased for women of all ages who smoke and use oral contraceptives; however, because the actual incidence of cardiovascular events is so low at a young age, the real risk is very low for young women. An ex-smoker (for at least 1 year) should be regarded as a nonsmoker. Risk is only linked to active smoking.

# Hepatic Disease

Oral contraception can be utilized when liver function tests return to normal. Follow-up liver function tests should be obtained after 2–3 months of use.

# Hemorrhagic Disorders

Women with hemorrhagic disorders and women taking anticoagulants can use oral contraception, although the safety of estrogen-progestin methods has not been documented in women who are anticoagulated because of a past history of venous thrombosis. Inhibition of ovulation can avoid the real problem of a hemorrhagic corpus luteum in these patients. A reduction in menstrual blood loss is another benefit of importance. Progestin-only methods do not increase the risk of venous thrombosis. Depot medroxyprogesterone acetate would suppress ovulation and the risk of ovarian hemorrhage, whereas the levonorgestrel-releasing IUD is especially effective for reducing menstrual bleeding.

# Obesity

An obese woman who is otherwise healthy can use low-dose oral contraception. However, there are special considerations associated with obesity:

- Obesity and aging are independent risk factors for venous thrombosis, and case-control studies have indicated this risk adds to that associated with oral contraceptives.<sup>196,619,620</sup> Progestin-only methods should receive serious consideration for use by obese women, especially the levonorgestrel intrauterine system. However, the additional risk with oral contraceptives is less than the risk associated with pregnancy and the postpartum period.<sup>621</sup> **Oral contraceptives with the lowest doses of estrogen should be used for overweight and older women, but progestin-only methods are an even better choice. The same considerations apply to the other methods of estrogen-progestin contraception, the vaginal and transdermal methods.**
- There is modest evidence that hormonal contraceptive failure is increased in overweight women (over 155 lb).<sup>622,623,624,625,626,627</sup> On the other hand, no effect of body weight on oral contraceptive failure was detected in a large, prospective European cohort.<sup>628</sup> Older clinical trials excluded women with high body weight, and for this reason, the effect of body weight on contraception was not well studied. Keep in mind that the positive conclusions regarding failure rates and weight were based on differences of only 2 to 4 pregnancies per 100 women per year. Efficacy in overweight women would still be greater than that with barrier methods. But most importantly, recent clinical trials, especially those with extended regimens, detected no increase in failure rates associated with heavier body weights.<sup>71,85,628,629</sup>
- Obese women on oral contraceptives with a traditional 7-day pill-free period took twice as long (10 days) to achieve a steady-state concentration of the administered progestin, and this was associated with more frequent ovulation.<sup>630</sup> Outliers can take even longer! **We strongly encourage the use of an extended regimen or continuous dosing in these patients.**
- Obesity is increasingly being treated with a method of bariatric surgery. Postoperatively, it is currently recommended that pregnancy be avoided for 12–18 months. Studies indicate that steroid levels after ingestion of oral contraceptives are lower in these patients for at least several years.<sup>631,632</sup> Alternative routes of administration are best for these patients, including the vaginal insertion of oral contraceptives (discussed later), injections, implants, and intrauterine contraception.

# **Benign Breast Disease**

Benign breast disease is not a contraindication for oral contraception; with 2 years of use, the condition may improve.

# **Congenital Heart Disease or Valvular Heart Disease**

Oral contraception is contraindicated only if there is marginal cardiac reserve or a condition that predisposes to thrombosis.

# Polycystic Ovaries and Insulin Resistance

Because older, high-dose oral contraceptives increased insulin resistance, it had been suggested that this treatment should be avoided in anovulatory, overweight women. However, low-dose oral contraceptives have minimal effects on carbohydrate metabolism, and the majority of hyperinsulinemic, hyperandrogenic women can be expected to respond favorably to treatment with oral contraceptives.<sup>633</sup> The administration of a low-dose oral contraceptive to women with extreme obesity and very severe insulin resistance resulted in only a mild deterioration of glucose tolerance.<sup>634</sup> Impressively, in a follow-up study (about 10 years) of women with polycystic ovaries and hyperinsulinism, comparing oral contraceptive users with nonusers, the metabolic parameters not only did not worsen in the users, but they actually improved, including body weight, glucose tolerance, insulin levels, and HDL cholesterol levels, which was in striking contrast to the metabolic worsening observed in the nonusers.<sup>635</sup> This experience supports the safety of oral contraceptive treatment for anovulatory, hyperandrogenic, hyperinsulinemic women.

# Eating Disorders

In patients with eating disorders, bone density correlates with body weight. The bone response to hormone therapy will be impaired as long as an abnormal weight is maintained and low caloric intake persists.<sup>636</sup> The failure to respond to estrogen treatment with an increase in bone density may be due to the adverse bone effects of the hypercortisolism associated with stress disorders. Furthermore, because the pubertal gain in bone density is so significant, individuals who fail to experience this adolescent increase may continue to have a deficit in bone mass despite hormone treatment. Reduced menstrual function for any reason early in life (even beyond adolescence) may leave a residual deficit in bone density that cannot be totally retrieved with resumption of menses or with hormone treatment.<sup>637,638</sup> Steroid contraception can be used in patients with eating disorders, and a failure to gain bone density is a clue that the eating disorder is not resolved.

# **Pituitary Prolactin-Secreting Adenomas**

Low-dose oral contraception can be used in the presence of microadenomas.

# **Infectious Mononucleosis**

Oral contraception can be used as long as liver function tests are normal.

# Inflammatory Bowel Disease

Oral contraceptives are absorbed mainly in the small bowel; women who have an ileostomy after lower bowel surgery have normal steroid absorption with the use of oral contraceptives.<sup>639,640</sup>

The risk of regional enteritis (Crohn disease) was reported to be increased in oral contraceptive users but only in current smokers.<sup>641</sup> Other reports indicated that smoking and oral contraceptive use were independently associated with an increased risk of both incidence and relapse.<sup>642,643</sup> However, these associations were not strong and mostly reflected the use of older, higher-dose formulations. At least one case-control study could detect no link between oral contraceptive use and the incidence of Crohn disease.<sup>644</sup> In a prospective cohort of women with regional enteritis, no adverse impact of oral contraceptives could be detected on the clinical course, specifically on flare-ups.<sup>645</sup>

The impact of low-dose steroid contraception on the risk of inflammatory bowel disease is negligible. In addition, there is no firm reason to withhold these methods from women with these conditions.

# Organ Transplantation

Organ transplantation is followed by immunosuppressive therapy to prevent rejection. Although barrier methods of contraception are usually recommended, there is no reason that postoperative women with good hepatic function and normal blood pressures cannot use steroid contraception.<sup>646,647</sup> The use of steroid contraception in transplant patients will not only provide wanted, effective contraception but also prevent the irregular and heavy menses that are commonly experienced.

# An Alternative Route of Administration

Occasionally, a situation may be encountered when an alternative to oral administration of contraceptive pills is required. For example, patients receiving chemotherapy can have either significant nausea and vomiting or mucositis, both of which would prevent oral drug administration. Pregnancy should be avoided in the 18 months following bariatric surgery, but this time period is associated with gastrointestinal malabsorption. The low-dose oral contraceptives can be administered vaginally. A large clinical trial demonstrated typical contraceptive efficacy with one pill administered vaginally per day.<sup>648</sup> In a comparative study, a major reduction in side effects was associated with vaginal administration.<sup>649</sup>

# ATHLETES AND ORAL CONTRACEPTION

---

Because athletes are often amenorrheic and hypoestrogenic, oral contraceptives provide not only confidence against the risk of an unwanted pregnancy but also estrogen support against bone loss. This is a situation where bone density measurements are worthwhile. A low bone density can help motivate an athlete to take hormone therapy, and a subsequent bone density measurement that reveals a failure of response to estrogen can indicate the presence of a hidden eating disorder.

Competing athletes are often concerned that oral contraceptives could reduce exercise performance. A rationale for the concern can be traced to the physiologic increase in ventilation during pregnancy, mediated by progesterone. Thus, progestin enhancement of ventilatory response could consume energy otherwise available for athletic performance. Indeed, reports have generated conflicting data as measured by laboratory testing. However, experimental studies that simulate athletic events can find no adverse effects on oxygen uptake or respiratory rate.<sup>650</sup> In fact, one study of strenuous exercise in a laboratory setting documented improved aerobic power with increases in time to exhaustion and total work performed in oral contraceptive users.<sup>651</sup> Another study reported decreased soreness, both perceived and with palpation, after exercise in women using oral contraceptives.<sup>652</sup> Oral contraceptive use has no effect on prevalence or severity of low back pain, a common problem among female athletes.<sup>653</sup>

Oral contraceptives have a lot to offer with no serious drawbacks for athletes. In athletes who wish to avoid menstrual bleeding, oral contraceptives can be administered on a daily basis, with no breaks, preventing withdrawal bleeding. Continuous dosing is also a good choice for women in the military. The vaginal and transdermal methods can be used in a similar fashion.

# **THE NONCONTRACEPTIVE BENEFITS OF HORMONAL CONTRACEPTION**

---

The noncontraceptive benefits of low-dose hormonal contraception can be grouped into two main categories: benefits that incidentally accrue when hormonal contraception is specifically utilized for contraceptive purposes and benefits that result from the use of hormonal contraceptives to treat problems and disorders.

The noncontraceptive incidental benefits can be listed as follows:

## **Effective contraception**

**-Less need for induced abortion**

**-Less need for surgical sterilization**

**Less endometrial cancer**

**Less ovarian cancer**

**Less colorectal cancer**

**Fewer ectopic pregnancies**

**More regular menses:**

**-Less flow**

**-Less dysmenorrhea**

**-Less anemia**

**Less salpingitis**

**Less benign breast disease**

**Increased bone density**

**Less endometriosis**

**Possibly less rheumatoid arthritis**

**Possibly protection against atherosclerosis**

**Possibly fewer ovarian cysts**

Many of these benefits have been previously discussed. The low-dose contraceptives are as effective as higher-dose preparations in reducing menstrual flow and the prevalence and severity of dysmenorrhea.<sup>654,655,656</sup> The use of oral contraception is

associated with a lower incidence of endometriosis, although the protective effect is probably limited to current or recent use.<sup>657,658,659</sup> These benefits involving two common gynecologic problems have an important, positive impact on compliance.

Progestational drugs have been used to treat the pain of endometriosis for a long time. In fact, norethindrone and norethynodrel were approved by the FDA for this purpose in 1957, 3 years before approval of the first oral contraceptive. By 1960, 500,000 women were using these agents, although it is unlikely that all had endometriosis or even dysmenorrhea. Therefore, there is an enormous clinical history supporting the use of oral contraceptives for the treatment of endometriosis.

A Japanese double-blind, placebo-controlled, randomized multicenter trial evaluated the use of a low-dose oral contraceptive for the treatment of dysmenorrhea associated with endometriosis.<sup>660</sup> The oral contraceptive, given for 3 out of 4 weeks for 4 cycles, consisted of 35 µg ethinyl estradiol and 1 mg norethindrone. Dysmenorrhea pain interestingly decreased in the placebo group, but the decrease in the oral contraceptive group was about twice as great. The treatment group demonstrated a decrease in pelvic induration that did not achieve statistical significance. Only the treated group demonstrated a reduction in the size of ovarian endometriomas that were larger than 3 cm in diameter at baseline. This Japanese study provides clinical trial data for a low-dose oral contraceptive that confirms years of experience. It is worth noting that a randomized, placebo-controlled trial using a 20 µg estrogen oral contraceptive has documented effective treatment of primary dysmenorrhea in adolescents.<sup>661</sup>

For years, many clinicians have believed that the daily use of an oral contraceptive without a break is more effective for the treatment of endometriosis. A randomized trial with 239 women found equally effective reductions in the recurrence of endometriomas comparing cyclic and continuous oral contraceptive regimens over 2 years.<sup>662</sup>

Low-dose estrogen-progestin contraception is a good first choice to treat pain associated with endometriosis. It is a less expensive option than gonadotropin-releasing hormone (GnRH) analogs, side effects are not a major problem, and treatment can be maintained for long durations. This is also a good option to maintain suppression of endometriosis after surgical or GnRH analog treatment; remember that treatments only suppress and don't cure or eliminate endometriosis. Another advantage of oral contraceptive treatment is that endometriosis may be associated with a slight increase in ovarian cancer (as well as adenocarcinoma in endometriosis tissue), and the profound reduction in the risks of ovarian and endometrial cancer well demonstrated in women without endometriosis is observed equally in women with endometriosis.<sup>663,664</sup> However, endometriosis is often progestin resistant or can acquire resistance; in this setting, oral contraceptives may not be effective, and alternative therapies should be considered as discussed in the chapter on endometriosis.

An Austrian study concluded that osteoporosis occurs later and is less frequent in women who have used long-term oral contraception.<sup>665</sup> Most studies indicate that prior use of oral contraception is associated with higher levels of bone density and that the degree of protection is related to duration of exposure.<sup>666,667,668,669,670,671,672</sup> However, other studies reflecting modern use of low-dose products indicate little impact of oral contraceptive use on bone.<sup>673,674,675</sup> These measurements of bone density are not as important as the clinical outcome: fractures. The available evidence fails to provide a clear-cut picture. Retrospective studies indicated a reduction in fractures in postmenopausal women who had previously used oral contraceptives.<sup>676,677,678,679</sup> In the Royal College of General Practitioners' study, the overall risk of fractures in ever users of oral contraceptives was actually slightly increased.<sup>680</sup> Similar results have been observed in the Oxford Family Planning Association Study.<sup>681</sup> It is likely that the increased risk reflects lifestyle effects among oral contraceptive users, but there was no evidence of a protective effect against fractures. In contrast, a case-control study from Sweden found a reduction in the risk of postmenopausal hip fractures when oral contraceptives (mostly older high-dose products) were used after age 40 by women who were not overweight, with an increasing benefit with increasing duration of use.<sup>682</sup> Previous oral contraceptive users are just now becoming elderly and reaching the age of greatest fracture prevalence. Future studies of postmenopausal women should eventually reveal the accurate relationship between oral contraceptive use and osteoporotic fractures.

The literature on rheumatoid arthritis has been controversial, with studies in Europe finding evidence of protection and studies in North America failing to demonstrate such an effect. An excellent Danish case-control study was designed to answer criticisms of shortcomings in the previous literature.<sup>683</sup> Ever use of oral contraception reduced the relative risk of rheumatoid arthritis by 60%, and the strongest protection was present in women with a positive family history. One meta-analysis concluded that the evidence consistently indicated a protective effect, but that rather than preventing the development of rheumatoid arthritis, oral contraception may modify the course of disease, inhibiting the progression from mild to severe disease, whereas a later meta-analysis concluded there was no evidence of a protective effect.<sup>684,685</sup> More recent studies suggest a reduction in severity with long-term use.<sup>686</sup>

Oral contraceptives are frequently utilized to manage the following problems and disorders:

**Definitely beneficial:**

**-Dysfunctional uterine bleeding**

- Dysmenorrhea**
- Mittelschmerz**
- Endometriosis prophylaxis**
- Acne and hirsutism**
- Hormone therapy for hypothalamic amenorrhea**
- Prevention of menstrual porphyria**
- Control of bleeding (dyscrasias, anovulation)**

**Possibly beneficial:**

- Functional ovarian cysts**
- Premenstrual syndrome**

Oral contraceptives have been a cornerstone for the treatment of anovulatory, dysfunctional uterine bleeding; the only randomized, placebo-controlled trial documented the beneficial impact long recognized by clinicians.<sup>665</sup> For patients who need effective contraception, oral contraceptives are a good choice to provide hormone therapy for amenorrheic patients, as well as to treat dysmenorrhea. Oral contraceptives are also a good choice to provide prophylaxis against the recurrence of endometriosis in a woman who has already undergone more vigorous treatment with surgery or the GnRH analogs.

The low-dose oral contraceptives are effective in treating acne and hirsutism. Suppression of free testosterone levels is comparable with that achieved with higher dosage.<sup>687,688</sup> The beneficial clinical effect is the same with low-dose preparations containing levonorgestrel, previously recognized to cause acne at high dosage.<sup>689</sup> It is likely that all low-dose formulations, through the combined effects of an increase in SHBG and a decrease in testosterone production, produce an overall similar clinical response, especially over time (a year or more).

Oral contraceptives have long been used to speed the resolution of ovarian cysts, but the efficacy of this treatment has not been established. Randomized trials have been performed with women who develop ovarian cysts after induction of ovulation.<sup>690,691,692</sup> No advantage for the contraceptive treatment could be demonstrated. The cysts resolved completely and equally fast in both treated and nontreated groups. Of course, these were functional cysts secondary to ovulation induction, and this experience may not apply to spontaneously appearing cysts. Two short-term (5 and 6 weeks) randomized studies could document no greater effect of oral contraceptive treatment on resolution of spontaneous ovarian cysts when compared with expectant management.<sup>693,694</sup> Clinical

experience (untested by studies) leads us to believe that oral contraception does provide protection in women against the recurrent formation of ovarian cysts.

# CONTINUATION: FAILURE OR SUCCESS?

---

Despite the fact that oral contraception is highly effective, hundreds of thousands of unintended pregnancies occur each year in the United States because of the failure of oral contraception. Worldwide, millions of unintended pregnancies result from poor compliance. In general, the most important determinants of pill failure are age, intention toward a future birth, parity, and marital status. Interestingly, once these factors are accounted for, duration of use, race, ethnicity, and poverty status no longer affected the risk of pill failure.<sup>101</sup> Overall, the failure rate with actual use is as high as 8%. This difference between the theoretical efficacy and actual use largely reflects noncompliance. Noncompliance includes a wide variety of behaviors: failure to fill the initial prescription, failure to continue on the medication, and incorrectly taking oral contraception. Compliance (continuation) is an area in which personal behavior, biology, and pharmacology come together. Oral contraceptive continuation reflects the interaction of these influences. Unfortunately, women who discontinue oral contraception often utilize a less effective method or, worse, fail to substitute another method.

There are three major factors that affect continuation:

1. The experience of side effects, such as breakthrough bleeding and amenorrhea, and perceived experience of “minor” problems, such as headaches, nausea, breast tenderness, bloating, and weight gain. Multiple side effects dramatically and progressively increase the likelihood of discontinuation.<sup>58,695</sup> Because these complaints respond well even to placebo treatment,<sup>696</sup> it is reasonable to expect a favorable response to sensitive and attentive counseling, as well as changing to a different product.
2. Fears and concerns regarding cancer, cardiovascular disease, and the impact of oral contraception on future fertility.
3. Nonmedical issues, such as inadequate instructions on pill taking, complicated pill packaging, difficulties arising from the patient package insert, and, most importantly, contraceptive access and expense.

The information in this chapter is the foundation for good continuation, but the clinician must go beyond the presentation of information and develop an effective means of communicating that information. We recommend the following approach to the clinician-patient encounter as one way to improve continuation with oral contraception.

1. Explain how oral contraception works.
2. Review briefly the risks and benefits of oral contraception, but be careful to put the

risks in proper perspective and to emphasize the safety and noncontraceptive benefits of low-dose oral contraceptives. The risks are low and less than the risks associated with pregnancy.

3. Show and demonstrate to the patient the package of pills she will use.

4. Explain how to take the pills:

-When to start.

-The importance of developing a daily routine to avoid missing pills.

-What to do if pills are missed (identify a backup method).

-Consider the use of an extended regimen (with the potential of greater efficacy).

-Dispense as many packages as possible; evidence indicates that the more packages dispensed, the higher the continuation rate.<sup>94</sup>

5. Review the side effects that can affect continuation, such as amenorrhea, breakthrough bleeding, headaches, weight gain, nausea, etc., and what to do if one or more occurs. The key is to provide anticipatory guidance.

6. Explain the warning signs of potential problems: abdominal or chest pain, trouble breathing, severe headaches, visual problems, leg pain, or swelling.

7. Ask the patient to be sure to call if another clinician prescribes other medications.

8. Ask the patient to repeat critical information to make sure she understands what has been said. Ask if the patient has any questions.

9. Schedule a return appointment in 1–2 months to review understanding and address fears and concerns; a visit at 3 months is too late because most questions and side effects occur early.<sup>63</sup> Inconsistent use of oral contraceptives is more common in women who are new starters.<sup>697</sup>

10. Make sure a line of communication is open to clinician or office personnel. Ask the patient to call for any problem or concern before she stops taking the oral contraceptives.

11. Inform the patient about the availability and the proper use of emergency contraception.

# THE PROGESTIN-ONLY MINIPILL

---

The minipill contains a small dose of a progestational agent and must be taken daily, in a continuous fashion.<sup>698,699</sup> There is no evidence for any major differences in clinical behavior among the available minipill products.

Minipills available worldwide:

1. Micronor, Nor-QD, Noriday, Norod \_\_\_\_\_ 0.350 mg norethindrone
2. Microval, Noregeston, Microlut \_\_\_\_\_ 0.030 mg levonorgestrel
3. Ovrette, Neogest \_\_\_\_\_ 0.075 mg norgestrel (equivalent to 0.0375 mg levonorgestrel)
4. Exluton \_\_\_\_\_ 0.500 mg lynestrenol
5. Femulen \_\_\_\_\_ 0.500 mg ethynodiol diacetate
6. Cerazette \_\_\_\_\_ 0.075 mg desogestrel

# Mechanism of Action

After taking a progestin-only minipill, the small amount of progestin in the circulation (about 25% of that in combined oral contraceptives) will have a significant impact only on those tissues very sensitive to the female sex steroids, estrogen and progesterone. The contraceptive effect is more dependent on endometrial and cervical mucus effects, because gonadotropins are not consistently suppressed. The endometrium involutes and becomes hostile to implantation, and the cervical mucus becomes thick and impermeable. Approximately 40% of patients will ovulate normally.<sup>700,701</sup> Tubal physiology may also be affected, but this is speculative. The progestin-only minipill containing 0.075 mg desogestrel appears to be slightly more effective, probably because it exerts a greater inhibition of ovulation.<sup>702</sup>

**Because of the low dose, the minipill must be taken every day at the same time of the day.** The change in the cervical mucus requires 2–4 hours to take effect, and, most importantly, the impermeability diminishes 22 hours after administration, and by 24 hours, some sperm penetration occurs. Midday administration is recommended.

Ectopic pregnancy is not prevented as effectively as intrauterine pregnancy. Although the overall incidence of ectopic pregnancy is not increased (it is still much lower than the incidence in women not using a contraceptive method), when pregnancy occurs, the clinician must suspect that it is more likely to be ectopic. A previous ectopic pregnancy should not be regarded as a contraindication to the minipill.

There are no significant metabolic effects (lipid levels, carbohydrate metabolism, and coagulation factors remain unchanged),<sup>703,704</sup> and there is an immediate return to fertility on discontinuation. An increase in the risk of venous thrombosis has not been observed in users of progestin-only minipills containing levonorgestrel, norethindrone, or desogestrel.<sup>141,160</sup>

# Efficacy

Failure rates have been documented to range from 1.1 to 9.6 per 100 women in the first year of use.<sup>705</sup> The failure rate is higher in younger women (3.1 per 100 woman-years) compared with women over age 40 (0.3 per 100 woman-years).<sup>706</sup> In motivated women, the failure rate is comparable to the rate (<1 per 100 woman-years) with combination oral contraception.<sup>707,708</sup>

# Pill Taking

The minipill should be started on the first day of menses, and although a backup method for the first 7 days has been the standard recommendation, this extra precaution should not be necessary. A backup method for 7 days is necessary with either a Quick-Start or a Sunday start. The minipill can be started immediately postpartum or after a miscarriage or induced abortion.

Pill taking should be keyed to a daily event to ensure regular administration at the same time of the day. If pills are forgotten or gastrointestinal illness impairs absorption, the minipill should be resumed as soon as possible, and a backup method should be used immediately and until the pills have been resumed for at least 2 days. If 2 or more pills are missed in a row and there is no menstrual bleeding in 4–6 weeks, a pregnancy test should be obtained. **If more than 3 hours late in taking a pill, a backup method should be used for 48 hours. Cerazette (desogestrel) is more forgiving, allowing a 12-hour late time period.**

# Problems

In view of the unpredictable effect on ovulation, it is not surprising that irregular menstrual bleeding is the major clinical problem. The daily progestational impact on the endometrium also contributes to this problem. Patients can expect to have normal, ovulatory cycles (40–50%); short, irregular cycles (40%); or a total lack of cycles ranging from irregular bleeding to spotting and amenorrhea (10%). This is the major reason why women discontinue the minipill method of contraception.<sup>686</sup> Doxycycline, 100 mg b.i.d. for 5 days, is effective in decreasing bleeding associated with progestin-only treatment, apparently by suppressing matrix metalloproteases in endometrial cells.<sup>709</sup>

Women on progestin-only contraception develop more functional, ovarian follicular cysts.<sup>571,710</sup> Nearly all, if not all, regress. This is not a clinical problem of any significance. Women who have experienced frequent ovarian cysts would be happier with methods that effectively suppress ovulation (combined oral contraceptives and depot medroxyprogesterone acetate).

The levonorgestrel minipill may be associated with acne. The mechanism is similar to that seen with Norplant. The androgenic activity of levonorgestrel decreases the circulating levels of SHBG.<sup>711</sup> Therefore, free steroid levels (levonorgestrel and testosterone) will be increased despite the low dose. This is in contrast to the action of combined oral contraception where the effect of the progestin is countered by the estrogen-induced increase in SHBG.

The incidence of the other minor side effects is very low, probably at the same rate that would be encountered with a placebo.

# Clinical Decisions

There are two situations in which excellent efficacy, probably near-total effectiveness, is achieved: lactating women and women over age 40. In lactating women, the contribution of the minipill is combined with prolactin-induced suppression of ovulation, adding up to very effective protection.<sup>712</sup> In women over age 40, reduced fecundity adds to the minipill's effects.

There is another reason why the minipill is a good choice for the breast-feeding woman. There is no evidence for any adverse effect on breast-feeding as measured by milk volume and infant growth and development.<sup>494,495,496</sup> In fact, there is a modest positive impact; women using the minipill breast-feed longer and add supplementary feeding at a later time.<sup>498</sup> Because of the slight positive impact on lactation, the minipill can be started immediately after delivery. A study investigating the impact of early initiation found no adverse effects on breast-feeding.<sup>501</sup>

The minipill is a good choice in situations where estrogen is contraindicated, such as women smokers over the age of 35 or patients with serious medical conditions (diabetes with vascular disease, severe systemic lupus erythematosus,<sup>713</sup> cardiovascular disease). It should be noted that the freedom from estrogen effects, although likely, is presumptive. Substantial data, for example, on associations with vascular disease, blood pressure, and cancer, are not available because relatively small numbers have chosen to use this method of contraception. On the other hand, it is logical to conclude that any of the progestin effects associated with the combination oral contraceptives can be related to the minipill according to a dose-response curve; all effects should be reduced. Both the World Health Organization case-control study and the transnational case-control study could find no indication for increased risks of stroke, myocardial infarction, or venous thromboembolism with oral progestin-only contraceptives.<sup>502,503</sup> No impact can be measured on the coagulation system.<sup>700,714</sup> The minipill can probably be used in women with previous episodes of thrombosis, and the package insert in the United States was revised, eliminating vascular disease as a contraindication.

The minipill is a good alternative for the occasional woman who reports diminished libido on combination oral contraceptives, presumably due to decreased androgen levels. The minipill should also be considered for the few patients who report minor side effects (gastrointestinal upset, breast tenderness, headaches) of such a degree that the combination oral contraceptive is not acceptable.

Because of the relatively low doses of progestin administered, patients using medications that increase liver metabolism should avoid this method of contraception. These drugs include the following:

Carbamazepine (Tegretol)

Felbamate

Lamotrigine

Nevirapine

Oxcarbazepine

Phenobarbital

Phenytoin (Dilantin)

Primidone (Mysoline)

Rifabutin

Rifampicin (Rifampin)

St. John's wort

Topiramate

Vigabatrin

**Possibly** valproic acid, ethosuximide, griseofulvin, and troglitazone

Do the noncontraceptive benefits associated with combination oral contraception apply to the minipill? Studies are unable to help us with this issue, again because of the relatively small numbers of users. However, the progestin impact on cervical mucus, endometrium, and ovulation leads one to think the benefits will be present (reduced risks of pelvic infection, endometrial cancer, and ovarian cancer). Although limited by small numbers, one case-control study indicated that protection against endometrial cancer was even greater with progestin-only pills than with combination oral contraceptives.<sup>715</sup>

Good efficacy with the minipill requires regularity, taking the pill at the same time each day. There is less room for forgetting, and, therefore, the minipill is probably not a good choice for a disorganized adult or for the average adolescent.

# EMERGENCY CONTRACEPTION

# POSTCOITAL

The use of a method after intercourse to prevent pregnancy is commonly called postcoital contraception, or the “morning after” treatment. “Emergency contraception” is a more accurate and appropriate name, indicating the intention to be one-time protection. It is an important option for patients and should be considered when condoms break, when sexual assault occurs, if diaphragms or cervical caps dislodge, or with the lapsed use of any method. In studies at abortion units, 50–60% of the patients would have been suitable for emergency contraception and would have used it if readily available.<sup>716,717</sup> In the United States, it is estimated that emergency contraception could annually prevent 1.7 million unintended pregnancies and the number of induced abortions would decrease by about 40%.<sup>718</sup> Nevertheless, increasing access to emergency contraception has not had an impact on pregnancy or abortion rates in clinical trials, apparently because the actual use is insufficient to have an impact on the general population.<sup>719,720,721</sup> Availability must be accompanied by education and motivation. Clinicians should be aware that younger adolescents can safely use emergency contraception.<sup>722</sup>

Many women do not know of emergency contraception, and it has been difficult to obtain.<sup>717,723</sup> Even if women are aware of this method, accurate and detailed knowledge is lacking.<sup>724</sup> A favorable attitude toward this method requires both knowledge and availability. **The United States by the recent Food and Drug Administration approved over-the-counter levonorgestrel emergency contraception; it is available without a prescription.**

Women who have used emergency contraception are very satisfied with the method and, most importantly, do not express an intention to substitute this method for regular contraception.<sup>725</sup> The use of emergency contraception by adolescents is not associated with an increase in STIs.<sup>726</sup>

The use of large doses of estrogen to provide emergency contraception was pioneered by John Morris and Gertrude van Wageningen at Yale in the 1960s. The initial work in monkeys led to the use of high doses of diethylstilbestrol (25–50 mg/day) and ethinyl estradiol in women.<sup>727</sup> It was quickly appreciated that these extremely large doses of estrogen were associated with a high rate of gastrointestinal side effects. Albert Yuzpe developed a method utilizing a combination oral contraceptive, resulting in an important reduction in dosage.<sup>728</sup> The following treatment regimens, or their generic equivalents, have been documented to be effective:

**Ovral: 2 tablets followed by 2 tablets 12 hours later**

**Allesse: 5 tablets followed by 5 tablets 12 hours later**

**Lo Ovral, Nordette, Levlen, Triphasil, Trilevlen: 4 tablets followed by 4 tablets 12 hours later**

**The method of choice for emergency contraception is levonorgestrel alone**

**Levonorgestrel in a dose of 0.75 mg given twice, 12 hours apart, is more successful and better tolerated than the combination oral contraceptive method.<sup>729,730</sup> In many countries, special packages of 0.75 mg levonorgestrel (Plan B, NorLevo, Vikela) are available for emergency contraception. Greater efficacy and fewer side effects make low-dose levonorgestrel the treatment of choice.**

In the United States, Plan B containing only levonorgestrel (two 0.75-mg tablets) was approved by the FDA for nonprescription sales; one tablet is taken within 120 hours of intercourse and the second 12 hours later. **The two tablets can be combined into a single, one-time dose of 1.5 mg levonorgestrel with no loss of efficacy or increase in side effects.<sup>731,732</sup> The single-dose product, Plan B One-Step, is approved and available in the United States, also without a prescription.** The two-dose product is now available in the United States in a generic version known as Next Choice.

**Clinicians should consider providing advance information and a prescription or an emergency contraceptive kit to patients (a kit can be a simple envelope containing instructions and the appropriate number of oral contraceptives) to be taken when needed.** It would be a major contribution to our efforts to avoid unwanted pregnancies for all patients without contraindications to oral contraceptives to have emergency contraception available for use when needed. In our view, this would be much more effective in reducing the need for abortion than waiting for patients to call. In studies of self-administration, adult women in Scotland and younger women in California increased the use of emergency contraception without adverse effects such as increasing unprotected sex.<sup>733,734,735</sup> Women are able to use this nonprescription access effectively and do not develop a reliance on emergency contraception as a regular method.<sup>736</sup>

# Mechanism and Efficacy

There is strong evidence that treatment with emergency contraception acts primarily by preventing or delaying ovulation and by preventing fertilization.<sup>737,738,739,740,741</sup> Studies have indicated that emergency contraception does not prevent implantation.<sup>742,743,744</sup> Experiments in monkeys and rats could detect no effect of a high dose of levonorgestrel administered postcoitally once fertilization had occurred.<sup>745,746</sup> **The evidence indicates that a postfertilization effect does not contribute to the efficacy of emergency contraception.**<sup>740,745,746,747,748</sup> **Clinicians, pharmacists, and patients can be reassured that treatment with emergency contraception is not an abortifacient.**

Efficacy has been confirmed in large clinical trials and summarized in complete reviews of the literature.<sup>730,749,750,751</sup> Treatment with high doses of estrogen or with levonorgestrel yields a failure rate of approximately 1%, with the combination oral contraceptive, about 2–3%. The failure rate is lowest with high doses of ethinyl estradiol given within 72 hours (0.1%), but the side effects make this a poor choice. In general clinical use, the method with oral contraceptives can reduce the risk of pregnancy by about 75%; this degree of reduction in probability of conception (given the relatively low chance, about 8%, for pregnancy associated with one act of coitus)<sup>752</sup> yields the 2% failure rate measured in clinical studies.<sup>753,754,755</sup>

**Results with levonorgestrel are better, about an 85% reduction in the risk of pregnancy; in the worldwide World Health Organization study, the risk of pregnancy was 60% lower with the levonorgestrel-only method compared with the oral contraceptive method, with less than half as much nausea and vomiting.**<sup>730</sup>

# Treatment Method

Treatment should be initiated as soon after exposure as possible, and the standard recommendation is that it be no later than 120 hours. Careful assessment of the reported experience with emergency contraception indicated that the method is equally effective when started on the first, second, or third day after intercourse (which would allow user-friendly scheduling) and that efficacy extends beyond 72 hours.<sup>756,757</sup> Data from the World Health Organization randomized, clinical trial, however, support the importance of timing, finding a reduction in efficacy after 72 hours, and the greatest protection occurring when the medication is taken within 24 hours of intercourse.<sup>758</sup> Postponing the dose by 12 hours raises the chance of pregnancy by almost 50%. For this reason, the treatment should be initiated as soon as possible after sexual exposure, an important argument in favor of advance provision. Emergency contraception is ineffective in the presence of an established pregnancy. A delay in menses after treatment warrants testing for pregnancy and consideration for the possibility of an ectopic pregnancy.

When using oral contraceptives for emergency contraception, it is worth adding an antiemetic, oral or suppository, to the treatment; a long-acting nonprescription agent, 25 or 50 mg meclizine (Bonine, Dramamine II, Antivert), is recommended, to be taken 1 hour before the emergency contraception treatment. Side effects reflect the high doses used: nausea and vomiting, 50% and 20% with estrogen-progestin oral contraceptives, but only 18% and 4% with levonorgestrel.<sup>730,731,732</sup> Other reactions include breast tenderness, headache, dizziness, and bleeding or spotting in the month after treatment. If a patient vomits within an hour after taking pills, additional pills must be administered as soon as possible. Nausea and vomiting are experienced at such a lower rate with the levonorgestrel-only method that an antiemetic is not necessary.

An analysis of the U.K. General Practice Research Database could find no evidence for an increased risk of venous thromboembolism with the short-term use of oral contraceptives for emergency contraception (indeed, no cases were found for as long as 60 days after use in more than 100,000 episodes of use).<sup>759</sup> Short-term treatment with combined oral contraceptives has been documented to have no effect on clotting factors.<sup>760</sup> **Because of the high dose of estrogen, emergency contraception with combined oral contraceptives should be hesitantly used in women with either a personal or close family history (parent or sibling) of idiopathic thrombotic disease—consideration should be given to the copper IUD or the levonorgestrel-only method.**

A 3-week follow-up visit should be scheduled to assess the result and to counsel for routine contraception. **Even better, a method of contraception should be initiated immediately after the use of emergency contraception to avoid an unwanted**

**pregnancy.**

Could other combination oral contraceptive products be used? A norethindrone-ethinyl estradiol combination was found to be equally effective to the levonorgestrel-ethinyl estradiol formulation, and it is likely that any combination oral contraceptive would be successful.<sup>761</sup> However, this is a moot point because the levonorgestrel-only method is now the treatment of choice. The sustained release of estrogen or progestins from intrauterine (the levonorgestrel-releasing IUS), subdermal, or vaginal delivery methods cannot be used as emergency contraception because systemic hormone concentrations are too low and too slowly achieved.

# The Use of Progesterone Receptor Modulators for Emergency Contraception

## Mifepristone

Mifepristone in a single oral dose of 600 mg is associated with markedly less nausea and vomiting than with oral contraceptives and an efficacy rate of nearly 100%.<sup>762,763</sup> In randomized trials, 10 mg mifepristone was as effective as 25, 50, or 600 mg, preventing about 80–85% of expected pregnancies (the same efficacy and side effects as with the levonorgestrel method), with a slight decrease in efficacy when treatment was delayed to 5 days after intercourse.<sup>731,764,765,766</sup> Because the next menstrual cycle is delayed after mifepristone, contraception should be initiated immediately after treatment. Ironically, mifepristone, around which swirls the abortion controversy, can make an effective contribution to preventing unwanted pregnancies and induced abortions.

## Ulipristal Acetate

Ulipristal acetate (ellaOne) has similar biologic effects as mifepristone and is approved for emergency contraception in Europe and in the United States in a single oral dose of 30 mg. **Randomized trials demonstrated that ulipristal acetate is slightly more effective than the single 1.5-mg dose of levonorgestrel when used within 72 hours after sexual intercourse and even between 72 and 120 hours.**<sup>767,768</sup> Side effects are not severe and similar to those with levonorgestrel. Progesterone receptor modulators like ulipristal acetate and mifepristone suppress ovarian follicular growth and also delay endometrial maturation, manifested by a delay in menstruation after treatment. Ovulation can be temporarily postponed. **Thus, immediate initiation of a contraceptive method after treatment is even more important with the use of these drugs.**

## Other Methods

The three major problems with the available methods of emergency contraception are the high rate of side effects, the need to start treatment within 120 hours after intercourse, and the small, but important, failure rate.

Another method of emergency contraception is the insertion of a copper IUD, anytime during the preovulatory phase of the menstrual cycle and up to 5 days after ovulation. The failure rate (in a small number of studies) is very low, 0.1%.<sup>749,750</sup> This method definitely prevents implantation, but it is not suitable for women who are not candidates for intrauterine contraception, for example, multiple sexual partners or a rape victim. The use of a copper IUD for emergency contraception is expensive, but not if it is retained as an ongoing method of contraception.

The use of danazol for emergency contraception is not effective.<sup>762</sup>

# STEROID CONTRACEPTION FOR OLDER WOMEN

---

The years from age 35 to menopause can be referred to as the transition years. Preventive health care for women is especially important during the transition years. The issues of preventive health care are familiar ones. They include contraception, cessation of smoking, prevention of heart disease and osteoporosis, maintenance of mental well-being (including sexuality), and cancer screening. Management of the transition years should be significantly oriented to preventive health care, and the use of low-dose steroid contraception (including oral, vaginal, and transdermal methods of administration) can now legitimately be viewed as a component of preventive health care. **A discussion of the noncontraceptive health benefits of low-dose oral contraception is especially important with patients in their transition years. This group of women appreciates and understands decisions made with the risk/benefit ratio in mind.**

During this period of time, there are several medical needs that must be addressed: the need for contraception, the management of persistent anovulation, and, finally, menopausal and postmenopausal hormone therapy.

At approximately 40 years of age, the frequency of ovulation decreases. This initiates a period of waning ovarian function called the climacteric, which lasts several years, carrying a woman through decreased fertility and menopause to the postmenopausal years. Prior to menopause, the remaining follicles perform less well. As cycles become irregular, vaginal bleeding occurs at the end of an inadequate luteal phase or after a peak of estradiol without subsequent ovulation and corpus luteum formation. Eventually, many women live through a period of anovulation. Occasionally, corpus luteum formation and function occur, and therefore the older woman is not totally safe from the threat of an unplanned and unexpected pregnancy.

Because of a high rate of unintended pregnancy and less than adequate use of contraception, American women older than age 40 have had for the last two decades a high ratio of abortions per live births, a ratio very similar to that of teenagers.<sup>769</sup> Fortunately, clinicians and patients have recognized that low-dose steroid contraception is safe for healthy, nonsmoking, normotensive older women. Oral contraception fulfills a need, and we would argue that this population of women has a series of benefits to be derived from oral contraception that tilts the risk/benefit ratio to the positive side. The benefits of oral contraceptives reviewed in this chapter are especially pertinent for older women. A case-control study could find no evidence for an increased risk of breast cancer in women who used oral contraceptives **after age 40.**<sup>770</sup>

Despite the widespread teaching and publicity that smoking is a contraindication to oral contraceptive use over the age of 35, more older women who use oral contraceptives smoke and smoke heavily, compared with young women.<sup>206</sup> This strongly implies that older smokers are less than honest with clinicians when requesting oral contraception. **A former smoker must have stopped smoking for at least 12 consecutive months to be regarded as a nonsmoker. Women who have nicotine in their bloodstream obtained from patches or gum should be regarded as smokers.** Smokers over age 35 should continue to be advised that combined estrogen-progestin contraceptives are not a good choice, regardless of the number of cigarettes smoked. In view of the unreported high rate of smoking in older women who use oral contraceptives, clinicians should use 20- $\mu$ g estrogen products for women over age 35.

A product containing 20  $\mu$ g ethinyl estradiol and 150  $\mu$ g desogestrel has been demonstrated in multicenter studies of women over age 30 to have the same efficacy and side effects as pills containing 30 and 35  $\mu$ g of estrogen.<sup>771,772,773</sup> In a randomized study of women over age 30, this formulation was associated with the virtual elimination of any effects on coagulation factors.<sup>733</sup> Indeed, formulations with 20  $\mu$ g ethinyl estradiol have no significant impact on the measurements of clotting factors, even in smokers.<sup>119,120,774,775</sup>

Although it is true that the implied safety of the lowest estrogen dose remains to be documented by epidemiologic studies, it seems clinically prudent to maximize the safety margin in this older age group of women. Although there may be some increase in breakthrough bleeding, we believe that older women who understand the increased safety implicit in the lowest estrogen dose are more willing to endure breakthrough bleeding and maintain continuation. With avoidance of risk factors and use of lowest-dose pills, health risks are negligible for healthy nonsmoking, normotensive women. For healthy nonsmoking women, no specific laboratory screening is necessary beyond that, which is usually incorporated in a program of preventive health care.

As discussed previously, because of reduced fecundity, the minipill achieves near-total efficacy in women over age 40. Therefore, the progestin-only minipill is a good choice for older woman and especially for those women in whom estrogen is contraindicated. Older women are more accepting of irregular menstrual bleeding when they understand its mechanism and, thus, are more accepting of the progestin-only minipill. Older women who are smokers or women with hypertension, migraine headaches with aura, obesity, or vascular disease should be encouraged to use progestin-only methods or an intrauterine device.

# Anovulation and Bleeding

Throughout the transitional period of life, there is a significant incidence of dysfunctional uterine bleeding due to anovulation. While the clinician is usually alerted to this problem because of irregular bleeding, clinician and patient often fail to diagnose anovulation when bleeding is not abnormal in schedule, flow, or duration. As a woman approaches menopause, a more aggressive attempt to document ovulation is warranted. A serum progesterone level measured approximately 1 week before menses is simple enough to obtain and worth the cost. The prompt diagnosis of anovulation (serum progesterone  $<3$  ng/mL) will lead to appropriate therapeutic management that will have a significant impact on the risk of endometrial cancer.

In an anovulatory woman with proliferative or hyperplastic endometrium (unaccompanied by atypia), periodic oral progestin therapy is mandatory, such as 5–10 mg medroxyprogesterone acetate given daily the first 2 weeks of each month. If hyperplasia is already present, follow-up aspiration office curettage after 3–4 months is required. If progestin treatment is ineffective and histologic regression is not observed, more aggressive treatment is warranted. Monthly progestin treatment should be continued until withdrawal bleeding ceases or menopausal symptoms are experienced. These are reliable signs (in effect, a bioassay) indicating the onset of estrogen deprivation and the need for the addition of estrogen in a postmenopausal hormone program.

Two case-control studies, one using data from the WHO Collaborative Study and one using the data from the U.K. General Practice Research Database, assessed the risk of idiopathic venous thrombosis in users of progestins alone for therapeutic purposes and concluded that therapeutic progestins alone may be associated with an increased risk of venous thromboembolism.<sup>776,777</sup> These epidemiologic conclusions were based on extremely small numbers and had very wide confidence intervals. Patients who receive progestin only for therapeutic reasons are probably older and are more likely to have family histories of cardiovascular disease. In addition, a problem of preferential prescribing is probably present in that clinicians are more likely to promote the use of progestin only for women they perceive to be at greater risk of venous thromboembolism. Thus, it is likely that the case groups represented a higher-risk group than the control groups in these reports. For these reasons, we do not believe progestins are associated with an increased risk of venous thromboembolism.

If contraception is desired, the clinician and patient should seriously consider the use of steroid contraception. The anovulatory woman cannot be guaranteed that spontaneous ovulation and pregnancy will not occur. The use of a low-dose oral contraceptive will at the same time provide contraception and prophylaxis against irregular, heavy anovulatory bleeding and the risk of endometrial hyperplasia and

neoplasia. In some patients, oral contraceptive treatment achieves better regulation of menses than monthly progestin administration.

Clinicians often prescribe a traditional postmenopausal hormone regimen to treat a woman with the kind of irregular cycles usually experienced in the perimenopausal years. This addition of exogenous estrogen without a contraceptive dose of progestin when a woman is not amenorrheic or experiencing menopausal symptoms is inappropriate and even risky (exposing the endometrium to excessively high levels of estrogen). **And most importantly, a postmenopausal hormonal regimen does not inhibit ovulation and provide contraception.**<sup>778</sup> The appropriate response is to regulate anovulatory cycles with monthly progestational treatment along with an appropriate contraceptive method or to utilize low-dose steroid contraception. The oral contraceptive that contains 20 µg estrogen provides effective contraception, improves menstrual cycle regularity, diminishes bleeding, and relieves menopausal symptoms.<sup>779</sup>

# When to Change from Oral Contraception to Postmenopausal Hormone Therapy

A common clinical dilemma is when to change from steroid contraception to postmenopausal hormone therapy. It is important to change because even with the lowest-estrogen dose oral contraceptive available, the estrogen dose is fourfold greater than the standard postmenopausal dose, and with increasing age, the dose-related risks with estrogen become significant. One approach to establish the onset of the postmenopausal years is to measure the FSH level, beginning at age 50, on an annual basis, being careful to obtain the blood sample on day 6 or 7 of the pill-free week in a standard regimen (when steroid levels have declined sufficiently to allow FSH to rise). When FSH is greater than 20 IU/L, it is time to change to a postmenopausal hormone program. Because of the variability in FSH levels experienced by women around the menopause, this method is not always accurate.<sup>780,781</sup> Indeed, in some women, FSH will not rise until 2 weeks after the last pill. To wait 2 weeks is not very practical and places the patient at risk for an unwanted pregnancy. However, the pill-free week method is practical and works for most women. Of course, this approach is not usable for women on extended regimens. An empiric approach allows patients to enter their mid-50s on low-dose steroid contraception and then switches to a postmenopausal hormone regimen when she is almost certainly in menopause.

# CONCLUDING THOUGHTS

---

In the 1970s, as epidemiologic data first became available, we emphasized in our teaching and in our communication with patients the risks and dangers associated with oral contraceptives. In the 1990s, with better patient screening and epidemiologic data documenting the effects of low-dose products, we appropriately emphasized the benefits and safety of modern oral contraceptives. In the new millennium, we can with confidence promote the idea that the use of oral contraceptives yields an overall improvement in individual health, and from a public health point of view, the collection of effects associated with oral contraceptives leads to a decrease in the cost of health care.

Contraceptive advice is a component of good preventive health care, and the clinician's approach is a key factor. Patients deserve to know the facts and need help in dealing with the state of the art and those issues clouded by uncertainty. But there is no doubt that patients are influenced in their choices by their clinician's advice and attitude. Although the role of a clinician is to provide the education necessary for the patient to make proper choices, one should not lose sight of the powerful influence exerted by the clinician in the choices ultimately made. Emphasizing the safety and benefits of oral contraceptives, and the contribution of oral contraceptives to individual and public health, allows a clinician to present oral contraception with a very positive attitude, an approach that makes an important contribution to a patient's ability to make appropriate health choices.

## Long-Acting Methods of Contraception

The rate of unintended pregnancies and the relatively high failure rates with the typical use of hormonal and barrier methods of contraception are strong indications of a need for long-acting contraceptive methods that simplify compliance. Three effective and popular methods are available, contraceptive implants (systems with the sustained release of a progestin), depot-medroxyprogesterone acetate (Depo-Provera), and intrauterine devices (IUDs).

Injectable depot-medroxyprogesterone acetate is a long-acting (3 months) agent that has been part of the contraceptive programs of many countries for more than 30 years. This experience has demonstrated it to be safe and effective. It is not a “sustained-release” system, but its action is essentially the same. Over 35 million women worldwide use this as their primary method of contraception.<sup>1</sup>

The contraceptive implant uses either levonorgestrel or etonogestrel as the progestin. Nexplanon is currently available in the United States, replacing Implanon, and is a single rod releasing etonogestrel. The Norplant and Jadelle (formerly called Norplant-2) systems release levonorgestrel. A Chinese version is called Sinoplant II. Jadelle is approved by the U.S. Food and Drug Administration, but is not marketed, and Norplant was withdrawn from the U.S. market. In many parts of the world, Jadelle has replaced the use of Norplant; however, Norplant is still used worldwide.

Norplant consists of six capsules, and Jadelle has two rods. Like Norplant, Nexplanon and Implanon have been extensively marketed throughout the world with a good track record and high continuation rates. Contraceptive implants are approved in more than 60 countries and used by approximately five million women.<sup>1</sup>

Current intrauterine contraceptives include hormonal systems and copper systems. Hormonal systems release levonorgestrel and include the Mirena, Skyla, Kyleena, and Liletta—these release between 12 and 20 mcg of levonorgestrel a day. Copper IUDs contain between 200 and 380 mm<sup>2</sup> of copper wire. This group of IUDs is represented in the United States by the TCu-380A (the ParaGard) and in the rest of the world by the TCu-200, the TCu-220C, the Nova T, the Multiload-250, and the Multiload-375. The Sof-T is a copper IUD used only in Switzerland. More flexible and even frameless IUDs are being marketed in Europe, such as the FlexiGard, the Ombrelle-250, and the Ombrelle-380. Over 103 million woman worldwide use an IUD as their contraceptive choice.<sup>1</sup>

The long-acting progestin methods and IUDs are as effective as sterilization and more effective than oral and barrier contraception.<sup>2</sup> An important reason for this high efficacy in actual use is the nature of the delivery systems themselves, which require little effort on the part of the user. Because compliance does not require frequent resupply or instruction in use, as with oral contraception, the actual or typical use effectiveness is very close to the theoretical (lowest expected) effectiveness.

Sustained-release methods require less of the user, but they demand more of the clinician. Implants and IUDs involve minor operative procedures for placement and for discontinuation. Clinicians have a special responsibility to become skillful in these operations and to be available to women when those skills are required to terminate use. Disturbances of menstrual patterns and other side effects prompt many more questions from patients about these methods than about the use of the familiar oral and barrier contraceptives.<sup>3</sup> When women do switch to long-acting methods, there may be a higher continuation rate and a lower unintended pregnancy rate.<sup>4</sup>

# IMPLANT SYSTEMS

---

Norplant was developed by the Population Council and first approved in 1983 in Finland, where it was manufactured. It was approved in the United States in 1990, marketed in 1991, and withdrawn from the market in 2002. Norplant is a “sustained-release” system using silastic tubing permeable to steroid molecules to provide stable circulating levels of synthetic progestin over years of use. The Norplant system consists of six capsules, each measuring 34 mm in length with a 2.4 mm outer diameter and containing 36 mg crystalline levonorgestrel. The capsules are made of flexible, medical-grade silastic (polydimethylsiloxane and methylvinyl siloxane copolymer) tubing that is sealed shut with silastic medical adhesive (polydimethylsiloxane).

Jadelle was also developed by the Population Council and manufactured in Finland. It was approved in the United States in 1996, but never marketed. The thin, flexible Jadelle rods are wrapped in silastic tubing (the same material used by Norplant), 43 mm in length and 2.5 mm in diameter, thus slightly longer and thicker than Norplant.<sup>5</sup> Each rod contains 75 mg levonorgestrel for a total of 150 mg, 66 mg less than that in the six Norplant capsules. Whereas the levonorgestrel in Norplant is packed into the capsules in crystal form, the core of the Jadelle rod is a mixture of levonorgestrel and an elastic polymer (dimethylsiloxane/methylvinylsiloxane). Long-term clinical trials indicate that the performance and side effects are similar to Norplant, but removal is faster (Table 23.1).<sup>6,7</sup>

## TABLE 23.1 Norplant and Jadelle Average Release Rates

## Norplant

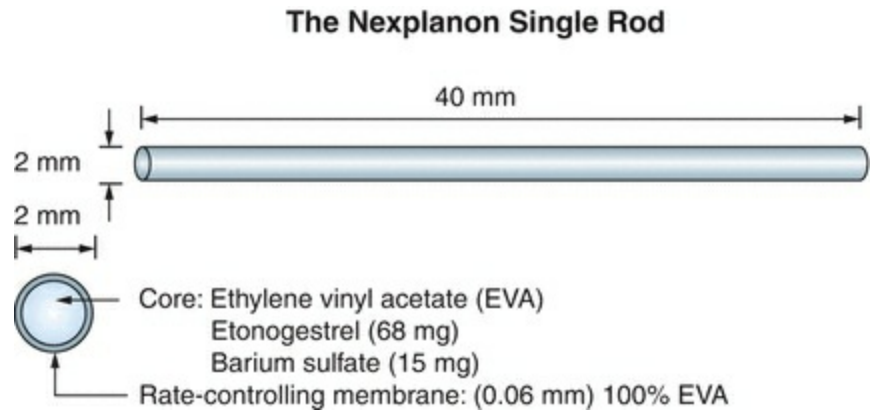

First month	85 mg levonorgestrel daily
After 1 year	35 mg
After 2 years	30 mg

## Jadelle

First month	100 mg levonorgestrel daily
After 1 year	40 mg
After 2 years	30 mg

Because the release rates with the two levonorgestrel systems are comparable, it is reasonable to conclude that clinical studies with Norplant and Jadelle should yield similar results. In the discussion that follows, the more-studied product, Norplant, is often cited, but clinicians can assume that the findings apply as well to Jadelle.

Nexplanon is a single flexible rod 4 cm long and 2 mm in diameter that contains 68 mg of 3-keto desogestrel (etonogestrel, the active metabolite of desogestrel) and 15 mg barium sulfate (for radio-opacity) dispersed in a core of ethylene vinyl acetate. There is no evidence that either ethylene vinyl acetate or silastic has toxic effects when implanted.<sup>8</sup> Randomized controlled trials showed no significant difference in etonogestrel secretion compared with the Implanon. The hormone is released at an initial rate of about 67 mg/day decreasing to 30 mg after 2 years; concentrations that inhibit ovulation are achieved within 8 hours of insertion.<sup>9,10</sup> A steady state is achieved after 4 months; after which there is a gradual decline. Nexplanon, placed subdermally with a disposable inserter, can be expected to suppress ovulation for 2.5 years and provide effective contraception for at least 3 years. Side effects are similar to those with Norplant or Jadelle, except for less bleeding and a higher rate of amenorrhea with etonogestrel implant<sup>11,12,13,14</sup> (**Figure 23.1**).

**FIGURE 23.1**

# Indications

Contraceptive implants are a good choice for women of reproductive age who are sexually active and desire long-term, continuous contraception. Implants should be considered for women who:

1. Want to delay the next pregnancy for at least 2–3 years
2. Desire a highly effective, long-term method of contraception
3. Experience serious or minor estrogen-related side effects with estrogen-progestin contraception
4. Have difficulty remembering to take pills every day, have contraindications or difficulty using IUDs, or desire a non-coitus-related method of contraception
5. Have completed their childbearing but are not yet ready to undergo permanent sterilization
6. Have a history of anemia with heavy menstrual bleeding
7. Intend to breast-feed for a year or two
8. Have chronic illnesses, in which health will be threatened by pregnancy

# **Absolute Contraindications**

Implant use is contraindicated in women who have:

- 1. Active thrombophlebitis or thromboembolic disease**
- 2. Undiagnosed genital bleeding**
- 3. Acute liver disease**
- 4. Benign or malignant liver tumors**
- 5. Known or suspected breast cancer**

# Other Medical Eligibility Criteria

Based on clinical judgment and appropriate medical management, implants **MAY BE USED** by women with a history of or current diagnosis of the following conditions:

1. Heavy cigarette smoking (15 or more daily) in women older than 35 years
2. History of ectopic pregnancy
3. Diabetes mellitus. Because multiple studies have failed to observe a significant impact on carbohydrate metabolism, implants, in our view, are particularly well suited for diabetic women.
4. Hypercholesterolemia
5. Hypertension
6. History of cardiovascular disease, including myocardial infarction, cerebral vascular accident, coronary artery disease, angina, or a previous thromboembolic event
7. Patients with artificial heart valves
8. Gallbladder disease
9. Chronic disease, such as immunocompromised patients

Implants are not contraindicated in the following situations, but other methods are preferable:

1. Severe acne
2. Severe vascular or migraine headaches
3. Severe depression
4. Concomitant use of medications that induce microsomal liver enzymes:

Carbamazepine (Tegretol)

Felbamate

Griseofulvin

Lamotrigine

Nevirapine

Oxcarbazepine

Phenobarbital

Phenytoin (Dilantin)

Primidone (Mysoline)

Rifabutin

Rifampicin (Rifampin)

St. John's wort

Topiramate

Vigabatrin

Possibly troglitazone

We do not recommend the use of implants with any of the previously listed drugs because of a likely increased risk of pregnancy due to lower blood levels of the progestin.<sup>15,16,17</sup>

## Mechanism of Action

The release rate of the contraceptive implants is determined by the total surface area and the density of the implant in which the progestin is contained. The progestin diffuses from the implant into the surrounding tissues where it is absorbed by the circulatory system and distributed systemically, avoiding an initial high level in the circulation as with oral or injected steroids. Within 8 hours after insertion of Nexplanon, plasma concentrations of etonogestrel are about 300 ng/mL, high enough to prevent ovulation.<sup>18</sup> A study of cervical mucus changes with Norplant indicates that a backup method should be used for 3 days after insertion of Norplant or Jadelle; this is not necessary when Nexplanon is inserted as directed.<sup>19,20</sup> Progestin concentrations are much more variable with Norplant and Jadelle than with the etonogestrel implants.<sup>18</sup>

The Nexplanon rod releases 60 mg of etonogestrel per 24 hours at 3 months of use. This rate declines gradually to 40–50 mg daily by 12 months and 30 mg/day by 2 years of use. The 85 mg of hormone released by Norplant or the 100 mg released by Jadelle during the first few months of use is about equivalent to the daily dose of levonorgestrel delivered by the progestin-only minipill oral contraceptive and 25–50% of the dose delivered by low-dose combined oral contraceptives. After 6 months of use, daily levonorgestrel concentrations are about 0.35 ng/mL; at 2.5 years, the levels decrease to 0.25–0.35 ng/mL. Until the 8-year mark, mean levels remain above 0.25 ng/mL.<sup>21</sup> Mean plasma concentrations below 0.2 ng/mL are associated with increased pregnancy rates for Norplant (lower levels are more likely in heavier women).

Body weight affects the circulating levels of levonorgestrel; the greater the weight of the user, the lower the levonorgestrel concentrations at any time during Norplant or Jadelle use. The greatest decrease over time occurs in women weighing more than 70 kg (154 lb), but even for heavy women, the release rate is high enough to prevent pregnancy at least as reliably as oral contraceptives. In Nexplanon users, etonogestrel concentrations are affected very little by body weight, and failure rates did not increase with increasing body weight in the small numbers of overweight women in clinical trials.<sup>22,23</sup> Although the data with overweight women are limited, it is likely that Nexplanon is a good contraceptive choice for obese women.

Levonorgestrel levels can also be affected by the circulating levels of sex hormone-binding globulin (SHBG). Levonorgestrel has a higher affinity for SHBG than does etonogestrel. In the week after Norplant or Jadelle insertion, SHBG levels decline rapidly and then return to approximately half of preinsertion levels by 1 year of use. This effect on SHBG is not uniform and may account for some of the individual variations in circulating progestin concentrations.<sup>24</sup>

Implants are highly effective contraceptives. There are three probable modes of

action, which are similar to those attributed to the contraceptive effect of the progestin-only minipills, but because daily dosing is not required, implants are more effective than oral methods:

1. The progestin suppresses, at both the hypothalamus and the pituitary, the luteinizing hormone (LH) surge necessary for ovulation. As determined by progesterone levels in many users over several years, approximately one-third of all cycles in Norplant users are ovulatory.<sup>21,25</sup> During the first 2 years of use, only about 10% of women are ovulatory, but by 5 years of use, more than 50% are. In those cycles that are ovulatory, there is a high incidence of luteal insufficiency. The etonogestrel implant inhibits ovulation throughout a 3-year period, accounting for almost all of the contraceptive effect.<sup>10</sup> However, follicular development does occur, avoiding the problem of clinically significant hypoestrogenemia, and in the last 6 months of the 3-year period, there is an occasional ovulation.<sup>18,26</sup>
2. The steady release of progestin has a prolonged effect on the cervical mucus. The mucus thickens and decreases in amount, forming a barrier to sperm penetration.<sup>20,26,27,28</sup>
3. The progestin suppresses the estradiol-induced cyclic maturation of the endometrium and eventually causes atrophy. These changes could prevent implantation should fertilization occur; however, no evidence of fertilization can be detected in Norplant users.<sup>29</sup>

# Advantages

Implants are a safe, highly effective, continuous method of contraception that requires little user effort and, unlike long-acting injectable contraception, is rapidly reversible. Because this is a progestin-only method, it can be used by women who have contraindications for the use of estrogen-containing contraceptives. The sustained release of low doses of progestin avoids the high initial dose delivered by injectables and the daily hormone surge associated with oral contraceptives. Implants are an excellent choice for a breast-feeding woman and can be inserted immediately postpartum. There are no effects on breast milk quality or quantity, and infants grow normally.<sup>30,31,32,33</sup> Another advantage of the implant method is that it allows women to plan their pregnancies precisely; return of fertility occurs within a few weeks, in contrast to the 6–18-month delay in ovulation that can follow depot-medroxyprogesterone acetate injections.<sup>22,34,35,36</sup>

The degree of efficacy of long-acting contraceptive methods is nearly equivalent to the theoretical effectiveness. In couples for whom elective abortion is unacceptable in the event of an unplanned pregnancy, the high efficacy rate is especially important. Additionally, users should be reassured that implant use has not been associated with changes in carbohydrate or lipid metabolism, coagulation, liver or kidney function, or immunoglobulin levels. Because women wanting implants may have had negative experiences with other contraceptives, it is important that the differences between this method and previous methods be explained.

Exposure of endometriosis to progestin-only contraceptive methods is an effective method to manage the pain associated with this condition. Etonogestrel implants, depot-medroxyprogesterone acetate, and the levonorgestrel-containing IUD have all been reported to reduce endometriosis pain ([Chapter 32](#)).<sup>37,38,39,40,41</sup> As discussed in the chapter on endometriosis, this disease can become resistant to progesterone action, and low concentrations of progestins provided by these devices do not always suffice to fully treat aggressive forms of the disease.

# Disadvantages

There are some disadvantages associated with the use of the implant systems. Implants cause disruption of bleeding patterns, and 11% of women may discontinue etonogestrel implants due to bleeding irregularities they find unacceptable.<sup>22</sup> Endogenous estrogen is nearly normal, and unlike the estrogen-progestin contraceptives, progestin is not regularly withdrawn to allow endometrial sloughing. Consequently, the endometrium sheds at unpredictable intervals.

The implants must be inserted and removed in a surgical procedure performed by trained personnel. Women cannot initiate or discontinue the method without the assistance of a clinician. The incidence of complicated removals is approximately 5% for Norplant or Jadelle and lower for Nexplanon, an incidence that can be best minimized by good training and careful insertion.<sup>42,43</sup> The implants can be visible under the skin. This sign of the use of contraception may be unacceptable for some women and for some partners.

Implants do not provide protection against sexually transmitted infections (STIs) such as herpes, human papillomavirus, human immunodeficiency virus (HIV), gonorrhea, or chlamydia. Although users may be less likely to use a second method because of the high contraceptive efficacy,<sup>44</sup> users at risk for STIs must use condoms as a second method to prevent infection.

Because the insertion and removal of implants require minor surgical procedures, initiation and discontinuation costs are higher than with oral contraceptives or barrier methods. The cost of implants plus fees for insertion totals an amount that may seem high to patients unless they compare it with the total cost of using other methods (including the higher risk of an unintended pregnancy).<sup>45,46,47</sup> Studies have shown that cost neutrality is achieved at 1–2 years of use. Nevertheless, short-term use is expensive compared with the relatively low initial costs of other reversible methods, and most women do not use long-acting methods for their full duration of action.

Cultural factors can influence the acceptability of menstrual changes. Some cultures restrict a woman from participating in religious activity, household activities, or sexual intercourse while menstruating. All users must be aware of the possible menstrual changes. It is important to stress that all of the menstrual changes are expected, that they do not cause or represent illness, and that most women revert back to a more normal pattern with increasing duration of use.

Insertion and removal of implants will be a new experience for most women. As with any new experience, women will approach it with varying degrees of apprehension and anxiety. In reality, most patients are able to watch in comfort as implants are inserted or removed. Women should be told that the incisions used for the procedures

are very small and heal quickly, leaving small scars that are usually difficult to see because of their location and size.

We encourage prospective users to see and touch implants. Women can be reassured that the implants will not be damaged or move if the skin above them is accidentally injured. Normal activity cannot damage or displace the implants. Most women do not notice their presence. The implants are more visible in slender women with good muscle tone. Darker-skinned users may notice further darkening of the skin directly over the implants; this resolves after removal.

# Efficacy

Contraceptive implants provide highly effective birth control. In 2-year or 3-year studies in 11 international clinical trials of 942 women using an etonogestrel implant, no pregnancies occurred.<sup>22</sup> In studies of Norplant conducted in 11 countries, totaling 12,133 woman-years of use, the pregnancy rate was 0.2 pregnancies per 100 woman-years of use.<sup>16,34</sup> All but one of the pregnancies that occurred during the Norplant evaluation were present at the time of implant insertion. If these luteal phase insertions are excluded from analysis, the 1st-year pregnancy rate was 0.01 per 100 woman-years. In adolescents, Norplant implants provide better protection against unwanted pregnancy compared with oral contraceptives and are more likely to be continued.<sup>44,48,49</sup> A recent review shows the 1-year continuation rate of implants among adolescents is 84%<sup>50</sup> (Table 23.2).

## **TABLE 23.2 Failure Rates During the 1st Year of Use, United States**

Method	Percent of Women with Pregnancy	
	Lowest Expected	Typical
No method	85%	85%
Combination pill	0.3%	8.7%
Progestin only	0.5%	3.0%
IUDs		
Levonorgestrel IUS	0.1%	0.1%
Copper T-380A	0.6%	1.0%
Implants		
Six levonorgestrel capsules (Norplant)	0.05%	0.2%
Two levonorgestrel rods (Jadelle)	0.06%	0.06%
One etonogestrel rod (Implanon)	0.01%	0.01%
Injectable		
3 months	0.3%	0.3%
1 month	0.05%	3.0%
Patch	0.3%	8.0%
Vaginal ring	0.3%	8.0%
Female sterilization	0.5%	0.7%
Male sterilization	0.1%	0.2%

Data from **Trussell J, Vaughan B**, Contraceptive failure, method-related discontinuation and resumption of use: results from the 1995 National Survey of Family Growth, *Fam Plann Perspect* 31:64, 1999; **Fu H, Darroch JE, Haas T, Ranjit N**, Contraceptive failure rates: new estimates from the 1995 National Survey of Family Growth, *Fam Plann Perspect* 31:58, 1999; **Kost K, Singh S, Vaughan B, Trussell J, Bankole A**, Estimates of contraceptive failure from the 2002 National Survey of Family Growth, *Contraception* 77:10, 2008.

**There are no weight restrictions for Norplant or Jadelle users, but heavier women (more than 70 kg) may experience slightly higher pregnancy rates in the later years of use compared with lighter women. Even in the later years, however, pregnancy rates for heavier women using Norplant are lower than with oral contraception.** The differences in pregnancy rates by weight are probably due to the dilutional effect of larger body size on the low, sustained serum levels of levonorgestrel.

The contraceptive efficacy of etonogestrel implants surpasses that of Norplant and sterilization.<sup>22</sup> Only a rare pregnancy occurs, resulting in a Pearl Index of about 0.01.<sup>26,51</sup> In over 70,000 cycles, no pregnancies were recorded because of total inhibition of ovulation until ovulations were observed in the last 6 months of the 3-year period.<sup>26,52</sup> Postmarketing surveillance of pregnancies in Australia, where nearly one-quarter of contraceptors relied on etonogestrel implants in 2004, revealed that of 218 pregnancies, only 13 could possibly have been failures of the method.<sup>53</sup> In Australia and the Netherlands, pregnancies commonly were the consequence of poor insertion technique, especially allowing the implant to fall unnoticed to the floor.

**Implants have an immediate contraceptive effect when inserted within the first 7 days of a menstrual cycle, but when insertion is after day 7, a backup method of contraception is necessary for at least 3 days.**<sup>54</sup>

# Ectopic Pregnancy

The ectopic pregnancy rate during Norplant use is 0.1–2.9 per 1,000 woman-years.<sup>55</sup> Although the risk of developing an ectopic pregnancy during the use of Norplant is low, when pregnancy does occur, ectopic pregnancy should be suspected because approximately 30% of Norplant pregnancies are ectopic. It is estimated that 2.3% of pregnancies with the etonogestrel implant in place are ectopic<sup>55</sup> (Table 23.3).

**TABLE 23.3 Ectopic Pregnancy Rates Per 1,000 Woman-Years**

Noncontraceptive users, all ages	3.0–4.5
Copper T-380 IUD	0.20
Norplant	0.28

Data from **Centers for Disease Control and Prevention**, Ectopic pregnancy—United States, 1988–1989, MMWR 41:591, 1992; **Franks AL, Beral V, Cates W Jr, Hogue CJ**, Contraception and ectopic pregnancy risk, Am J Obstet Gynecol 163:1120, 1990; **Sivin I**, International experience with Norplant and Norplant-2 contraceptives, Stud Fam Plann 19:81, 1988.; **Sivin I**, International experience with Norplant and Norplant-2 contraceptives, Stud Fam Plann 19:81, 1988.

# Menstrual Effects

Menstrual bleeding patterns are highly variable among users of implant contraception. With levonorgestrel implants, some alteration of menstrual patterns will occur during the 1st year of use in approximately 80% of users, later decreasing to about 40% and, by the 5th year, to about 33%.<sup>56,57,58,59</sup> The changes include alterations in the interval between bleeding, the duration and volume of menstrual flow, and spotting. Oligomenorrhea and amenorrhea also occur but are less common, less than 10% after the 1st year and diminishing thereafter. Studies of the endometrium in Norplant users experiencing abnormal bleeding indicate the presence of enlarged venous sinusoids (fragile vessels) and a reduction in the expression of the proteins involved in the initiation of hemostasis.<sup>60</sup> It is believed that bleeding is a consequence of rapid endometrial regression and the apparent increase in the density and tortuosity of blood vessels seen after Norplant insertion.<sup>61</sup>

Etonogestrel implants alter menstrual patterns, but amenorrhea occurs more often (21% of users in the 1st year, 30–40% after 1 year) than with Norplant.<sup>12,14</sup> A single etonogestrel rod completely suppresses ovulation for 2.5 years, and, therefore, menses do not become more regular after the first 2 years as with Norplant. After 2 years, ovulation occurs in about half of the menstrual cycles. Bleeding is lighter and less frequent among etonogestrel implant users because more profound ovarian suppression results in less follicular estrogen production and less endometrial stimulation; nevertheless, irregular bleeding continues to be a major reason for discontinuation.<sup>14</sup>

Despite an increase in the number of spotting and bleeding days over preinsertion menstrual patterns, hemoglobin concentrations rise in Norplant users because of a decrease in the average amount of menstrual blood loss.<sup>62,63,64 65</sup> Etonogestrel implants likewise are not associated with anemia.<sup>13</sup>

Implant users who can no longer tolerate prolonged bleeding will benefit from a short course of oral estrogen: conjugated estrogens, 1.25 mg, or estradiol, 2 mg, administered daily for 7 days.<sup>66</sup> Another approach is to administer an estrogen-progestin oral contraceptive for 1–3 months.<sup>67</sup>

**Although implants are very effective, pregnancy must be considered in women reporting amenorrhea who had been ovulating previously, as evidenced by regular menses prior to an episode of amenorrhea.** A sensitive urine pregnancy test should be obtained. Women who remain amenorrheic throughout their use of implants are unlikely to become pregnant.<sup>57</sup> It is important to explain to patients the mechanism of the amenorrhea: the local progestational effect causing decidualization and atrophy.

# Metabolic Effects

Exposure to the sustained, low doses of progestin delivered by the implants is not associated with significant metabolic changes. Studies of liver function,<sup>11,68,69</sup> blood coagulation,<sup>11,70,71,72</sup> immunoglobulin levels,<sup>73,74</sup> serum cortisol levels,<sup>75</sup> and blood chemistries<sup>69,73</sup> have failed to detect changes outside of normal ranges in Norplant users. No major impact on the lipoprotein profile can be demonstrated with Norplant.<sup>68,76,77</sup> Minor changes are transient, and, with prolonged duration of use, lipoproteins return to preinsertion levels. There are no clinically important effects on carbohydrate metabolism.<sup>73,78,79</sup> No effect on insulin sensitivity can be detected.<sup>80</sup> In a cohort study of 5 years' duration, no increase was observed in diabetes mellitus, depression, lupus erythematosus, and cardiovascular diseases—in fact, there was no increase in serious morbidity.<sup>81</sup> A slight increase in gallbladder disease has been noted in Norplant users.<sup>11,82</sup> This is at best just a word of caution because the association is weak and may reflect preexisting disease, and there is no apparent biologic mechanism.

**There are no significant metabolic differences when using the etonogestrel implant, as compared with the levonorgestrel implant and as compared with a nonhormonal method of contraception.**<sup>83,84,85</sup> One study showed that fasting glucose and insulin sensitivity markers may worsen in obese etonogestrel implant users.<sup>86</sup> Neither implant system has important clinical effects on the lipoprotein profile, carbohydrate metabolism, thyroid and adrenal function, liver function tests, nor the clotting mechanism.<sup>11,82,87</sup> Implant contraception is a good choice for a woman at risk for estrogen-associated thromboembolism. Because of the lower androgenic characteristic of etonogestrel, Nexplanon does not cause a decrease in the levels of SHBG.<sup>87</sup>

Measurements of bone density in young women reveal that etonogestrel implants and Norplant do not affect the teenage gain in the bone; similar gains in the bone were recorded in implant users and control subjects.<sup>88,89</sup> In older women, an increase in forearm, spine, and femur bone density has been documented after 6 and 12 months of Norplant use.<sup>90,91</sup> An international cross-sectional study reported a small loss in bone density with Norplant that was rapidly regained after discontinuation.<sup>92</sup>

# Effects on Future Fertility

Circulating levels of progestin become too low to measure within 48 hours after removal of implants. Most women resume normal ovulatory cycles during the 1st month after removal. The pregnancy rates during the 1st year after removal are comparable with those of women not using contraceptive methods and trying to become pregnant. There are no long-term effects on future fertility nor are there any effects on sex ratios, rates of ectopic pregnancy, spontaneous miscarriage, stillbirth, or congenital malformations.<sup>34,35</sup> The rate and outcome of subsequent pregnancies are not influenced by duration of use.

For women who are spacing their pregnancies, the difference between implants and depot-medroxyprogesterone acetate in the timing of the return to fertility can be critical. Implants allow precise timing of pregnancy because the return of ovulation after removal is prompt. Etonogestrel serum levels are undetectable within 1 week after removal of Nexplanon, and ovulation can be expected in the 1st month after discontinuation.<sup>9,10</sup> Depot-medroxyprogesterone acetate, on the other hand, can cause up to 18 months' delay in return to fertility. By that time, 90% of users of either method will have ovulated, but in the first several months, the difference is dramatic. By 3 months after removal, half of implant users will have ovulated, but 10 months must elapse before half of depot-medroxyprogesterone acetate users are ovulatory.

## Side Effects

The occurrence of serious side effects is very rare, no different in incidence than that observed in the general population. In addition to the menstrual changes, levonorgestrel implant users have reported the following side effects: headache, acne, weight change, mastalgia, hyperpigmentation over the implants, hirsutism, depression, mood changes, anxiety, nervousness, ovarian cyst formation, and galactorrhea.<sup>16,56,57,58</sup> Attribution of these side effects to levonorgestrel is difficult. Careful study fails to reveal a relationship between Norplant use and depressive symptoms.<sup>93</sup> Although most of these side effects are minor in nature, they can cause patients to discontinue the method. Patients often find common side effects tolerable after assurance that they do not represent a health hazard.<sup>3</sup> Many complaints respond to reassurance; others can be treated with simple therapies. The most common side effect experienced by users is headache (16% of etonogestrel implant users); approximately 20% of women who discontinue use do so because of headache.<sup>22</sup>

Stroke, thrombotic thrombocytopenic purpura, thrombocytopenia, and pseudotumor cerebri have been reported with Norplant.<sup>94</sup> However, it is by no means established that the incidence of these problems is increased, and there is little reason to suspect a cause-and-effect relationship. In the follow-up study conducted by the World Health Organization in eight countries, no significant excess of cardiovascular events or malignant disease was observed.<sup>95</sup> Similarly, studies looking at rates of adverse events in etonogestrel implants found no increased likelihood.<sup>43</sup>

## Weight Change

Women using levonorgestrel implants more frequently complain of weight gain than of weight loss, but findings are variable and most studies have not been randomized.<sup>96</sup> Assessment of weight change in contraceptive implant users is confounded by changes in exercise, diet, and aging. Although an increase in appetite can be attributed to the androgenic activity of levonorgestrel, it is unlikely that the low levels with Norplant have any clinical impact. Counseling for weight changes focuses best on dietary review and dietary changes.

A 5-year follow-up of 75 women with Norplant implants could document no increase in the body mass index (nor was there a correlation between irregular bleeding and body weight).<sup>94</sup> A similar experience has been documented with etonogestrel implants.<sup>13</sup>

## Mastalgia

Approximately 10% of etonogestrel implant users will complain of bilateral mastalgia.<sup>13,22</sup> This symptom decreases with increasing duration of implant use. In women with the Norplant, it is noted premenstrually and is associated with complaints of fluid retention.

After pregnancy has been ruled out, reassurance and therapy aimed at symptomatic relief are indicated. The most effective treatments for mastalgia are the following: danazol (200 mg/day), vitamin E (600 U/day), bromocriptine (2.5 mg/day), or tamoxifen (20 mg/day), but there are no studies of these treatments in implant users.

## **Galactorrhea**

Galactorrhea is more common among women who have had insertion of the implants on discontinuation of lactation. Pregnancy and other possible causes should be ruled out by performing a pregnancy test and a thorough breast examination. Patients can be reassured that this is a common occurrence among implant and oral contraceptive users. Decreasing the amount of breast and nipple stimulation during sexual relations might alleviate the symptom, but if amenorrhea accompanies persistent galactorrhea, a prolactin level should be obtained.

## **Acne**

Acne, with or without an increase in oil production, is the most common skin complaint among levonorgestrel implant users. The acne is caused by the direct androgenic activity of the levonorgestrel and also a decrease in SHBG levels, leading to an increase in free steroid levels (both levonorgestrel and testosterone).<sup>21</sup> This is in contrast to combined oral contraceptives that contain levonorgestrel, as the estrogen effect on SHBG (an increase) produces a decrease in unbound, free androgens. Etonogestrel implants are less commonly associated with acne because this progestin is less androgenic than levonorgestrel.<sup>13,18</sup> Common therapies for complaints of acne include dietary change, practice of good skin hygiene with the use of soaps or skin cleansers, and application of topical antibiotics (e.g., 1% clindamycin solution or gel or topical erythromycin).

## **Ovarian Cysts**

Unlike oral contraception, the low serum progestin levels maintained by levonorgestrel implants do not suppress follicle-stimulating hormone (FSH), which continues to stimulate ovarian follicle growth in most users. The LH peak during the first 2 years of use, on the other hand, is usually abolished so that these follicles do not ovulate.<sup>18</sup> However, some continue to grow and cause pain or they are palpated at the time of

pelvic examination.<sup>97</sup> Because these are simple cysts (and most regress spontaneously within 1 month of detection), they need not be laparoscopically evaluated.<sup>43</sup> Further evaluation is indicated if they became large and painful or fail to regress. Etonogestrel implants suppress follicular development more profoundly; thus, ovarian cysts are less likely than with levonorgestrel implants.

## Cancer

We can speculate on possible effects of implants based on our experience with oral contraceptives and depot-medroxyprogesterone acetate. The risk of endometrial cancer should be reduced. A study of the endometrial effects of Norplant failed to find any evidence of hyperplasia, even when levonorgestrel levels were low and endogenous estradiol production was normal.<sup>98</sup> The risk of ovarian cancer is also probably reduced, and we would expect a greater effect with Nexplanon because it more effectively suppresses ovulation. Breast and cervical cancer effects will be difficult to assess because of confounding variables as they are with oral contraception and depot-medroxyprogesterone acetate. The low progestin dose of implants, however, would be unlikely to have effects different from other hormonal contraceptives. In a very large case-control study, neither depot-medroxyprogesterone acetate nor implants were associated with an increase in the risk of breast cancer.<sup>99</sup>

# Postmarketing Surveillance Study

A large 5-year follow-up study in developing countries confirmed the low pregnancy rates associated with Norplant, 0.23 per 100 woman-years for intrauterine pregnancy and 0.03 per 100 woman-years for ectopic pregnancy.<sup>96</sup> When the women using Norplant were compared with women using nonhormonal methods of contraception and to the expected population rates, there was no excess of cancers, connective tissue diseases, or cardiovascular events. Importantly, the complaints of headache and mood disturbances (including anxiety and depression) were similar to those reported by women using oral contraceptives, although higher than for women using IUDs.

# Insertion and Removal

The usual personal and family medical history and physical examination should concentrate on factors that might contraindicate the use of the various contraceptive options. If a patient elects to use contraceptive implants, a detailed description of the method, including effectiveness, side effects, risks, benefits, as well as insertion and removal procedures, should be provided. Before insertion, the patient is asked to read and sign a written consent for the surgical placement of the implants. The consent reviews the potential complications of the procedure that include reaction to the local anesthetic, infection, expulsion of the implants, superficial phlebitis, bruising, and the possibility of a subsequent difficult removal.

Insertion can be performed at any time during the menstrual cycle as long as pregnancy can be ruled out. If the patient's last menstrual period was abnormal, if she has recently had sexual intercourse without contraception, or if there are reasons to suspect pregnancy, a sensitive urine pregnancy test is a wise precaution. Based on cervical mucus changes, a backup method need be used no more than 3 days after insertion.<sup>20</sup> Implants can be inserted immediately postpartum but certainly should be initiated no later than the 3rd postpartum week in non-breast-feeding women and the 3rd postpartum month in breast-feeding women. Acne and headache are less common in women who receive Norplant immediately postpartum, and there is no difference in postpregnancy weight loss compared with women who receive it 4–6 weeks later.<sup>100</sup>

## Key Points

- Insert anytime during the first 5 days of the menstrual cycle if hormonal contraception is not being used.
- If hormonal contraception is being used, insert anytime during the hormone-free interval. If steroid contraception is used continuously, insert at anytime.
- If progestin-only contraception is being used, insert on the same day the next progestin injection is due or an implant or IUD is removed. With progestin-only oral contraception, insertion can be performed anytime.
- Insert anytime within the first 5 days after an abortion or before the 4th postpartum week in non-breast-feeding women.
- Insert before the 4th postpartum month in breast-feeding women.
- An implant can be inserted immediately postpartum.
- No backup method is necessary if timing of insertion follows the above suggestions. If insertion occurs at other times, backup contraception is necessary for at least 3 days after insertion.

---

Patients should be questioned about allergies to local anesthetics, antiseptic solutions, and tape. A discussion about the technique of insertion and anticipated sensations is an important part of preparing the patient for the experience. All patients approach insertion with some degree of apprehension that can be decreased by detailed explanations and preparation.<sup>101,102</sup>

Selection of the site for placement of implants is based on both functional and esthetic factors. Various sites (the upper leg, forearm, and upper arm) have been used in clinical trials. The nondominant, upper, inner arm is the best site. This area is easily accessible to the clinician with minimal exposure of the patient. It is well protected during most normal activities. It is not highly visible, and migration of the implants from this site has not been documented. The site of placement does not affect circulating progestin levels. Careful implant insertion is the key to trouble-free removal.

The etonogestrel implant offers important insertion advantages compared with Norplant.<sup>103</sup> The single-rod system simplifies and shortens both insertion and removal. In addition, a preloaded applicator is provided that facilitates placement. If necessary, Nexplanon can usually be visualized by ultrasonography.<sup>104</sup> However, if a nonpalpable rod is not visible on ultrasonography, definitive localization can be achieved with x-ray.<sup>9</sup> Removal of the etonogestrel rod uses the “fingers alone” technique with a 2-mm incision.<sup>105</sup> Insertion complications (mainly deep insertions) are rare, and removal complications (difficulty finding the implant or a broken implant) occur at a far greater lower frequency compared with Norplant.<sup>103</sup>

## Insertion Technique

Insertion is carried out under local anesthesia in the office or clinic by someone, usually a physician or nurse practitioner, trained in the technique described here.<sup>106,107</sup> The procedure takes 5–10 minutes for a six-implant system and 2–3 minutes for a single implant<sup>108</sup> (Table 23.4, Figure 23.2).

### **TABLE 23.4 Required Equipment for Nexplanon Insertion**

---

2.5-mL syringe

---

0.5-inch, 25-gauge needle for injecting the anesthetic

---

1% chlorprocaine or lidocaine without epinephrine

---

Antiseptic solution

---

Adhesive strip for puncture closures

---

Elastic pressure bandage

---

**FIGURE 23.2**

## Positioning the Patient

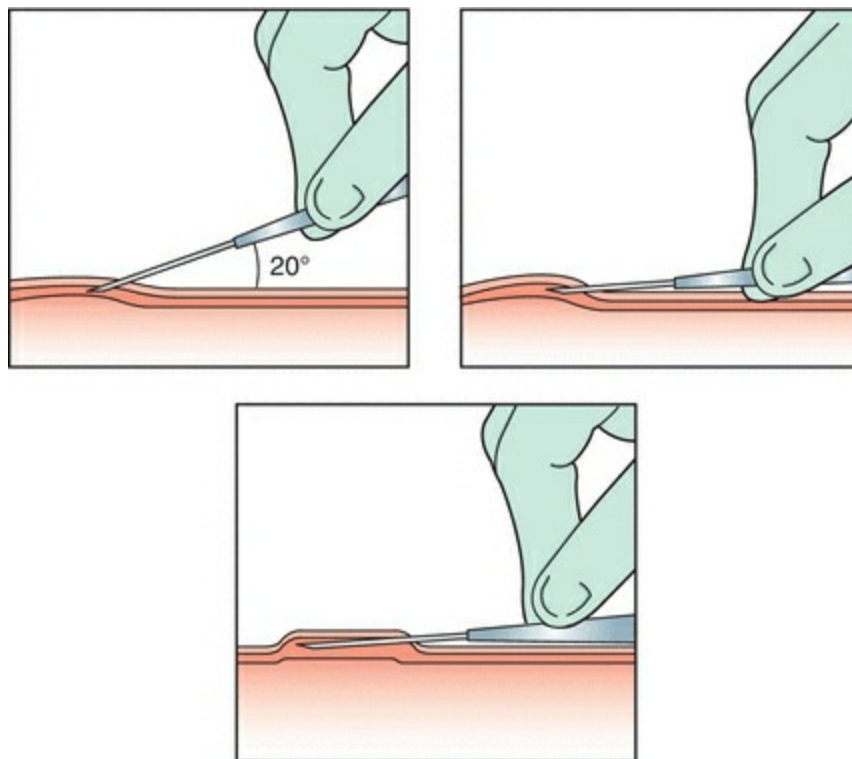

The patient is placed in a supine position with the full length of her arm exposed. The

upper inner arm is positioned by bending the elbow to 90 degrees and rotating the arm out, allowing full exposure of the insertion site at the crease between the biceps and triceps muscles. Adequate support under the arm should be provided to ensure comfort. To minimize the risk of infection, strict aseptic technique should be maintained throughout the procedure. An insertion site approximately 8–10 cm superior and lateral to the medial epicondyle of the humerus is identified. A sterile drape is placed under the arm, and the insertion site on the arm is cleaned with an antiseptic such as povidone-iodine.

## Anesthesia

Local anesthesia for the incision is obtained by raising a wheal of 1% chloroprocaine or lidocaine using a 25-gauge needle and injecting 2 mL under the skin along the track of the implant insertion needle.

**Verify the presence of Nexplanon** by looking carefully at the tip of the needle. If the implant (a white rod) is not visible, turn the applicator needle down and gently tap on a surface with the needle cover in place until the Nexplanon is seen; then tap the base of the applicator with the needle pointed up until the implant is no longer visible. Keep the applicator sterile ([Figure 23.3](#)).

**FIGURE 23.3**

## Incision and Placement

The insertion needle can be pushed directly through the skin at no greater than a 20-degree angle without making an incision. The needle is advanced as superficially as possible under the skin by maintaining a slightly upward angle on the trocar. To minimize the chance of too deep insertion, lift or tent the skin with the tip of the needle. If the skin dimples, the needle is too superficial. Pull the needle back and redirect. Advance the needle to its full length while applying counter traction to the skin at the insertion site.

Once the needle has been fully advanced, move the purple slider on the applicator fully back until it stops. This will retract the needle inside the body of the applicator. The applicator can then be removed.

Immediately after insertion, palpate the implant to verify correct insertion (both ends should be palpable). Show the patient how to palpate the implant. If the implant is not palpable, look at the applicator and verify that only the purple tip of the obturator is visible inside the needle (the white rod cannot be seen). The location can also be confirmed with ultrasound or x-ray, and alternative contraception should be used until the location is confirmed. After the insertion, place an adhesive closure or bandage over the insertion site. Complete the patient chart label and the “User Card” that must be given to the patient.

Most women experience little pain during the insertion,<sup>103</sup> but if it occurs, the discomfort can be relieved with aspirin, acetaminophen, or a nonsteroidal anti-inflammatory agent. Infection or expulsion of the implants is rare (<1% with the Norplant system) and usually occurs when an implant is left pressing against the incision.<sup>106</sup>

The most commonly reported discomfort is a burning sensation during the injection of the local anesthetic. This effect of local anesthetic can be eliminated for most patients by adding 1 mEq of sodium bicarbonate to each 10 mL of anesthetic (this shortens shelf life to 24 hours).<sup>109</sup> After the onset of anesthesia in 2–3 minutes, most women feel no more than a pressure sensation.

# Complications of Insertion

Potential complications include infection, hematoma formation, local irritation or rash over the implants, expulsion of the implant, and allergic reactions to adhesives of the dressing. Etonogestrel implants can migrate a short distance (<2 cm) over time.<sup>110</sup> The incidence of complications is minimized by clinician training and experience and the use of strict aseptic technique.

## Infection

The rate of infection varies among clinics and countries. The overall risk of infection after Norplant insertion is 0.8%.<sup>111</sup> Infections usually occur within the 1st week after insertion but can present as long as 4–5 months later. Infection can be treated either by the removal of the implant or the administration of oral antibiotics while the implant remains in place. One-third of insertion site infections treated with antibiotics are unresponsive to therapy and require removal.<sup>111</sup> There have been no reports of infections leading to serious injury. Rarely, a superficial phlebitis develops. If it resolves over 1–2 weeks with heat and elevation of the arm, the implants need not be removed.

## Expulsion

Expulsion of one or more of the implants occurs in 0.4% of Norplant users, usually within the first few months.<sup>111</sup> In a large systematic review, no etonogestrel implant expulsions were noted.<sup>50</sup> The majority of expulsions are associated with concurrent infection at the insertion site. Another cause of expulsion is failure to advance the implants far enough from the incision, causing pressure on the incision by the distal tip of the implant.

## Local Reactions

Although not common, hematomas can form. The use of a pressure dressing for 72 hours will prevent enlargement. Application of an ice pack for 30 minutes immediately after insertion also helps. Local irritation, rash, pruritus, and pain occur in 4.7% of Norplant users, usually during the 1st month of use.<sup>111</sup> Allergies to skin closure strip adhesives or to latex gloves account for some reactions.<sup>112</sup> These problems resolve spontaneously, but itching can be relieved by topical corticoid steroids.

# Removal Techniques

Although implant removal is an office procedure requiring only a small amount of local anesthesia and a few simple instruments, instruction and practice are necessary.<sup>106,107</sup>

Practicing on a model arm after viewing an instructional video makes first removals faster and less uncomfortable for both clinician and patient. A removal kit with a model arm, a manual, and a compact disc illustrating the technique is available at no charge from Merck at 877-467-5266. As for insertion, the patient should read and sign an informed consent to be filed in her medical record. We recommend that the patient be given a copy.

Proper positioning of the implant at the time of insertion is the most important factor influencing ease of removal. If the Norplant implants have been inserted with the distal tips (those away from the axilla) far apart or with implants crossing or touching one another or too deeply, a larger incision and more time are required. Removal is easiest when the implants are just under the skin with their distal tips close together in a fan shape. The fibrous sheaths that form around implants can also make removal more difficult, especially if they are dense. The one and two implant systems can be removed faster and with less pain than the six Norplant capsules.<sup>103</sup>

Most removals are not painful (80% of patients reported pain as “none” or “slight”), and systemic analgesia is not required.<sup>108,113</sup> Time for removal of six capsules ranges from 5 to 40 minutes, with an average of 20 minutes. For the single rod (Nexplanon), the average time is about 4 minutes.<sup>108</sup> The most common cause of discomfort during the procedure is injection of the local anesthetic. Patients may feel pressure or tugging from manipulation of the fibrous sheaths and the implants, but these sensations are not severe if the clinician waits a few minutes after injection of the local anesthetic. The sheaths that form around the Nexplanon are less dense than those around Norplant capsules.

## Removal with Instruments

This approach to removal is the one described in the Nexplanon package insert. The patient is placed in a supine position with her arm flexed and externally rotated as for insertion. A sterile towel is placed under the arm. Palpate the implant and mark the end closest to the elbow. Clean the area overlying the implant with an antiseptic solution, preparing a wide area above and below the implant so that the incision won't be contaminated during manipulations for removal. Drape the arm with a fenestrated towel and use a third towel to create a sterile field for instruments on a Mayo stand or table.

Wearing sterile gloves, an incision site is selected by pressing down on the

proximal end of the implant and palpating their distal tips with a finger. Careful selection of the incision site is the most critical step for easy removal. The best incision site is right at the distal tip. This may be the same as the insertion site, but generally the removal incision is made a few millimeters higher up on the arm to ensure placing it as close as possible to the tip of the implant.

A local anesthetic containing 1:100,000 epinephrine reduces bleeding and allows better visualization of the implants. The 25-gauge needle is used to raise a wheal of local anesthetic just under the tip of the implant. About 1 mL is sufficient, although more may be required later. Injection of too much anesthetic over the implant can obscure the tip and make removal more difficult. A 2-mm incision is made with the no.11 scalpel at the preselected incision site. Implants can be removed by the clinician either sitting or standing, but if sitting, a wheeled stool allows repositioning as needed.

The implant is pushed gently toward the incision with the fingers until the tip is visible and can be grasped with a curved mosquito clamp. If a fibrous sheath is covering the implant, it is incised with the scalpel and the implant can be removed with forceps. If the implant tip cannot be guided to the incision with digital pressure on the skin at the proximal end of the implant, the jaws of the straight mosquito are inserted into the incision and opened just beneath the skin to separate the tissue layers. The curved clamp is inserted with the tips pointing upward toward the skin. The clamp is opened and the implant is guided down between the jaws with a forefinger on the skin above the implant. This downward pressure on the tips of the clamp is often the most painful part of the removal procedure. When the implant is pushed between the jaws of the clamp, the clamp is secured at the first or second ratchet. Too much pressure on the implant can fracture the silastic capsule, making removal more difficult. If the implant cannot be seen, after gentle traction, the clamp handle is flipped 180 degrees until it points in the opposite direction, toward the patient's head. A portion of the sheath is cleared with an opened sponge, or if necessary, the scalpel tip, incising longitudinally, not across the implant. The exposed portion is then grasped with the straight clamp, the curved clamp is released, and the implant is removed with gentle traction.

At the completion of the procedure, the implant should be inspected and measured to be sure it was removed in its entirety. The Nexplanon rod is 4 cm long. An adhesive strip is used to close the incision while pinching the skin edges together. A pressure dressing is then applied as after insertion and removed the next day. The fibrous sheath can remain for months causing the patient to think that implants were left behind. For that reason, it is important to show the implant to the patient at the time of removal.

If removal of some of the implant is difficult, painful, or prolonged, the procedure should be interrupted, and the patient should return in a few weeks to complete the removal. The location of the implant should always be known, either through palpation or imaging, prior to attempts at removal. A new incision can be made closer to the

implant or portion of implant that was difficult to remove the first time. Even if a portion of the implant remains, the patient should immediately begin to use another method of contraception.

## Difficult Removals

The incidence of difficult removals in the large postmarketing surveillance study of Norplant was 10.1 per 1,000 removals.<sup>94</sup> For the etonogestrel implant, the rate of difficult removals was 1.4 per 1,000 removals.<sup>107</sup> Removal is more difficult if the implant system is broken during attempts to extract them. Once an implant is damaged, it can fracture repeatedly with further attempts to grasp it with clamps. To decrease this risk, the implants should be grasped at their ends whenever possible and as little traction as possible should be used for exposure and removal. If the scalpel is required to open the fibrous sheath around the implant, care should be taken to avoid slicing the capsule. If it has not been possible to grasp the end of implant, in order to open the fibrous sheath, cut longitudinally along the length of the implant, not across. Rarely, removal of cut or broken implants will require an additional incision at the proximal end of the implant so that the remaining piece can be removed. Even more rarely, an implant can neither be palpated under the skin nor found through an incision. Such “lost” implants are most easily located with a high-frequency (7–10 mHz), short-focus ultrasound just prior to the removal procedure to help place the incision directly over the implant.<sup>114</sup> Use a transverse orientation to identify the shadow (the implant itself is more difficult to see), reposition the transducer to identify its length and both ends, and measure the depth with electronic calipers. Draw lines representing the location on the surface of the skin. Real-time sonography guidance can be useful during the removal procedure. Because it is readily available and can be employed during removal, sonography is a first choice. If a Nexplanon cannot be identified with ultrasonography, an x-ray can allow for better localization.

## Reinsertion

A new implant can be inserted immediately through the same incision used to remove the old implant, or a new implant can be placed in the other arm.

# Reasons for Termination

Approximately 56% of women continue etonogestrel implants for the entire 3 years.<sup>115</sup> Discontinuation of implants occurs at a rate of 10–15% yearly, about the same as for intrauterine contraception but lower than for barrier or oral contraception.<sup>16,58,115,116,117</sup> Bothersome side effects, such as menstrual changes, headache, or weight change, are the primary reasons for termination of implant use.<sup>43,93,118,119</sup> Menstrual changes are the most common cause for discontinuation of implants in the 1st year of use. An unspoken concern for many patients and their partners is the fact that bleeding irregularity interferes with sexual interactions. Users who cannot tolerate these symptoms request removal in the first 2 years of use, whereas women who want another pregnancy, the most common personal reason for removal, are more likely to terminate use in the 3rd or 4th year.

# User Acceptance of Contraceptive Implants

Overall, interview surveys throughout the world have indicated that women perceive sustained-release methods as highly acceptable methods of contraception.<sup>102,119,120</sup> The most popular feature of implants is their ease of use. Approximately 20% of US patients reported that friends and relatives notice their implants. This may be a greater problem in warmer climates with less encompassing clothing. Only 25% of the women who report that the implants were noticed were bothered by this attention.<sup>3</sup>

In the United States, the primary motivations for implant use have been problems with previous contraceptive methods and ease of implant use. Although fear of pain during implant insertion is a prominent source of anxiety for many women, the actual pain experienced does not match the expectations. The level of satisfaction has been high in self-motivated and well-informed users.<sup>4</sup> Teenagers provide an example of well-documented success. Their 1-year pregnancy rates are much lower, and continuation rates much higher than that with oral contraceptives.<sup>50,121,122,123,124</sup> However, teenage discontinuation of the method due to side effects (especially irregular bleeding and weight gain) is more common with Norplant.<sup>48</sup> The lower rate of irregular bleeding with Nexplanon contributes to higher patient acceptability, but irregular bleeding continues to be the major reason for discontinuation.<sup>14,119</sup>

# Counseling Women

Frank information about negative factors such as irregular bleeding will avoid surprise and disappointment and encourage women to continue use long enough to enjoy the positive attributes such as convenience, safety, and efficacy. Open discussion of side effects will lead to public and media awareness of the disadvantages as well as the advantages of these methods. Helping women decide if they are good candidates for use of implants before they invest too much time and money in long-acting contraception is a very important objective of good counseling.

Common patient questions regarding contraceptive implants are as follows:

- Is it effective?
- How is it inserted and removed; how long do these procedures take; does it hurt; and will it leave scars?
- Will the implants be visible under the skin?
- Will the implants be uncomfortable or restrict movement of the arm?
- Will the implants move in the body?
- Will the implants be damaged if they are touched or bumped?
- Will this contraceptive change sexual drive and enjoyment?
- What are the short- and long-term side effects?
- Are there any effects on future fertility?
- What do the implants look and feel like?
- What happens if pregnancy occurs during use?
- How long will it take for the method to be effective after insertion?
- Can a partner tell if this method is being used?

## Other Single-Rod Systems

Uniplant (also Surplant) is a single implant contraceptive, containing 55 mg nomegestrol acetate in a 4-cm silicone capsule with a 100 mg/day release rate. It provides contraception for 1 year.<sup>125</sup> A single silicone implant containing nesterone (Nestorone) is effective for 2 years; another version (Elcometrine) lasts 6 months.<sup>126,127</sup>

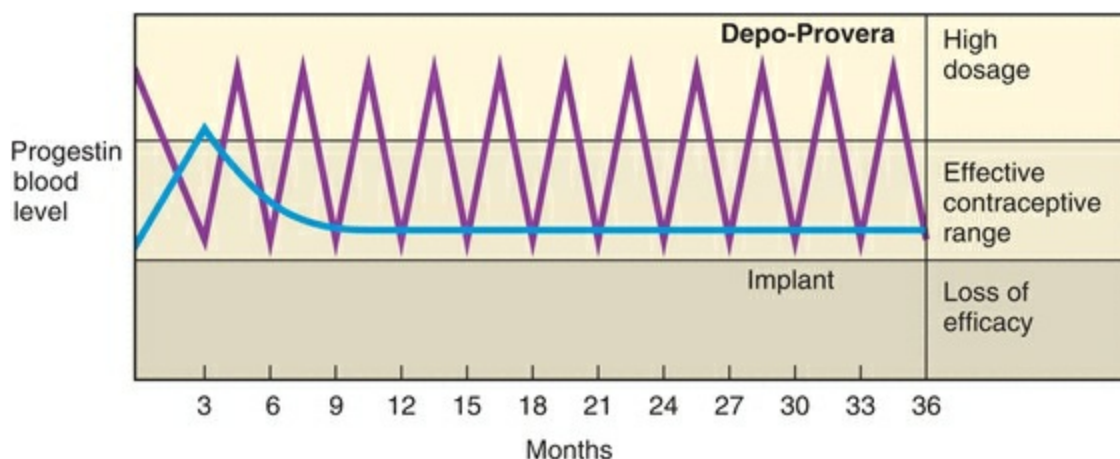

# INJECTABLE CONTRACEPTION

Depot-medroxyprogesterone acetate (Depo-Provera) is the most thoroughly studied progestin-only contraceptive. It has been available in some countries since the mid-1960s and in the United States since 1992. Much of our knowledge of the safety, efficacy, and acceptability of long-acting hormonal contraception comes from Indonesia, Sri Lanka, Thailand, and Mexico where depot-medroxyprogesterone acetate has been used and studied for decades. The long-delayed approval as a contraceptive in the United States was based on political and economic considerations, not scientific ones.<sup>128</sup>

Depot-medroxyprogesterone acetate is formulated as microcrystals, suspended in an aqueous solution. The correct dose for contraceptive purposes is 150 mg intramuscularly (gluteal or deltoid) every 3 months. A comparative trial established that the 100-mg dose is significantly less effective.<sup>129</sup> The contraceptive level is maintained for at least 14 weeks, providing a safety margin for one of the most effective contraceptives available, about 1 pregnancy per 100 women after 5 years of consistent use.<sup>129,130</sup>

A newer formulation allows the self-administration into a thigh or the abdomen of a subcutaneous dose of 104 mg every 3 months.<sup>131,132,133</sup> Prefilled syringes contain 0.65 mL of an aqueous suspension of medroxyprogesterone acetate.

Depot-medroxyprogesterone acetate is not a “sustained-release” system; it relies on higher peaks of progestin to inhibit ovulation and thicken cervical mucus. The difference between serum levels of progestins in a sustained-release system like Nexplanon and a depot system like depot-medroxyprogesterone acetate is illustrated in [Figure 23.4](#).

**FIGURE 23.4**

Other widely used injectables are norethindrone enanthate, 200 mg every 2 months, and the monthly injectables, Lunelle (25 mg medroxyprogesterone acetate and 5 mg estradiol cypionate) and Mesigyna (50 mg norethindrone enanthate and 5 mg estradiol valerate).

# Mechanism of Action

The mechanism of action of depot-medroxyprogesterone acetate is different from the other lower-dose, progestin-only methods because, in addition to thickening of the cervical mucus and alteration of the endometrium, the circulating level of the progestin is high enough to effectively block the LH surge, and, therefore, ovulation does not occur.<sup>134</sup> FSH is not suppressed as it is with the combination oral contraceptive; therefore, follicular growth is maintained sufficiently to produce estrogen levels comparable to those in the early follicular phase of a normal menstrual cycle.<sup>135</sup> Symptoms of estrogen deficiency, such as vaginal atrophy or a decrease in breast size, do not occur.

Accidental pregnancies occurring at the time of the initial injection of depot-medroxyprogesterone acetate have been reported to be associated with higher neonatal and infant mortality rates, probably due to an increased risk of intrauterine growth restriction.<sup>136,137</sup> The timing of the first injection is, therefore, very important. To ensure effective contraception, the first injection should be administered within the first 5 days of the menstrual cycle (before a dominant follicle emerges), or a backup method is necessary for 7 days.<sup>131,138,139,140</sup> The Quick Start, same-day start protocol can be used with depot-medroxyprogesterone acetate, with special care to rule out pregnancy and providing a backup method for 7 days.<sup>141</sup> Same-day starts with depot-medroxyprogesterone acetate produce better continuation rates with fewer unintended pregnancies.<sup>142</sup>

The duration of action can be shortened if attention is not paid to proper administration. The intramuscular injection must be given deeply by the Z-track technique and not massaged. It is prudent to avoid locations at risk for massage by daily activities.

When given properly, there is an effective 2-week grace period that allows for late reinjections; a study of women arriving late for reinjections concluded that even a 4-week late reinjection provided equivalent protection against pregnancy.<sup>143</sup> Women who are more than 4 weeks late for reinjection should be tested for pregnancy, reinjected if the test is negative, and advised to use backup contraception for 7 days.

# Efficacy

The efficacy of this method (in both the intramuscular and subcutaneous formulations) is slightly better than that of sterilization and better than that of all the other temporary methods.<sup>49,50,131,132,133,144,145</sup> In a comparison of the intramuscular and subcutaneous methods, the blood levels of medroxyprogesterone acetate are approximately 30% lower with subcutaneous administration of the lower dose, but efficacy is not impaired.<sup>131</sup> Because serum concentrations are relatively high, efficacy is not influenced by weight (making this method a good choice for overweight women) or by the use of medications that stimulate hepatic enzymes.<sup>131,132</sup>

# Indications

1. At least 1 year of birth spacing desired
2. Highly effective long-acting contraception not linked to coitus
3. Private, coitally independent method desired
4. Estrogen-free contraception needed
5. Breast-feeding
6. Sickle cell disease
7. Seizure disorder

# **Absolute Contraindications**

1. Pregnancy
2. Unexplained genital bleeding
3. Severe coagulation disorders
4. Previous sex steroid-induced liver adenoma

# Relative Contraindications

1. Liver disease
2. Severe cardiovascular disease
3. Rapid return to fertility desired
4. Difficulty with injections
5. Severe depression

# Advantages

Like sustained-release forms of contraception, depot-medroxyprogesterone acetate is not associated with compliance problems and is not related to the coital event. Continuation rates are better and repeat pregnancy rates are reduced compared with oral contraceptive use in teenagers; however, continuation and repeat pregnancy rates are similar when adolescents begin these methods in the immediate postpartum period.<sup>146,147</sup> Depot-medroxyprogesterone acetate is useful for women whose ability to remember contraceptive requirements is limited. It should be considered for women who lead disorganized lives or who are mentally challenged.

The freedom from the side effects of estrogen allows depot-medroxyprogesterone acetate to be considered for patients with congenital heart disease, sickle cell anemia, patients with a previous history of thromboembolism, and women over age 30 who smoke or have other risk factors such as hypertension or diabetes mellitus. The absolute safety in regard to thrombosis is mainly theoretical; it has not been proven in a controlled study. However, an increased risk of thrombosis has not been observed in epidemiologic evaluation of depot-medroxyprogesterone acetate users nor in a systematic review, and a World Health Organization (WHO) case-control study could find no evidence for increased risks of stroke, myocardial infarction, or venous thromboembolism.<sup>130,148,149</sup>

Two case-control studies, one using data from the WHO Collaborative Study and one using the data from the UK general practice research database, assessed the risk of idiopathic venous thrombosis in users of progestins alone for therapeutic purposes, not for contraception, and concluded that therapeutic progestins alone may be associated with an increased risk of venous thromboembolism.<sup>150,151</sup> These epidemiologic conclusions were based on extremely small numbers (only three cases in one report and five in the other) and had very wide confidence intervals. Patients who receive progestin only for therapeutic reasons are probably older and are more likely to have family histories of cardiovascular disease. In addition, a problem of preferential prescribing is present in that clinicians are more likely to promote the use of progestin only for women they perceive to be at greater risk of venous thromboembolism. Thus, it is likely that the case groups represented a higher risk group than the control groups in these reports. For these reasons, we do not believe progestins are associated with an increased risk of venous thromboembolism.

An important advantage exists for patients with sickle cell disease because evidence indicates an inhibition of in vivo sickling with hematologic improvement during treatment.<sup>152</sup> Both the frequency and the intensity of painful sickle cell crises are reduced.<sup>153</sup>

Another advantage is the finding that depot-medroxyprogesterone acetate increases the quantity of milk in nursing mothers, a direct contrast to the effect seen with estrogen-progestin oral contraception. The concentration of the drug in the breast milk is negligible, and no effects of the drug on infant growth and development have been observed.<sup>154,155,156</sup> In a careful study of male infants being breast-fed by women treated with depot-medroxyprogesterone acetate, no metabolites of depot-medroxyprogesterone acetate could be detected in the infant's urine, and no alterations could be observed in the infant levels of FSH, LH, testosterone, and cortisol.<sup>157</sup> Because of the slight positive impact on lactation, depot-medroxyprogesterone acetate can be administered immediately after delivery. A study to investigate the impact of early initiation found no adverse effects on breast-feeding.<sup>158</sup> In breast-feeding, overweight, Latina women with prior gestational diabetes, depot-medroxyprogesterone acetate was associated with a small increase in subsequent diabetes mellitus that was not statistically significant, a risk that was even lower and less significant when adjusted for the higher body weights and a greater prevalence of family history for diabetes in the users of injected contraception.<sup>159</sup>

Depot-medroxyprogesterone acetate is an excellent contraceptive choice for women taking antiepileptic drugs because the high progestin levels raise the seizure threshold.<sup>160</sup> An improvement in seizure control can be achieved probably because of the sedative properties of progestins.<sup>160</sup>

Women who are anticoagulated or who have bleeding disorders are prone to develop heavy menstrual bleeding and hemorrhagic ovarian cysts. Experience with depot-medroxyprogesterone acetate in these patients is limited; however, we would expect a beneficial reduction in bleeding and a reduced risk of ovarian hemorrhage, especially from a corpus luteum.<sup>161</sup>

Other benefits associated with depot-medroxyprogesterone acetate use include a decreased risk of endometrial cancer comparable with that observed with oral contraceptives.<sup>162</sup> A case-control study showed an association between 3 or more years of depot-medroxyprogesterone use and reduced risk of epithelial ovarian cancer.<sup>163</sup> A failure to document a reduced risk of ovarian cancer by the World Health Organization probably reflects the study's low statistical power and the high parity in the depot-medroxyprogesterone acetate users.<sup>164</sup> Depot-medroxyprogesterone has also been associated with other benefits of the progestin component of oral contraceptives, including decreased development of uterine fibroids,<sup>165</sup> decreased risk of ectopic pregnancy,<sup>55</sup> and less pelvic inflammatory disease (PID).<sup>166</sup>

The greater the number of choices that women have, the more likely they are to find a contraceptive that works well for them. For some women, the primary advantages of

depot-medroxyprogesterone acetate are privacy and ease of use. No one but the user needs to know about the injection, and the 3-month schedule can be easy to maintain for women who do not mind injections. In some societies, depot-medroxyprogesterone acetate is the most popular contraceptive despite bleeding changes and other side effects.

## Key Points: Summary of Advantages

- Easy to use, no daily or coital action required
- Safe, no serious health effects
- Very effective, as effective as sterilization, intrauterine contraception, and implant contraception
- Free from estrogen-related problems
- Private, use not detectable
- Lactation enhanced
- Noncontraceptive benefits

# Problems with Depot-Medroxyprogesterone Acetate

Major problems with depot-medroxyprogesterone acetate are irregular menstrual bleeding, breast tenderness, weight gain, and depression.<sup>129,130</sup> By far, the most common problem is the change in menstrual bleeding. Up to 25% of patients discontinue in the 1st year because of irregular bleeding.<sup>130</sup> The incidence of irregular bleeding is 70% in the 1st year, and 10% thereafter. Bleeding and spotting decrease progressively with each reinjection so that after 5 years, 80% of users are amenorrheic (compared with 10% of Norplant users).<sup>167</sup> With the subcutaneous preparation, the bleeding pattern is similar to that with the intramuscular product; 55% achieve amenorrhea at the end of the 1st year of treatment and 70% after 2 years.<sup>132,145,168</sup> Irregular bleeding can be disturbing and annoying, and, for many patients, it inhibits sexuality; therefore, most users prefer the amenorrhea that comes with prolonged use.

If necessary, breakthrough bleeding can be treated with exogenous estrogen, 1.25 mg conjugated estrogens, or 2 mg estradiol, given daily for 7 days. A nonsteroidal anti-inflammatory product given for a week is also effective, and another option is to administer an oral contraceptive for 1–3 months. Giving the depot-medroxyprogesterone acetate injection earlier (more frequently) does not change the bleeding pattern.<sup>169</sup> Most women can wait for amenorrhea without treatment if they know what to expect with time. Trying to regulate breakthrough bleeding with planned cyclic transdermal estradiol exposure has proved to be ineffective.<sup>170</sup> Chlamydia infection of the endometrial cavity is not a cause of the irregular bleeding associated with depot-medroxyprogesterone acetate.<sup>171</sup>

In a large international study, the most common medical reasons for discontinuing depot-medroxyprogesterone acetate during the first 2 years of use are noted in [Table 23.5](#).<sup>30</sup>

## TABLE 23.5 Common Medical Complaints for Discontinuing the Use of Depot-Medroxyprogesterone Acetate

Headaches	2.3%
-----------	------

Weight gain	2.1%
-------------	------

Dizziness	1.2%
-----------	------

Abdominal pain	1.1%
----------------	------

Anxiety	0.7%
---------	------

In Western societies, depression, fatigue, decreased libido, and hypertension are also encountered. Whether medroxyprogesterone acetate causes these side effects is difficult to know because they are very common complaints in nonusers as well.<sup>172</sup> When studied closely, no increase in depressive symptoms can be observed, even in women with significant complaints of depression prior to treatment.<sup>173,174</sup> In postpartum women, a randomized controlled trial comparing depot-medroxyprogesterone to the copper-containing IUD did show higher scores on depression inventories in women using injectable contraception, as well as higher rates of major depression at 3 months of postpartum.<sup>175</sup>

Attempts to document a greater weight gain specifically associated with depot-medroxyprogesterone acetate have had mixed results, some finding no increase and others a small increase (e.g., about 4 kg over 5 years in one study and 11 kg over 10 years in another).<sup>176,177,178,179</sup> In an excellent large cohort study, 3-year users of depot-medroxyprogesterone acetate increased their body weight by 5.1 kg, body fat by 4.1 kg, and percent body fat by 3.4% and developed an increase in central, visceral fat, all mostly in the first 18 months and in contrast to no weight gain in oral contraceptive users.<sup>180</sup> With the subcutaneous method, an average weight gain of 1.5 kg was observed after 1 year and 4.5 kg after 3 years, changes that are comparable to the intramuscular formulation.<sup>132,145,181</sup> In a cohort comparison study of adolescents, obese girls gained more weight (9.4 kg after 18 months) with depot-medroxyprogesterone acetate when compared with oral contraceptives or no hormonal method.<sup>182</sup> A longitudinal 4–5-year follow-up study of adolescents in South Africa documented about a 4 kg greater weight gain with injectable contraception (both depot-medroxyprogesterone acetate and

norethindrone enanthate) compared with nonusers or oral contraceptive users.<sup>183</sup> Specific individuals and certain ethnic groups may be more susceptible to weight gain; for example, significant weight gain was reported in Navajo women using depot-medroxyprogesterone acetate.<sup>184,185</sup> In a prospective cohort study, women who experienced a significant weight gain within 6 months gained an average of about 7 kg more over 3 years, thus identifying a susceptible group of women, about 25% of depot-medroxyprogesterone acetate users.<sup>186</sup>

Is weight gain a general reaction to depot-medroxyprogesterone acetate or does it occur only in vulnerable individuals? An answer to this question is hindered by limitations in the available studies. The evidence is not derived from randomized trials. Therefore, results can be influenced by those reasons for which subjects choose a certain method and responses that affect continuation with methods. The individuals who choose to use depot-medroxyprogesterone differ in their socioeconomic status, contraceptive practices, and sexual histories, thus the difficulty in matching users and nonusers.

**Although it is difficult to separate the hormone effect from the impact of lifestyle and aging, it is best to conclude that depot-medroxyprogesterone acetate injections are associated with a small increase in body fat and body weight in some women.**

Remember that if symptoms are truly due to the progestin, unlike pills and implants, depot-medroxyprogesterone acetate takes 6–8 months to be gone after the last injection.<sup>131</sup> Clearance is slower in heavier women. Approximately half of women who discontinue depot-medroxyprogesterone acetate can expect normal menses to return in 6 months after the last injection, but 25% will wait a year before resumption of a normal pattern.<sup>131,167</sup>

Several prospective studies have suggested that the use of depot-medroxyprogesterone acetate is associated with an increased risk of cervical infections, especially chlamydia and/or gonorrhea.<sup>187,188,189,190</sup> This finding could very well be influenced by the inability to perform a randomized trial and reflect the difficulty in matching users and nonusers. The women who chose to use depot-medroxyprogesterone acetate in these cohort studies were notably different in their socioeconomic status, contraceptive practices, and sexual histories; thus, the results could reflect a higher rate of infection in the user group at baseline. Studies have not linked the use of depot-medroxyprogesterone acetate and an increased risk of HIV infection.<sup>191,192</sup>

## **Anaphylaxis**

As of 2017, there were four case reports of anaphylactic shock within minutes after

receiving intramuscular injections of depot-medroxyprogesterone acetate.<sup>193,194,195,196</sup> The reactions were most likely to one of the inert substances present in the injections: parabens, polyethylene glycols, and polysorbates. Depot-medroxyprogesterone acetate intramuscular injections are best given by trained personnel in a clinic or office setting with resuscitation equipment and drugs available. No such reactions have been reported with subcutaneous administration.

## Breast Cancer

A very large, hospital-based, case-control WHO study conducted over 9 years in three developing countries indicated that exposure to depot-medroxyprogesterone acetate is associated with a very slightly increased risk in breast cancer in the first 4 years of use, but there was no evidence for an increase in risk with increasing duration of use.<sup>197</sup> The number of cases with recent use was not large, and the confidence intervals reflected this. A possible explanation for this finding is the combination of detection/surveillance bias and accelerated growth of an already present tumor, a situation similar to those described with oral contraceptives ([Chapter 22](#)) and postmenopausal hormone therapy ([Chapter 17](#)).

Two earlier population-based, case-control studies indicated a possible association between breast cancer and depot-medroxyprogesterone acetate. One, from Costa Rica, was based on only 19 cases.<sup>198</sup> The other, from New Zealand, did not find an increased relative risk in ever users but did find an indication of increased risk shortly after initiating use at an early age, younger than age 25.<sup>199</sup> A pooled analysis of the WHO and New Zealand data indicated an increased risk in recent users and that the highest risk was in women who had received a single injection.<sup>200</sup> The risk, if real, is very slight, and it is equally possible that the suggestions of increased risk based on a small number of cases have not been free of confounding variables. A case-control study from Cape Town, South Africa, and a very large case-control study in the United States found no overall increase in the risk of breast cancer and no effect of increasing duration of use or recent use.<sup>99,201</sup> Because recent use may be the key factor, it is appropriate to emphasize that all of these studies did not find evidence for an overall increased risk of breast cancer, and the risk did not increase with duration of use. However, clinicians should consider informing patients that depot-medroxyprogesterone acetate might accelerate the growth of an already present occult cancer. We would expect such tumors to be detected at an earlier stage and grade of disease and to be associated with a better outcome.

## Other Cancers

An increased risk of cervical dysplasia cannot be documented even with long-term use

(4 or more years).<sup>202</sup> No increase in adenocarcinoma or adenosquamous carcinoma of the cervix could be detected in the WHO study.<sup>203</sup> The WHO study did not detect an increased risk of invasive squamous cell cancer of the cervix in depot-medroxyprogesterone acetate users; however, the risk of cervical carcinoma in situ was slightly elevated in the WHO case-control study, and it is not certain whether this is a real finding or a consequence of unrecognized biases, especially detection bias.<sup>204,205</sup> In New Zealand, a modest increase in the risk of cervical dysplasia among users of depot-medroxyprogesterone acetate could be attributed to an increased prevalence of known risk factors for dysplasia among women who choose this method of contraception.<sup>202</sup> Nevertheless, it is prudent to insist on Pap smear surveillance in all users of contraception, no matter what method. An immature cellular pattern in Pap smears from long-term depot-medroxyprogesterone acetate users can suggest the presence of squamous intraepithelial premalignant lesions, but biopsies in these cases reveal epithelial atrophy.<sup>206</sup>

As noted, depot-medroxyprogesterone acetate is associated with a reduction in the risk of endometrial cancer, and there is probably a modest reduction in the risk of ovarian cancer. There is no evidence that liver cancer risk is changed by the use of depot-medroxyprogesterone acetate.<sup>207</sup>

## Metabolic Effects

The impact of depot-medroxyprogesterone acetate on the lipoprotein profile is uncertain. Although some fail to detect an adverse impact and claim that this is due to the avoidance of a first pass through effect in the liver, others have demonstrated at least a transient decrease in HDL cholesterol and increases in total cholesterol and LDL-cholesterol.<sup>208,209,210</sup> In a multicenter clinical trial by the World Health Organization, the adverse impact was present only in the few weeks after injection when blood levels were high.<sup>211</sup> The clinical impact of these changes, if any, has yet to be reported.

There are no clinically significant changes in carbohydrate metabolism or in coagulation factors in healthy women.<sup>212,213</sup> As noted earlier, the use of progestin-only contraception may increase the risk of type 2 diabetes mellitus, especially in Latina breast-feeding women.<sup>159</sup> However, these studies have also indicated that this risk is influenced by baseline body weights and by weight gain. It is possible that overweight women who already have significant insulin resistance become overtly diabetic by the added effect of progestins in a low-estrogen environment (lactation) or in an induced relatively low-estrogen state (depot-medroxyprogesterone acetate). But, it is likely that excess body weight is the more critical factor.

## Effect on Bone Density

The contraceptive use of depot-medroxyprogesterone acetate is associated with the short-term loss of bone. This is attributed to the fact that blood levels of estrogen with depot-medroxyprogesterone acetate are relatively lower over a period of time compared with a normal menstrual cycle, an explanation that is supported by the demonstration that estrogen treatment prevents the bone loss.<sup>213,214</sup> Lumbar and hip bone loss has been documented in both cross-sectional and longitudinal studies.<sup>91,215,216,217,218,219</sup> This bone loss has also been observed in women receiving a high oral dose of medroxyprogesterone acetate, 50 mg daily, a dose that suppresses LH, resulting in low estrogen levels.<sup>220</sup> Another study documented decreased bone density that was enhanced by lower body weight and duration of amenorrhea.<sup>221</sup> An American cross-sectional study indicated a greater bone loss with increasing duration of use, especially in younger women, 18–21 years old.<sup>222</sup> The bone loss with intramuscular and subcutaneous administration of depot-medroxyprogesterone acetate is comparable.<sup>133</sup>

The bone loss associated with the use of depot-medroxyprogesterone acetate can be minimized by focusing on risk factors. Women at greater risk for losing bone density with this method of contraception are those who have not experienced childbirth, who smoke, and who have an inadequate intake of calcium.<sup>223</sup> Calcium and vitamin D supplementation should be encouraged in most women, not just depot-medroxyprogesterone acetate users, and an emphasis on smoking cessation is always worthwhile. A randomized controlled trial also showed that patients using DMPA for more than 2 years had an arrest of bone loss when randomized to receive conjugated estrogens.<sup>224</sup>

Bone density increases rapidly and significantly during adolescence. Almost all of the bone mass in the hip and the vertebral bodies will be accumulated in young women by age 18, and the years immediately following menarche is especially important.<sup>225,226</sup> For this reason, any drug that prevents this increase in bone density might increase the risk of osteoporosis later in life. Studies in adolescents have documented bone loss with depot-medroxyprogesterone acetate compared with normal controls and young women using oral contraceptives.<sup>87,227,228</sup> But, there are reasons to expect this bone loss is regained.

An example of bone loss that is regained is the bone loss associated with lactation. Secretion of calcium into the milk of lactating women approximately doubles the daily loss of calcium.<sup>229</sup> In women who breast-feed for 6 months or more, this is accompanied by significant bone loss even in the presence of a high calcium intake.<sup>230</sup> However, bone density rapidly returns to baseline levels in the 6 months after

weaning.<sup>231,232,233</sup> The bone loss is due to increased bone resorption, probably secondary to the relatively low estrogen levels associated with lactation. Calcium supplementation has no effect on the calcium content of breast milk or on bone loss in lactating women who have normal diets.<sup>234</sup> Most importantly, studies indicate that any loss of calcium and bone associated with lactation is rapidly restored; therefore, there is no impact on the risk of postmenopausal osteoporosis.<sup>235,236,237,238,239</sup>

The degree of bone loss in the previously mentioned depot-medroxyprogesterone acetate studies is not as severe as that observed in the early postmenopausal years. Furthermore, this amount of bone loss is not so great that it cannot be regained. Bone density measurements in women who stopped using depot-medroxyprogesterone acetate indicated that the loss was regained in the lumbar spine but not in the femoral neck within 2 years even after long-term use, but in other cohorts of past users, both spinal density and hip density were regained in the 3–4 years after discontinuation.<sup>216,240,241</sup> A 7-year prospective cohort study demonstrated unequivocally that bone is regained, almost 100% within 2 years after depot-medroxyprogesterone acetate is discontinued in both the lumbar spine and the hip.<sup>242</sup> Cohort studies in adolescents and young women demonstrated a similar gain in bone after discontinuation.<sup>243,244</sup> Most importantly, cross-sectional studies of postmenopausal women in New Zealand and a large multicenter, worldwide population could not detect a difference in bone density comparing former users of depot-medroxyprogesterone acetate to never users, indicating that any loss of bone during use is regained.<sup>91,245</sup>

In 2004 (and it stands in the revised 2010 package insert), the U.S. Food and Drug Administration indicated a concern for the bone loss associated with depot-medroxyprogesterone acetate and warned that this method should not be used longer than 2 years unless it was the only option. We agree that concern is appropriate but disagree with the warning. The degree of bone loss and the evidence that the bone loss is regained, plus the similarity to the benign bone loss associated with lactation, all argue that the use and duration of use of depot-medroxyprogesterone acetate should not be limited by this concern and that measurement of bone density or treatment with supplemental estrogen or bisphosphonates is not indicated (and would influence and complicate compliance). At the present time, in our view, the concern over bone loss should not be a reason to avoid this method of contraception, and there is no need to impose a time limit on duration of use. **It is unlikely that bone loss occurs sufficiently to raise the risk of osteoporosis later in life. However, women who discontinue DMPA at or near their menopause should be encouraged to use hormone therapy in order to regain the lost bone.**

## Galactorrhea

Galactorrhea is not associated with the use of depot-medroxyprogesterone acetate. Both estrogen and progesterone are necessary for the expression of the lactogenic receptor, but progesterone antagonizes the positive action of prolactin on its own receptor, while progesterone and pharmacologic amounts of androgens reduce prolactin binding.<sup>246,247,248</sup> For these reasons, exposure to high levels of progestational agents, such as depot-medroxyprogesterone acetate, is not associated with the clinical problem of galactorrhea.

## Effect on Future Fertility

The delay in becoming pregnant after ceasing use of depot-medroxyprogesterone acetate is a problem unique to injectable contraception; all the other temporary methods allow a more prompt return to fertility.<sup>249</sup> However, medroxyprogesterone acetate does not permanently suppress ovarian function, and the concern that infertility with suppressed menstrual function may be caused by depot-medroxyprogesterone acetate has not been supported by epidemiologic data. The pregnancy rate in women discontinuing the injections because of a desire to become pregnant is normal.<sup>250</sup> By 18 months after the last injection, 90% of depot-medroxyprogesterone acetate users have become pregnant, the same proportion as with other methods.<sup>251</sup> The delay to conception is about 9 months after the last injection, and the delay does not increase with increasing duration of use. Because of this delay, women who want to conceive promptly after discontinuing their contraceptive should not use depot-medroxyprogesterone acetate. Suppressed menstrual function persisting beyond 18 months after the last injection is not due to the drug and deserves evaluation (**Figure 23.5**).

## FIGURE 23.5

# Determining Menopause in Long-Term Users

Depot-medroxyprogesterone acetate will prevent the appearance of the two common markers for the onset of menopause: the loss of menstrual periods and hot flushing. Although the risk is small after age 50, pregnancy is still possible in some women. Knowing a woman is postmenopausal is important in order to minimize, if not eliminate, the risk of pregnancy, and there is reason to be concerned over the relatively low-estrogen state associated with depot-medroxyprogesterone acetate. FSH secretion is regulated by both estrogen and inhibin, and therefore pharmacologic amounts of progestins do not restore postmenopausal levels of FSH to premenopausal levels.<sup>252</sup> Greater reliability in measuring FSH is achieved with injectable methods of contraception if the blood sample is obtained prior to the next scheduled injection. We are reluctant to follow the empiric practice that allows women to continue oral contraceptives to age 55 because we believe there is some urgency to expeditiously transfer the patient from the low-estrogen state associated with depot-medroxyprogesterone acetate to the early benefits provided by a program of postmenopausal hormone therapy. We recommend measuring FSH annually beginning at age 50. An FSH level greater than 20 mIU/mL may suggest postmenopause, although a level of 35–40 mIU/mL is considered more reliable.<sup>253</sup> Two spaced measurements indicating menopause will allow reasonable certainty.

# SHORT-TERM CONTRACEPTIVES

# INJECTABLE

---

Monthly or every-other-month injectable combinations of estrogen and progestin are popular in China, Latin America, and Eastern Asia.<sup>254</sup> A preparation widely used in China consists of 250 mg 17 $\alpha$ -hydroxyprogesterone caproate and 5 mg estradiol valerate, known as Chinese Injectable No.1. A large follow-up study of Chinese women concluded that this monthly injection was associated with a significant reduction in endometrial cancer and no increase in other cancers, including breast cancer.<sup>255</sup>

## **Lunelle (Also Called Cyclofem, Cyclo-Provera, Feminena, or Lunella)**

Lunelle consists of 25 mg depot-medroxyprogesterone acetate and 5 mg estradiol cypionate and is administered every 28–30 days (not to exceed 33 days) as a deep intramuscular injection. This method is as effective as depot-medroxyprogesterone acetate but avoids the problems of menstrual irregularity and heavy bleeding, as well as amenorrhea.<sup>256,257,258,259,260,261</sup> In addition, the method is rapidly reversible; fertility rates after discontinuation are similar to oral contraceptives.<sup>262</sup> Besides the need for a monthly injection, another disadvantage is the likelihood that the combination of estrogen and progestin will inhibit lactation. The requirement for a monthly injection can be made more convenient by the use of an automatic device for self-administration.<sup>263</sup> Approximately 80% of women who are amenorrheic on depot-medroxyprogesterone acetate will develop vaginal bleeding if switched to Lunelle.<sup>264</sup> The same contraindications, concerns, problems, and probably benefits reported with oral contraception should apply to Lunelle.

# Norethindrone Enanthate

Norethindrone enanthate is given in a dose of 200 mg intramuscularly every 2 months. This progestin acts in the same way as depot-medroxyprogesterone acetate and has the same problems.<sup>130</sup> A combination (Mesigyna, Norigynon, Noristerat, Norigest, NET-EN) of norethindrone enanthate (50 mg) with estradiol valerate (5 mg) given monthly provides effective contraception with good cycle control.<sup>265</sup> Compared with Lunelle, this combination has less bleeding problems.<sup>266</sup> Fertility returns rapidly (by 1 month) after discontinuation.<sup>262</sup>

# **Dihydroxyprogesterone      Acetophenide      and Estradiol Enanthate**

The combination of 150 mg dihydroxyprogesterone acetophenide with 10 mg estradiol enanthate (various brand names) is the most widely used injectable contraceptive in Latin America. As with Lunelle and the norethindrone combination, the monthly regimen allows regular, and even reduced, cyclic bleeding.<sup>267</sup> A lower dose (90 mg dihydroxyprogesterone acetophenide and 6 mg estradiol enanthate) provides the same effective contraception as the higher dose with similar bleeding patterns.<sup>268</sup>

# INTRAUTERINE DEVICES

The forerunners of the modern IUD were small stem pessaries used in the 1800s that covered the opening of the cervix and were attached to stems extending into the cervical canal.<sup>269</sup> In 1902, a pessary that extended into the uterus was developed by Hollweg in Germany and used for contraception. This pessary was sold for self-insertion, but the hazard of infection was great, earning the condemnation of the medical community. In 1909, Richter, in Germany, reported success with a silkworm catgut ring that had a nickel and bronze wire protruding through the cervix.<sup>270</sup> Shortly after, Pust combined Richter's ring with the old button-type pessary and replaced the wire with a catgut thread.<sup>271</sup> This IUD was used during World War I in Germany, although the German literature was quick to report infections with its insertion and use. In the 1930s, Gräfenberg reported removing the tail and pessary because he believed this was the cause of infection, using rings made of coiled silver and gold and then steel (**Figure 23.6**).<sup>272</sup> The Gräfenberg ring was associated with a high rate of expulsion. This was solved by Ota in Japan who added a supportive structure to the center of his gold- or silver-plated ring in 1934.<sup>273</sup> During World War II, Gräfenberg and Ota fell victim to Nazi political philosophy that was bitterly opposed to contraception.

**FIGURE 23.6**

An awareness of the explosion in population and its impact began to grow in the first two decades after World War II. In 1959, reports from Japan and Israel by Ishihama and Oppenheimer once again stirred interest in the rings.<sup>274,275</sup> The Oppenheimer report was in the *American Journal of Obstetrics and Gynecology*, and several American gynecologists began to use rings of silver or silk, and others to develop their own devices.

In the 1960s and 1970s, the IUD thrived. Techniques were modified, and new types made of new materials, such as polyethylene impregnated with barium sulfate for x-ray opacity, were introduced. The Margulies Coil, developed by Lazer Margulies in 1960 at

Mt. Sinai Hospital in New York City, was the first plastic device with a memory, which allowed the use of an inserter and reconfiguration of the shape when it was expelled into the uterus. The coil was a large device (sure to cause cramping and bleeding), and its hard plastic tail proved risky for the male partner.

In 1962, the Population Council, at the suggestion of Alan Guttmacher, who that year became president of the Planned Parenthood Federation of America, organized the first international conference on IUDs in New York City. This conference led to the organization of a program to evaluate IUDs, the Cooperative Statistical Program. The Ninth Progress Report in 1970 was a landmark comparison of efficacy and problems with the various IUDs in use.<sup>276</sup>

It was at this 1962 conference that Jack Lippes presented experience with his device, which had a novel single filament thread as a tail to establish position and for easy removal. The Margulies Coil was rapidly replaced by the Lippes loop. Acquired by the Ortho Pharmaceutical Corporation in 1966, it quickly became the most widely prescribed IUD in the United States. The Population Council acquired international rights for the Lippes loop, and it became used by millions of women throughout the world.

The Dalkon Shield was introduced in 1970. Within 3 years, a high incidence of pelvic infection was recognized. There is no doubt that the problems with the Dalkon Shield were due to defective construction—the multifilamented tail provided a pathway for bacteria to ascend protected from the cervical mucous barrier.<sup>277</sup> Although sales were discontinued in 1975, a call for removal of all Dalkon Shields was not issued until the early 1980s. The large number of women with pelvic infections led to many lawsuits against the pharmaceutical company, ultimately causing its bankruptcy. Unfortunately, the Dalkon Shield problem tainted all IUDs, and for a long time, media and the public in the United States inappropriately regarded all IUDs in a single, generic fashion. Making the situation worse, changes in sexual behavior in the 1960s and 1970s, and failure to use infection preventing contraceptives (condoms and oral contraceptives), led to an epidemic of STIs and PID for which IUDs were held partially responsible.<sup>278</sup>

The first epidemiologic studies of the relationship between IUDs and PID used women who depended on oral contraception or barrier methods as controls and who were, therefore, at reduced risk of PID compared with noncontraceptors and IUD users.<sup>279,280</sup> In addition, these first studies failed to control for the characteristics of sexual behavior that are now accepted as risk factors for PID (multiple partners, early age at first intercourse, and increased frequency of intercourse).<sup>281</sup> The Dalkon Shield magnified the risk attributed to IUDs because its high failure rate in young women who were already at risk of STIs led to septic spontaneous abortions and, in some cases, death.<sup>282</sup> Reports of these events led the American public to regard all IUDs as

dangerous, including those that, unlike the Dalkon Shield, had undergone extensive clinical trials and postmarketing surveillance.

The 1980s saw the decline of IUD use in the United States as manufacturers discontinued marketing in response to the burden of litigation. The final blow to the IUD in the United States came in 1985 with the publication of two reports indicating that the use of IUDs was associated with tubal infertility.<sup>283,284</sup> Despite the fact that most of the lawsuits against the copper devices were won by the manufacturer, the cost of the defense combined with declining use affected the financial return.

Americans remained averse to IUDs even after better controlled studies that identified the Dalkon Shield as a high-risk device and failed to demonstrate an association between PID and other IUDs were published. Efforts to point out that the situation was different for the copper IUDs, and that, in fact, PID was not increased in women with a single sexual partner,<sup>285</sup> failed to prevent the withdrawal of IUDs from the American market and the negative reaction to IUDs by the American public. The number of reproductive-age women using the IUD in the United States decreased by two-thirds from 1982 to 1988 and further decreased in 1995, from 7.1% to 2% to 0.8%, respectively.<sup>286</sup> Since 1995, the use of the IUD in the United States has climbed to 6.4% of all women, or 10.3% of all women using contraceptives, reflecting the popularity of the levonorgestrel-releasing system.<sup>287</sup> In the rest of the world, the IUD is the most widely used method of reversible contraception, currently, with 13.5% of reproductive-age women using an IUD for contraception<sup>1</sup> (Table 23.6).

## **TABLE 23.6 Use of the IUD in the United States and China**

	<b>United States</b>	<b>China</b>	<b>Total World</b>
1981	4.8 million women	34.9 million	60 million
1991	1.0 million women	33.1 million	83 million
2001	1.9 million women	39.6 million	106 million
2010	8.9 million women	40.6 million	>180 million

# THE MODERN IUD

---

The addition of copper to the IUD was suggested by Jaime Zipper of Chile, whose experiments with metals indicated that copper acted locally on the endometrium.<sup>288</sup> Howard Tatum in the United States combined Zipper's suggestion with the development of the T-shape, which he felt would conform better to the shape of the uterus, and produced the copper-T. The first copper IUD had copper wire wound around the straight shaft of the T, the TCu-200 (200 mm<sup>2</sup> of exposed copper wire), also known as the Tatum-T.<sup>289</sup> The copper IUDs could be much smaller than those of simple, inert plastic devices and still provide effective contraception. Studies indicate that copper exerts its effect before implantation of a fertilized ovum; it may be spermicidal, or it may diminish sperm motility or fertilizing capacity. The addition of copper to the IUD and reduction in the size and structure of the frame improved tolerance, resulting in fewer removals for pain and bleeding.

The Cu-7 with a copper wound stem was developed in 1971 and quickly became the most popular device in the United States. Both the Cu-7 and the Tatum-T were withdrawn from the US market in 1986 by G.D. Searle and Company. IUD development continued, however. More copper was added by Population Council investigators, leading to the TCu-380A (380 mm<sup>2</sup> of exposed copper surface area) with copper wound around the stem plus a copper sleeve on each horizontal arm.<sup>290</sup> The "A" in TCu-380A is for arms, indicating the importance of the copper sleeves. Making the copper solid and tubular increased effectiveness and the life span of the IUD. The TCu-380A has been in use in more than 30 countries since 1982, and, in 1988, it was marketed in the United States as the "ParaGard."

# TYPES OF IUDS

---

# Unmedicated IUDs

The Lippes loop, made of plastic (polyethylene) impregnated with barium sulfate, is still used throughout the world (except in the United States). Flexible stainless steel rings were widely used in China but not elsewhere until 1994 when copper IUDs were mandated (Figure 23.7).<sup>291, 292</sup>

**FIGURE 23.7**

# Copper IUDs

The first copper IUDs were wound with 200–250 mm<sup>2</sup> surface area of wire, and two of these are still available (except in the United States): the TCU-200 and the Multiload-250. The more modern copper IUDs contain more copper, and part of the copper is in the form of solid tubular sleeves, rather than wire, increasing efficacy and extending life span. This group of IUDs is represented in the United States by the TCU-380A (the ParaGard) and in the rest of the world by the TCU-220C, the Nova T, and the Multiload-375. The Sof-T is a copper IUD used only in Switzerland.

The TCU-380A is a T-shaped device with a polyethylene frame holding 380 mm<sup>2</sup> of exposed surface area of copper that provides contraception for at least 10 years. Although the data are sparse, wearing the TCU-380A for 20 years carries only a very small risk of pregnancy.<sup>293</sup> The pure electrolytic copper wire wound around the 36-mm stem weighs 176 mg, and copper sleeves on the horizontal arms weigh 66.5 mg. A polyethylene monofilament is tied through the 3-mm ball on the stem, providing two white threads for detection and removal. The ball at the bottom of the stem helps reduce the risk of cervical perforation. The IUD frame contains barium sulfate, making it radiopaque. The TCU-380Ag is identical to the TCU-380A, but the copper wire on the stem has a silver core to prevent fragmentation and extend the lifespan of the copper. The TCU-380 Slimline has the copper sleeves flush at the ends of the horizontal arms to facilitate easier loading and insertion. The performance of the TCU-380Ag and the TCU-380 Slimline is equal to that of the TCU-380A.<sup>294 295</sup>

The Multiload-375 has 375 mm<sup>2</sup> of copper wire wound around its stem. The flexible arms were designed to minimize expulsions. This is a popular device in many parts of the world. The Multiload-375 and the TCU-380A are similar in their efficacy and performance.<sup>296</sup>

The Nova T is similar to the TCU-200, containing 200 mm of copper; however, the Nova T has a silver core to the copper wire, flexible arms, and a large, flexible loop at the bottom to avoid injury to cervical tissue. There was some concern that the efficacy of the Nova T decreased after 3 years in World Health Organization (WHO) data; however, results from Finland and Scandinavia indicate low and stable pregnancy rates over 5 years of use.<sup>296</sup>

The CuSAFE-300 IUD has 300 mm<sup>2</sup> of copper in its vertical arm and a transverse arm with sharply bent ends that are adapted to the uterine cavity and help hold this IUD in the fundus. It is made from a more flexible plastic and is smaller than the world's two most popular IUDs, the TCU-380A and the Multiload-375. Pregnancy rates with the CuSAFE-300 are comparable to these two devices, but rates of removal for pain and

bleeding are reported to be lower.<sup>297</sup>

# Hormone-Releasing IUDs

The LNG-IUS 20 (levonorgestrel-releasing intrauterine system, Mirena), manufactured by Bayer, in vitro releases 20 mcg of levonorgestrel per day.<sup>298</sup> This T-shaped device has a collar attached to the vertical arm, which contains 52 mg levonorgestrel dispersed in polydimethylsiloxane and released initially at a rate of 20 mcg/day in vivo, progressively declining (reaching half of the initial rate after 5 years). It is 32 mm long, the arm span is 32 mm wide, and the diameter of its insertion tube is 4.4 mm. The Mirena IUS is approved for 5 years, but lasts for 7 years, and perhaps up to 10 years, and reduces menstrual blood loss and pelvic infection rates.<sup>299, 300, 301</sup>

The Mirena is about as effective as endometrial ablation for the treatment of menorrhagia.<sup>302, 303</sup> The local progestin effect directed to the endometrium can be utilized in patients on tamoxifen,<sup>304</sup> in patients with dysmenorrhea,<sup>305</sup> and in postmenopausal women receiving estrogen therapy.<sup>306, 307, 308, 309, 310, 311</sup>

In the United States, three other levonorgestrel IUSs are available—the Liletta, which has 52 mg of levonorgestrel and is effective as contraception for up to 4 years; the Kyleena (LNG-IUS 12), which has 19.5 mg of levonorgestrel and is effective as contraception for up to 5 years; and the Skyla (LNG-IUS 8), which has 13.5 mg of levonorgestrel and is effective as contraception for up to 3 years. The Liletta releases 19.5 mcg/day of levonorgestrel, which decreases to 11.3 mcg/day by the 4th year of use and was FDA approved in 2015.<sup>312</sup> It also measures 32 mm long and its arms are 32 mm wide, but it has a cost advantage over the Mirena system. The Kyleena releases 17 mcg/day of levonorgestrel, which decreases to 7.4 mcg/day after 5 years and was FDA approved in 2016.<sup>312</sup> The Skyla releases 14 mcg/day of levonorgestrel, which decreases to 5 mcg/day after 3 years and was FDA approved in 2013.<sup>313</sup> The Kyleena and Skyla IUSs are smaller than the Mirena, and their insertion tubes are 3.8 mm in diameter, making them desirable for nulliparous patients. They are both manufactured by Bayer, like the Mirena IUS, but are indicated for contraception only.

A slightly smaller T-shaped device that releases 20 mg of levonorgestrel daily is called the Femilis LNG-IUS.<sup>314</sup> Smaller devices releasing 5 or 10 mcg levonorgestrel have been developed in Europe for use for at least 5 years in postmenopausal women.<sup>310</sup>

## Other IUDs

The Ombrelle-250 and Ombrelle-380, designed to be more flexible in order to reduce expulsion and side effects, have been marketed in France. A frameless IUD, the FlexiGard (also known as the Cu-Fix or the GyneFIX), invented by Dirk Wildemeersch in 1983 in Belgium, consists of six copper sleeves (330 mm<sup>2</sup> of copper) strung on a surgical nylon (polypropylene) thread that is knotted at one end. The knot is pushed into the myometrium during insertion with a notched needle that works like a miniature harpoon. Because it is frameless, it has a low rate of removal for bleeding or pain, but a more difficult insertion may yield a higher expulsion rate. However, when inserted by experienced clinicians, the expulsion rate is very low, and the device is especially suited for nulligravid and nulliparous women.<sup>315, 316, 317</sup> This IUD is increasingly popular in Europe. A shorter system combined with a reservoir for the sustained release of 14 mcg levonorgestrel per day (FibroPlant) is being tested for perimenopausal and postmenopausal use.<sup>318, 319</sup> FibroPlant effectively treats endometrial hyperplasia and menorrhagia.<sup>320, 321</sup>

# Mechanism of Action

The contraceptive action of all IUDs is mainly in the uterine cavity. Ovulation is not affected, and the IUD is not an abortifacient, even when used as emergency contraception.<sup>322, 323, 324, 325</sup> It is currently believed that the mechanism of action for IUDs is the production of an intrauterine environment that is spermicidal.

Nonmedicated IUDs depend for contraception on the general reaction of the uterus to a foreign body. It is believed that this reaction, a sterile inflammatory response, produces tissue injury of a minor degree but sufficient enough to be spermicidal. Very few, if any, sperm reach the ovum in the fallopian tube. Normally cleaving, fertilized ova cannot be obtained by tubal flushing in women with IUDs in contrast to noncontraceptors, indicating the failure of sperm to reach the ovum, and, thus, fertilization does not occur.<sup>326</sup> In women using copper IUDs, sensitive assays for human chorionic gonadotropin (hCG) do not find evidence of fertilization.<sup>327, 328</sup> This is consistent with the fact that the copper IUD protects against both intrauterine and ectopic pregnancies.

The copper IUD releases free copper and copper salts that have both a biochemical and morphologic impact on the endometrium, enhancing prostaglandin production, producing cytotoxic cytokine peptides, and inhibiting endometrial enzymes.<sup>329</sup> Endometrial receptivity is inhibited. An additional spermicidal effect probably takes place in the cervical mucus. There is no measurable increase in the serum copper level.

The progestin-releasing IUD adds the endometrial action of the progestin to the foreign body reaction. The endometrium becomes decidualized with atrophy of the glands.<sup>330</sup> The progestin IUD probably has two mechanisms of action: inhibition of implantation and inhibition of sperm capacitation, penetration, and survival. The levonorgestrel IUS produces serum concentrations of the progestin about half those of Norplant so that ovarian follicular development and ovulation are also partially inhibited; after the 1st year, cycles are ovulatory in 50–75% of women, regardless of their bleeding patterns.<sup>331</sup> Finally, the progestin IUD thickens the cervical mucus, creating a barrier to sperm penetration.

Following removal of IUDs, the normal intrauterine environment is rapidly restored. **In large studies, there is no delay, regardless of duration of use, in achieving pregnancy at normal rates, which belies the assertion that IUD use is associated with infection leading to infertility.**<sup>332, 333</sup> There has been no significant difference in cumulative pregnancy rates between parous and nulliparous or nulligravid women.<sup>334, 335</sup>

The levonorgestrel IUS may be associated with a slight increase in the formation of

ovarian cysts, but they are asymptomatic and resolve spontaneously.<sup>336</sup> An increase in the risk of venous thrombosis has not been observed in users of the levonorgestrel IUS.<sup>337</sup>

# Noncontraceptive Benefits with the Levonorgestrel IUS 20

Because of the favorable impact of locally released progestin on the endometrium, the Mirena IUS is very effective for the treatment of menorrhagia; is more effective than the administration of oral progestins, steroid contraceptives, or inhibitors of prostaglandin synthesis; and compares favorably with surgical treatment (hysterectomy or endometrial ablation).<sup>303, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347</sup>

The Mirena IUD rapidly decreases dysmenorrhea and menstrual blood loss (about 40–50%). Bleeding over time can be reduced by 90% and about 30–40% of women become amenorrheic 1 year after insertion.<sup>348, 349</sup> The LNG-IUS 12 is also associated with decreased bleeding, with 22.6% of women becoming amenorrheic and many women reporting less blood loss than before placement.<sup>350</sup> LNG-IUS 8 users report significant decreases in instances of heavy or prolonged bleeding, and 10.8% of women became amenorrheic prior to removal.<sup>351</sup> For the Mirena, average long-term hemoglobin and iron levels increase compared with preinsertion values.<sup>352</sup>

Bleeding is even reduced in the presence of leiomyomas.<sup>295, 353, 354, 355, 356</sup> There is some evidence that the Mirena reduces the prevalence of myomas and the uterine volume in the presence of myomas.<sup>352, 354, 355, 356</sup> Not all women with myomas respond favorably to the levonorgestrel IUS; this is usually because of the presence of submucosal myomas.<sup>357</sup> The Mirena also effectively reduces uterine volume and relieves dysmenorrhea secondary to adenomyosis.<sup>358, 359, 360, 361</sup>

Women with hemostatic disorders, such as von Willebrand disease, and women who are anticoagulated commonly have heavy menstrual bleeding. The insertion of the Mirena effectively reduces the amount of bleeding in many, but not all, of these patients, and there is a suggestion that with time the beneficial effect wanes and earlier replacement is necessary.<sup>362, 363, 364, 365, 366</sup>

In a randomized, 5-year trial comparing a copper IUD with the Mirena, pelvic infection was lower than the incidence in a general population with both devices, but the rate with the levonorgestrel IUS was significantly lower compared with the copper IUD.<sup>367</sup>

The Mirena has been used successfully to treat endometriosis and especially dysmenorrhea associated with endometriosis.<sup>37, 38, 305, 368, 369, 370</sup> Results may even be comparable to those obtained with GnRH agonist treatment.<sup>371</sup> The advantages of Mirena treatment of endometriosis include many years of efficacy, fewer side effects, and contraception.

The Mirena effectively protects the endometrium against hyperplasia and polyps in women using tamoxifen or postmenopausal estrogen therapy.<sup>304, 306, 307, 308, 309, 310, 372, 373, 374</sup> In addition, this IUD can be used to treat endometrial hyperplasia.<sup>320, 375, 376, 377, 378, 379</sup> Comparison studies indicate that the Mirena is as effective and probably better than standard treatment with an oral progestin.<sup>376, 380, 381</sup> **However, the persistence of atypia at biopsy follow-up after 6 months is an indication that regression is unlikely to occur.**

**Although the Mirena IUD confidently provides good protection against endometrial hyperplasia, clinicians should maintain a high degree of suspicion of unusual bleeding (bleeding that occurs after a substantial period of amenorrhea) and aggressively assess the endometrium.** Endometrial adenocarcinoma has been identified in users of the levonorgestrel IUS; rates of persistent disease may be as high as 14.3% of those treated for 6 months.<sup>382, 383, 384</sup> As noted however, many studies have documented protection against and even regression of endometrial hyperplasia.

## Key Points: Noncontraceptive Benefits with the Mirena

- Reduction of heavy menstrual bleeding and improvement of related anemia.
- Treatment of primary dysmenorrhea.
- Reduction of myoma prevalence as well as uterine volume and bleeding associated with myomas.
- Decrease in uterine volume and pain associated with adenomyosis.
- Reduction of menstrual bleeding in women with hemostatic disorders and in anticoagulated women.
- Protection against PID.
- Treatment of endometriosis and pain associated with endometriosis.
- Suppression of endometriosis.
- Protection against endometrial hyperplasia and polyps associated with postmenopausal estrogen therapy or tamoxifen treatment.
- Prevention of ectopic pregnancy.
- Reduction of endometrial cancer risk.

## Efficacy of IUDs

The TCU-380A is approved for use in the United States for 10 years. However, the TCU-380A has been demonstrated to maintain its efficacy over at least 12 years of use.<sup>385</sup> As previously noted, based on a small number of long-term users, wearing the TCU-380A for 20 years carries a very small risk of pregnancy.<sup>293</sup> The TCU-200 is approved for 4 years and the Nova T for 5 years. The Mirena IUD can be used for at least 7 years and probably for 10 years.<sup>295, 386</sup> The levonorgestrel device that releases 15–20 mg levonorgestrel per day is as effective as the copper IUDs that contain more than 250 mm<sup>2</sup> of copper surface area.<sup>34, 295, 299, 387</sup>

The nonmedicated IUDs never have to be replaced. The deposition of calcium salts on the IUD can produce a structure that is irritating to the endometrium. If bleeding increases after a nonmedicated IUD has been in place for some time, it is worth replacing it. Some clinicians (as do we) recommend replacing all older IUDs with the new, more effective medicated IUDs ([Table 23.7](#)).

### **TABLE 23.7 First Year Clinical Trial Experience in Parous Women**

Device	Pregnancy Rate (%)	Expulsion Rate (%)	Removal Rate (%)
Lippes loop	3	12–20	12–15
Cu-7	2–3	6	11
TCu-200	3	8	11
TCU-380A	0.5–0.8	5	14
Levonorgestrel IUS	0.2	6	17

Considering all IUDs together, the actual use failure rate in the 1st year is approximately 3%, with a 10% expulsion rate and a 15% rate of removal, mainly for bleeding and pain. With increasing duration of use and increasing age, the failure rate decreases, as do removals for pain and bleeding. The performance of the TCU-380A in recent years, however, has proved to be superior to previous IUDs ([Table 23.8](#)).

**TABLE 23.8 Ten-Year Experience with Paragard, TCU-380A Rate Per 100 Users Per Year**

	Year									
	1	2	3	4	5	6	7	8	9	10

Number starting each year	4,932	3,149	2,018	1,121	872	621	563	483	423	325

Data from **Sivin I, el Mahgoub S, McCarthy T, Mishell DR Jr, Shoupe D, Alvarez F, Brache V, Jimenez E, Diaz J, Faundes A, Diaz MM, Coutinho E, Mattos CER, Diaz S, Pavez M, Stern J**, Long-term contraception with the levonorgestrel 20 mcg/day (LNg 20) and the copper T 380Ag intrauterine devices: a five-year randomized study, *Contraception* 42:361, 1990; **Meirik O, Farley TMM, Sivin I; International Collaborative Post-Marketing Surveillance of Norplant**, Safety and efficacy of levonorgestrel implant, intrauterine device, and sterilization, *Am J Obstet Gynecol* 97:539, 2001; **Sivin I, Schmidt F**, Effectiveness of IUDs: a review, *Contraception* 36:55, 1987.

In careful studies, with attention to technique and participation by motivated patients, the failure rate with the TCu-380A is less than 1 per 100 women per year.<sup>296, 388, 389</sup> The cumulative net pregnancy rate after 7 years of use is 1.5 per 100 woman-years, and after 12 years, only 1.9 per 100 women (not a single pregnancy was reported after 8 years of use).<sup>385, 390</sup> In developing countries, the failure rate with IUDs is less than that with oral contraception.<sup>391</sup> Failure rates are slightly higher in younger (< age 25), more fertile women.

Women use IUDs longer than other reversible methods of contraception. The IUD continuation rate is higher than that with oral contraception, condoms, or diaphragms. This may reflect the circumstances surrounding the choice of an IUD (older, parous women).

# Expulsion

Approximately 5% of patients spontaneously expel the TCu-380A within the 1st year. Women younger than age 20 have a higher expulsion rate than older women.<sup>300, 392</sup> In a nulligravid, adolescent population, the cumulative expulsion rate with the Mirena system was 8%.<sup>393</sup> In a population of parous and nulliparous women with the Kyleena, the cumulative 5-year expulsion rate was 3.7%.<sup>350</sup> This event can be associated with cramping, vaginal discharge, or uterine bleeding. However, in some cases, the only observable change is lengthening or absence of the IUD strings. Patients should be cautioned to request immediate attention if expulsion is suspected. A partially expelled IUD should be removed. If pregnancy or infection is not present, a new IUD can be inserted immediately (in this instance, antibiotic prophylaxis is recommended).<sup>394</sup>

# Ectopic Pregnancy

The previous use of an IUD does not increase the risk of a subsequent ectopic pregnancy.<sup>335, 397, 398</sup> The current use of an IUD offers some protection against ectopic pregnancy.<sup>350, 395, 396, 397, 398, 399, 400</sup> The largest study, a WHO multicenter study, concluded that IUD users were 50% less likely to have an ectopic pregnancy when compared with women using no contraception.<sup>395</sup> This protection is not as great as that achieved by inhibition of ovulation with oral contraception. **Therefore, when an IUD user becomes pregnant, the pregnancy is more likely to be ectopic. However, the actual occurrence of an ectopic pregnancy in an IUD user is a rare event.**

The lowest ectopic pregnancy rates are seen with the most effective IUDs, like the TCu-380A (90% less likely compared with noncontraceptors).<sup>401</sup> The rate is about one-tenth of the ectopic pregnancy rate associated with the Lippes loop or with devices with less copper such as the TCu-200.<sup>401</sup> Very few ectopic pregnancies have been reported with levonorgestrel IUSs. In an 18-month study of 279 women who had a Skyla placed, 1 ectopic pregnancy was reported (of 2 pregnancies total).<sup>402</sup> With the Kyleena, a 5-year Pearl Index for ectopic pregnancy of 0.18 is reported.<sup>350</sup> In a 3-year study of 1,714 women with the Liletta, 4 ectopic pregnancies occurred (of 6 pregnancies total).<sup>403</sup> With the Mirena, a study reported the 5-year pregnancy rate for users was 0.5 per 100, and 53% of these pregnancies were ectopic.<sup>404</sup> The risk of ectopic pregnancy does not increase with increasing duration of use with the TCu-380A or the Mirena IUS.<sup>293, 390</sup> In a 7-year prospective study, not a single ectopic pregnancy was encountered with the levonorgestrel IUS, and in a 5-year study, only one.<sup>295, 367</sup> In 8,000 woman-years of experience in randomized multicenter trials, there was only a single ectopic pregnancy reported with the TCu-380A (which is one-tenth the rate with the Lippes loop or TCu-200).<sup>293</sup> Therefore, the risk of ectopic pregnancy during the use of the copper IUD or the levonorgestrel IUSs is much lower compared with noncontraceptive users; however, if pregnancy occurs, the likelihood of an ectopic pregnancy is high.<sup>404</sup>

**The protection against ectopic pregnancy provided by the TCu-380A and the levonorgestrel IUS makes these IUDs acceptable choices for contraception in women with previous ectopic pregnancies (Table 23.9).**

## TABLE 23.9 Ectopic Pregnancy Rates per 1,000 Woman-Years

Non contraceptive users, all ages	3.00–4.50

Data from **Franks AL, Beral V, Cates W Jr, Hogue CJ**, Contraception and ectopic pregnancy risk, *Am J Obstet Gynecol* 163:1120, 1990; **Sivin I**, Dose- and age-dependent ectopic pregnancy risks with intrauterine contraception, *Obstet Gynecol* 78:291, 1991.

## Side Effects

With effective patient screening and good insertion technique, the copper and levonorgestrel IUDs are not associated with an increased risk of infertility after their removal.<sup>405</sup> Even if IUDs are removed for pain or abnormal bleeding, subsequent fertility rates are normal.<sup>34,332,333</sup> Within 1 year, 5–15% of women discontinue IUDs because of these problems. Smaller copper and progestin IUDs have reduced the incidence of pain and bleeding considerably, but a careful menstrual history is still important in helping a woman consider an IUD. Women with prolonged, heavy menstrual bleeding or significant dysmenorrhea may not be able to tolerate copper IUDs but may benefit from a progestin IUD.<sup>339,340,341</sup> Because bleeding and cramping are most severe in the first few months after IUD insertion, treatment with a nonsteroidal anti-inflammatory drug (NSAID, an inhibitor of prostaglandin synthesis) during the first several menstrual periods can reduce bleeding and cramping. Even persistent heavy menses can be effectively treated with NSAIDs.<sup>406</sup> NSAID treatment should begin at the onset of menses and be maintained for 3 days. A copper IUD is available in China that also releases a small amount of indomethacin; this device is associated with markedly less bleeding.<sup>407</sup> It is not unusual to have a few days of intermenstrual spotting or light bleeding. Although aggravating, this does not cause significant blood loss. New-onset intermenstrual bleeding deserves the usual evaluation for cervical or endometrial pathology. These changes can be objectionable for women who are prevented from having intercourse while bleeding.

Following insertion of a modern copper IUD, menstrual blood loss increases by about 55%, and menstruation is prolonged 1–2 days, symptoms that continue for the duration of IUD use.<sup>408</sup> Over a year's time, this amount of blood loss does not result in changes indicative of iron deficiency (e.g., serum ferritin). With longer use, however, ferritin levels are lower, suggesting a depletion of iron stores.<sup>409</sup> Assessment for iron depletion and anemia should be considered in long-term users and in women susceptible to iron deficiency anemia. In populations with a high prevalence of anemia, these changes occur more rapidly, and iron supplementation is recommended.<sup>410</sup>

Because of a decidualizing, atrophic impact on the endometrium, amenorrhea can develop over time with the progestin-containing IUD. With the Mirena IUS, 70% of patients are oligomenorrheic and 30–40% are amenorrheic within 2 years.<sup>348,411</sup> In a group of women who used the levonorgestrel IUS for more than 12 years, 60% were amenorrheic; 12% experienced infrequent, scanty bleeding; and 28% had regular but light bleeding.<sup>349</sup> For some women, the lack of periods is so disconcerting that they request removal. On the other hand, this effect on menstruation is manifested by an increase in blood hemoglobin levels.<sup>298,387</sup>

Sufficient progestin reaches the systemic circulation from the levonorgestrel-containing IUS so that androgenic side effects, such as acne and hirsutism, can occur; however, in one study, no change could be detected in the circulating levels of SHBG, and, therefore, marked clinical effects are unlikely.<sup>412</sup> Occasionally a patient will experience facial, androgenic skin changes or breast tenderness. Spironolactone treatment for androgenic reactions (discussed in [Chapter 12](#)) is effective and can be titrated down to the lowest successful dose. There are no significant metabolic effects, including changes in glucose, insulin sensitivity, and lipids.<sup>413</sup> In a large postmarketing survey, the incidence of breast cancer in users of the levonorgestrel system was equivalent to that in the general population.<sup>414</sup> The combination of the levonorgestrel system and estrogen therapy in postmenopausal women did not increase breast density.<sup>415</sup>

Some women report an increased vaginal discharge while wearing an IUD. This complaint deserves examination for the presence of vaginal or cervical infection. Treatment can be provided with the IUD remaining in place.

Long-term use of the IUD is associated with impressive safety and lack of side effects. In a 7-year prospective study, the use of either the copper IUD or the levonorgestrel IUS beyond 5 years led to no increase in pelvic infection, no increase in ectopic pregnancy rates, no increase in anemia, and no increase in abnormal Pap smears.<sup>299</sup> Duration of use does not affect pregnancy rates or outcome.

The presence of copper may yield some benefits. There are epidemiologic data indicating that both the copper IUD and the inert IUD reduce the risks of endometrial cancer and invasive cervical cancer.<sup>418,419,420,421,422,423</sup> Presumably, this protective effect is due to induced biochemical alterations that affect cellular responses.

The copper IUD is not affected by magnetic resonance imaging, and therefore, the copper IUD need not be removed before MRI, and neither patients nor workers need be excluded from MRIs or the MRI environment.<sup>422,423</sup>

## Infections

IUD-related bacterial infection is due to contamination of the endometrial cavity at the time of insertion. Mishell's classic study indicated that the uterus is routinely contaminated by bacteria at insertion.<sup>424</sup> Infections that occur 3–4 months after insertion are believed to be due to acquired STIs, not the direct result of the IUD. The early, insertion-related infections, therefore, are polymicrobial and are derived from the endogenous cervicovaginal flora, with a predominance of anaerobes.

A review of the World Health Organization database derived from all of the WHO IUD clinical trials concluded that the risk of PID was six times higher during the 20

days after the insertion compared with later times during follow-up, but, most importantly, PID was extremely rare beyond the first 20 days after insertion.<sup>425</sup> In nearly 23,000 insertions, only 81 cases of PID were diagnosed. There was no statistically significant difference comparing the copper IUD to the inert Lippes loop or progestin-containing IUD. However, evidence indicates that the levonorgestrel IUS may reduce pelvic infection rates.<sup>300,367</sup>

These data confirm earlier studies that the risk of infection with intrauterine contraception does not increase with long-term use.<sup>281,284</sup> The problem of infection can be minimized with careful screening and the use of aseptic technique. Even women with insulin-dependent diabetes mellitus do not have an increased risk for infection.<sup>426</sup> Women with Chlamydia infections at the time of insertion of a levonorgestrel or copper IUD are unlikely to develop PID if the infection is treated with the IUD left in place after a positive culture is obtained.<sup>427,428</sup> The copper IUD is associated with lower titers of antichlamydial antibody.<sup>301,365,429</sup> In vitro, copper inhibits chlamydial growth in endometrial cells.<sup>430</sup> Women who received IUDs in a population unrestricted by risks for STIs were not more likely than women in the general population to develop PID.<sup>431</sup> The association between IUD use and pelvic infection (and infertility) brought about by the Dalkon Shield is now debunked.<sup>432</sup> Women who use IUDs must be counseled to use condoms along with the IUD whenever they have intercourse with a partner who could be an STI carrier. Because sexual behavior is the most important modifier of the risk of infection, clinicians should ask prospective IUD users about numbers of partners, their partner's sexual practices, the frequency and age of onset of intercourse, and history of STIs.<sup>433</sup> Women at low risk are unlikely to have pelvic infections while using IUDs.<sup>285</sup> Women at high risk should be encouraged to also use condoms.

It was previously thought that the IUD may be inappropriate for women who are at increased risk of bacterial endocarditis (previous endocarditis, rheumatic heart disease, or the presence of prosthetic heart valves). The bacteriologic contamination of the uterine cavity at insertion is short-lived.<sup>424</sup> Only one study has shown blood culture evidence of bacteremia following IUD insertion, and it was present transiently in only a few patients.<sup>434</sup> A review of patients with cardiovascular conditions found no association between endocarditis and IUD placement.<sup>435,436</sup> IUD is a safe and effective option for patients at risk of endocarditis.

Asymptomatic IUD users whose cervical cultures show gonorrhea or chlamydia infection should be treated with the recommended drugs without removal of the IUD. If, however, there is evidence that an infection has ascended to the endometrium or fallopian tubes, treatment must be instituted and the IUD removed promptly. Vaginal bacteriosis should be treated (metronidazole, 500 mg b.i.d. for 7 days), but the IUD

need not be removed unless pelvic inflammation is present. There is no evidence that the prevalence of bacterial vaginosis is influenced by IUD use.<sup>437</sup>

For simple endometritis, in which uterine tenderness is the only physical finding, doxycycline (100 mg b.i.d. for 14 days) is adequate. If tubal infection is present, as evidenced by cervical motion tenderness, abdominal rebound tenderness, adnexal tenderness or masses, or elevated white blood count and sedimentation rate, parenteral treatment is indicated with removal of the IUD **as soon as antibiotic serum levels are adequate**. The previous presence of an IUD does not alter the treatment of PID. IUD-associated pelvic infection is more likely to be caused by non-STI organisms.<sup>438</sup>

#### **Appropriate outpatient management of less severe infections:**

- Cefoxitin (2 g intramuscularly) plus probenecid (1 g orally) as a single dose, plus doxycycline (100 mg b.i.d. orally), for 14 days
- Ceftriaxone (250 mg IM) plus doxycycline (100 mg b.i.d. orally), for 14 days

**Severe infections (those associated with pregnancy, nonadherence to therapy, pelvic abscesses, inability to take oral medications due to nausea or vomiting, or high fever) require hospitalization and treatment with:**

- Cefoxitin (2 g intravenous q.i.d.)
- Cefotetan (2 g intravenous b.i.d.)
- Plus doxycycline (100 mg b.i.d. orally or intravenous)
- Followed by 14 days of an oral regimen of antibiotics

#### **The following is an alternative regimen:**

- Clindamycin (900 mg intravenously t.i.d.)
- Plus gentamicin (2 mg/kg intravenously or intramuscularly followed by 1.5 mg/kg t.i.d.)

Regimens with levofloxacin are no longer recommended by the CDC, except in patients with a severe penicillin allergy who are also unable to take clindamycin or gentamicin. In those rare instances, a single dose of azithromycin 2 g should be given with 14 days of levofloxacin 500 mg.

There was a suggestion (in cross-sectional studies) that IUD use increased the risk of HIV transmission from man to woman, especially when the IUD was inserted or removed during exposure to the infected man.<sup>439,440</sup> However, this association was not strong, because the risk with IUD use was ascertained compared with other contraceptive methods (which can protect against transmission), and various influencing

factors are difficult to adjust and control. In the only longitudinal study, no association was observed between IUD use and HIV acquisition by women.<sup>441</sup> In the only study reported, no evidence for female-to-male HIV transmission with IUD use was detected.<sup>442</sup> HIV-infected women who utilize IUDs for contraception do not have a greater incidence of complications (including PID and disease progression), and genital shedding of HIV is not affected.<sup>443,444,445,446,447</sup>

Hepatitis C virus is believed to be transmitted with sexual contact. A cross-sectional study in Turkey indicated that IUD use by women in stable, monogamous relationships did not increase the incidence of hepatitis C seropositivity.<sup>448</sup>

## **Actinomyces**

The significance of actinomycosis infection in IUD users is unclear. There are many reports of IUD users with unilateral pelvic abscesses containing gram-positive Actinomyces.<sup>449,450,451,452</sup> However, Actinomyces are part of the normal flora in the gastrointestinal tract and were found in Pap smears of up to 30% of plastic IUD wearers when cytologists take special care to look for the organisms.<sup>452</sup> The rate is much lower (1–7%) with copper devices and the levonorgestrel-releasing intrauterine system and increases with duration of use.<sup>450,453,454,455,456</sup> Additionally, Actinomyces are present on cervical smears of 3% of women without IUDs.<sup>457</sup> Previous clinical practice recommended treating asymptomatic women with actinomyces noted on pap smear with oral penicillin or doxycycline. However, recent data support managing these women expectantly.<sup>458</sup> If the patient is due for IUD replacement, the IUD can be removed and a new one immediately inserted with no adverse effects.<sup>459</sup> If uterine tenderness or a pelvic mass is present, the IUD should always be removed after the initiation of treatment with oral penicillin G, 500 mg q.i.d. for 1 month. Alternative antibiotic regimens include tetracycline 500 mg q.i.d., doxycycline 100 mg b.i.d., and amoxicillin/clavulanate 500 mg b.i.d. Another anaerobic, gram-positive rod, Eubacterium nodatum, resembles Actinomyces and has also been reported to be associated with colonization of an IUD.<sup>460</sup> E. nodatum can be mistaken for Actinomyces on Pap smears. Our recommendations can be applied to both E. nodatum and Actinomyces.

# Pregnancy with an IUD In Situ

## Spontaneous Miscarriage

Spontaneous miscarriage occurs more frequently among women who become pregnant with IUDs in place, a rate of approximately 50%. Because of this high rate of spontaneous miscarriage, IUDs should always be removed if pregnancy is diagnosed and the string is visible. The use of instruments inside the uterus should be avoided if the pregnancy is desired, unless sonographic guidance can help avoid rupture of the membranes.<sup>461</sup> After removal of an IUD with visible strings, the spontaneous miscarriage rate is approximately 30%.<sup>462,463</sup> Combining ultrasonography guidance with carbon dioxide or saline hysteroscopy, an IUD with a missing tail can be identified and removed during early pregnancy.<sup>464,465</sup> **If the IUD is easily removed without trauma or expelled during the first trimester, the risk of spontaneous miscarriage is not increased.**<sup>466,467</sup>

## Septic Abortion

In the past, if the IUD could not be easily removed from a pregnant uterus, the patient was offered induced abortion because it was believed that the risk of life-threatening septic, spontaneous miscarriage in the second trimester was increased 20-fold if the pregnancy continued with the IUD in utero. However, this belief was derived from experiences with the Dalkon Shield. There is no evidence that there is an increased risk of septic abortion if pregnancy occurs with an IUD in place other than the shield.<sup>467,468</sup> In 2010–2011, there were no deaths in the United States among women pregnant with an IUD.<sup>469</sup>

If a patient plans to terminate a pregnancy that has occurred with an IUD in place, the IUD should be removed immediately. If there is no evidence of infection, the IUD can safely be removed in a clinic or office. If an IUD is in an infected, pregnant uterus, removal of the device should be undertaken only after antibiotic therapy has been initiated, and the patient should be monitored closely for signs of septic shock.

## Congenital Anomalies

There is no evidence that exposure of a fetus to medicated IUDs is harmful. The risk of congenital anomalies is not increased among infants born to women who become pregnant with an IUD in place.<sup>467,470</sup> A case-control study did not find an increased incidence of IUD use in pregnancies resulting in limb-reduction deformities.<sup>471</sup>

## **Preterm Labor and Birth**

The incidence of preterm labor and delivery is approximately doubled when an IUD is left in place during pregnancy.<sup>469</sup>

## **Other Complications**

Obstetrical complications at delivery (e.g., hemorrhage, stillbirth, and difficulties with placenta removal) have been reported only with the Dalkon Shield in situ.

# IUD Insertion

## Patient Selection

Most patients are good candidates for IUD use. Risk factors for STIs are the most important consideration in patient selection. Women who have multiple sexual partners, whose partners have multiple partners, who are drug or alcohol dependent, and who are not in a stable sexual relationship are at greater risk of pelvic infection at the time of IUD insertion and at greater risk of acquiring a STI after IUD insertion.<sup>280,281,282</sup> It would be appropriate for these women to use condoms for STI protection and an IUD for effective contraception. Current PID is a contraindication for IUD use. Hormonal and barrier methods are better choices for these women. Nulliparous and nulligravid women can safely use the IUD, and the levonorgestrel-releasing IUS performs as well as oral contraceptives when used by young nulliparous women.<sup>472</sup> Complications, including expulsion and perforation, are no different comparing parous and nulliparous IUD users.<sup>473</sup>

Patients with heavy menstrual periods should be cautioned regarding the increase in menstrual bleeding associated with the copper IUD. Women who are anticoagulated or have a bleeding disorder are obviously not good candidates for the copper IUD, but they might benefit from the progestin IUD.

There are other conditions that can compromise success. Women who have abnormalities of uterine anatomy (bicornuate uterus, submucous myoma, cervical stenosis) may not accommodate an IUD. The IUD is not a good choice when the uterine cavity is distorted by leiomyomas. According to conventional wisdom, the few individuals who have allergies to copper or have Wilson disease (a prevalence of about 1 in 200,000) should not use copper IUDs; however, no cases of difficulty have ever been recorded, and it is doubtful, considering the low exposure to copper, that there would be a problem. The amount of copper released into the circulation per day is less than that consumed in a normal diet.<sup>474</sup> Nevertheless, barrier methods or long-acting progestin-only methods are recommended for individuals with Wilson disease.<sup>475</sup>

Because many older women have diabetes mellitus, it is worth emphasizing that no increase in adverse events has been observed with copper IUD use in women with either insulin-dependent or noninsulin-dependent diabetes.<sup>476</sup> Indeed, the IUD can be an ideal choice for a woman with diabetes, especially if vascular disease is present.

The IUD should not be dismissed just because the patient is an adolescent. Adolescents have equivocal IUD continuation rates to older women at 1 year after insertion.<sup>477</sup> Given appropriate screening, counseling, and care, the IUD can provide

long-term effective contraception for adolescents. The continuation rate with the levonorgestrel intrauterine system in a population of adolescents in the United States was 73% at 2 years and 46% at 5 years.<sup>116,478</sup> There are no major differences in IUD efficacy and side effects comparing nulligravid women with parous women.<sup>479</sup> Nulligravid women who are past users of the IUD did not have an increased risk of tubal infertility in a case-control study, but long-term IUD users in a cohort study were reported to have reduced fertility compared with oral contraceptive users and short-term IUD users.<sup>480,481</sup> The merits of the two studies can be debated (the cohort study had several confounding problems); by far most evidence indicates that IUD use does not impair fertility.<sup>332,333,334,385,482,483</sup>

A careful speculum and bimanual examination is essential prior to IUD insertion. It is important to know the position of the uterus; undetected extreme posterior uterine position is the most common reason for perforation at the time of IUD insertion. However, perforation is rare; the incidence is estimated to be less than 1 per 3,000 insertions.<sup>484</sup> A very small or large uterus, determined by examination and sounding, can preclude insertion. For successful IUD use, the uterus should preferably not sound less than 6 cm or more than 9 cm.

Preferably, the absence of cervical or vaginal infection should be established before insertion. If this is not feasible, insertion should definitely be delayed if a mucopurulent discharge of the cervix or a significant vaginitis (including vaginal bacteriosis) is present.

## Key Points: IUD Use and Medical Conditions

- A woman with a previous ectopic pregnancy can use a copper IUD or levonorgestrel IUS.
- Women with heavy menses and dysmenorrhea, including women who have a bleeding disorder or are anticoagulated, should consider the 52 mg levonorgestrel-releasing IUS.
- Current PID is a contraindication for IUD use.
- Women with diabetes mellitus, either insulin-dependent or noninsulin-dependent, can use IUDs.
- IUD insertion is relatively easier in breast-feeding women, and the rates of expulsion and uterine perforation are not increased.

## Key Points: Patient Counseling

- Protection against unwanted pregnancy begins immediately after insertion.
- Menses can be longer and heavier with the copper IUD; tampons can be used.
- There is a slightly increased risk of pelvic infection in the first few months after insertion.
- Protection against infections transmitted through the vaginal mucosa requires the use of condoms.
- Ectopic pregnancies can still occur.
- The IUD can be spontaneously expelled; monthly palpation of the IUD strings is important to avoid unwanted pregnancies. If the strings are not felt or something hard is palpable (suggestive of the IUD frame), a clinician should be notified as soon as possible. Backup contraception should be provided until the patient can be examined.

## Timing

An IUD can be safely inserted at any time after delivery, spontaneous miscarriage or induced abortion, or during the menstrual cycle. Expulsion rates were higher when the older, large plastic IUDs were inserted sooner than 8 weeks of postpartum; however, studies indicate that the copper IUDs can be inserted between 4 and 8 weeks of postpartum without an increase in pregnancy rates, expulsion, uterine perforation, or removals for bleeding and/or pain.<sup>485,486</sup> Insertion can even occur immediately after a vaginal delivery; it is not associated with an increased risk of infection, uterine perforation, postpartum bleeding, or uterine subinvolution.<sup>489,490</sup> Postvaginal delivery insertion is not recommended if intrauterine infection is present, and a slightly higher expulsion rate is to be expected compared with insertion 4–8 weeks of postpartum. The IUD can also be inserted at cesarean section; the expulsion rate is slightly lower than that with insertion immediately after vaginal delivery.<sup>489</sup>

Insertion of an IUD in breast-feeding women is relatively easier and is associated with a lower removal rate for bleeding or pain.<sup>487</sup> Reports disagree whether perforation is more common in lactating women.<sup>487,490,491</sup>

Insertions can be more difficult if the cervix is closed between menses. The advantages of insertion during or shortly after a menstrual period include a more open cervical canal, the masking of insertion-related bleeding, and the knowledge that the patient is not pregnant. These relative advantages may be outweighed by the risk of unintended pregnancy if insertion is delayed to await menstrual bleeding. In addition,

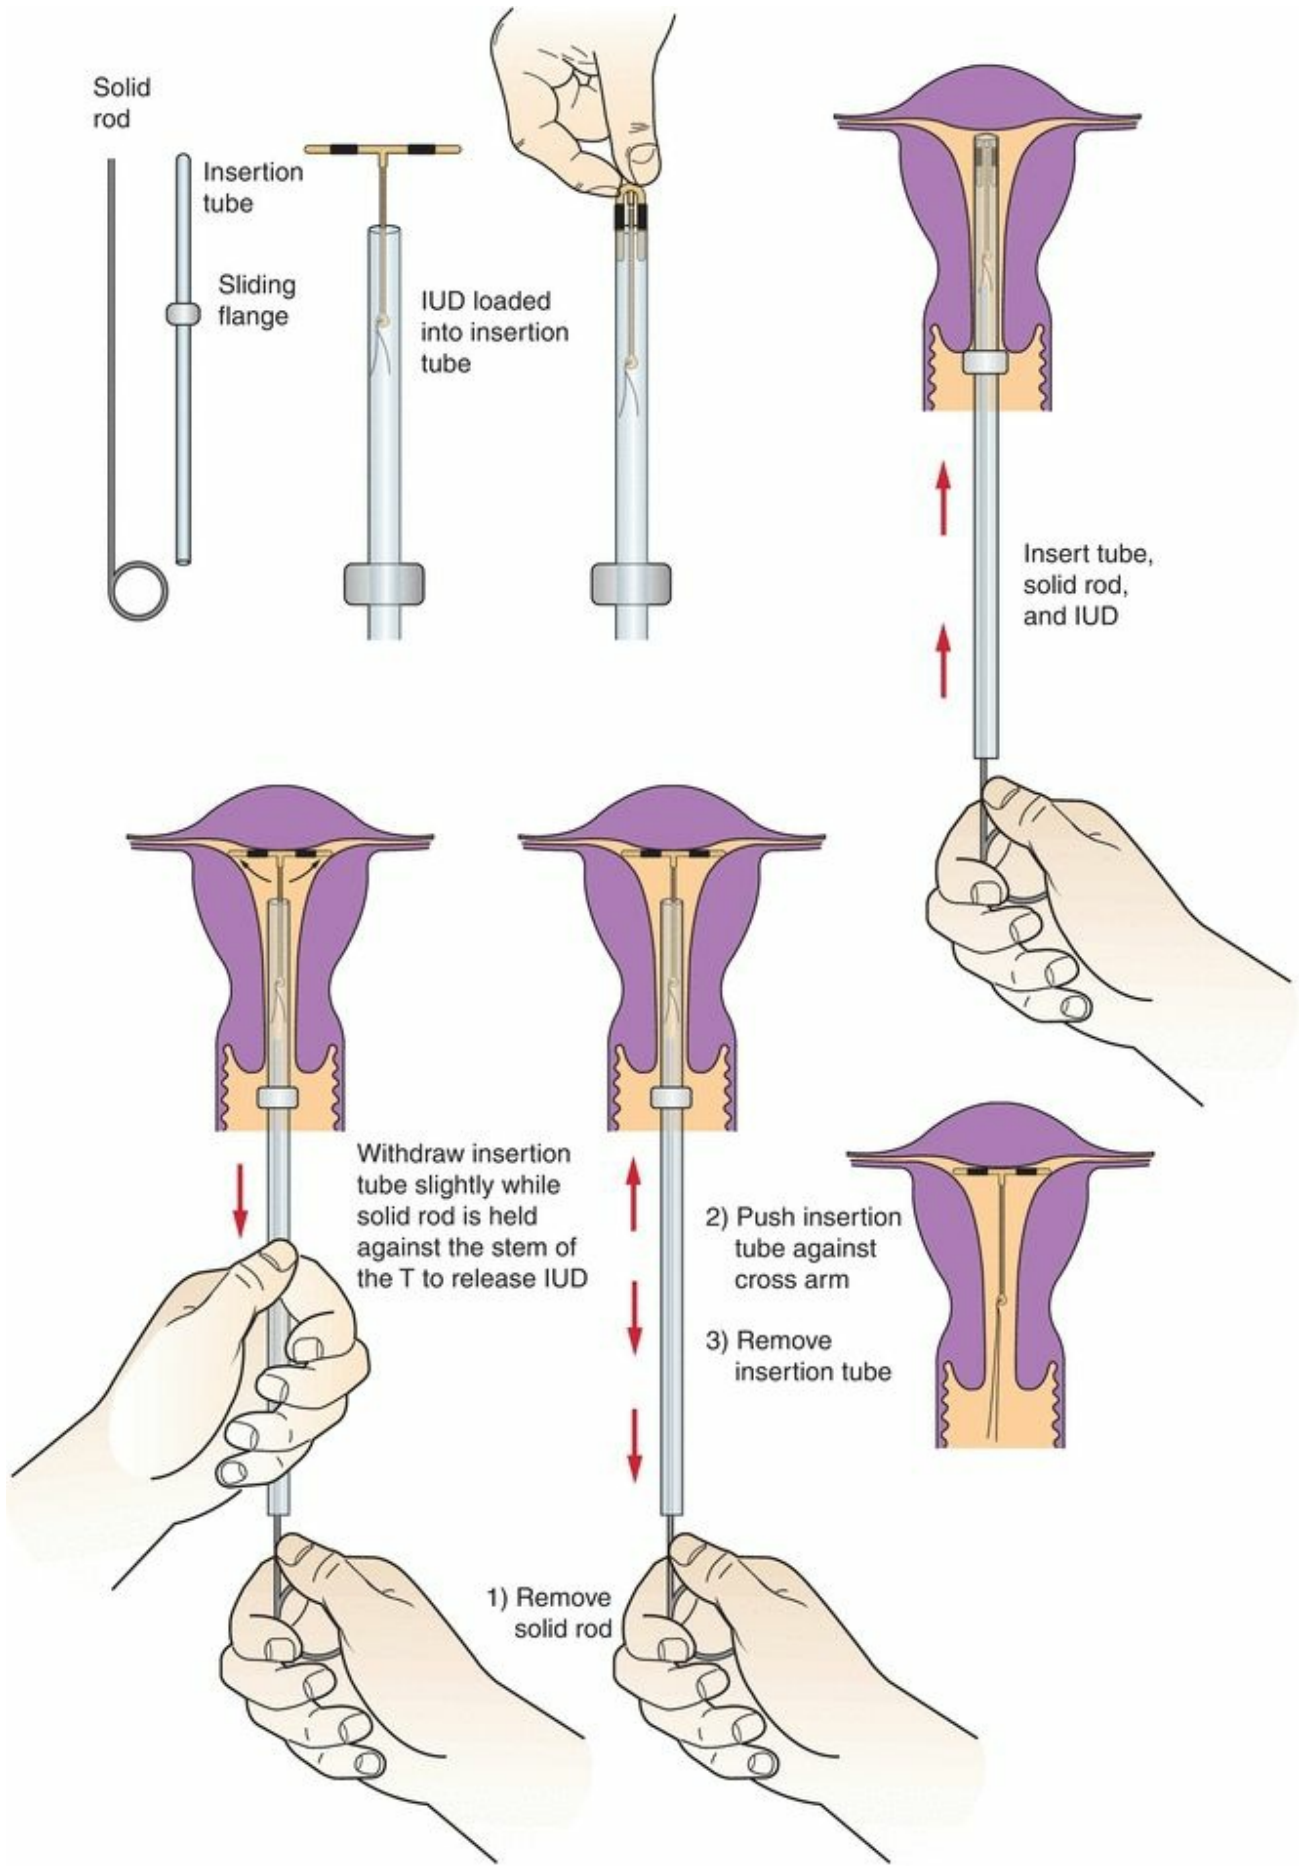

there is evidence that the expulsion rate and termination rates for pain, bleeding, and pregnancy are lower if insertions are performed after day 11 of the menstrual cycle, and the infection rate may be lower with insertions after the 17th cycle day.<sup>492</sup>

An IUD can be inserted immediately after a first-trimester abortion, but, after a second-trimester abortion, there is a higher risk of expulsion.<sup>493,494,495</sup> A decision analysis concluded that insertion of an IUD immediately after an abortion procedure would be associated with a major reduction in pregnancies compared with insertion at a follow-up visit, and, therefore, even considering expulsions, postabortion insertions are cost-effective.<sup>495</sup>

## Technique for the TCU-380A

Inserting an IUD requires only a few minutes, has few complications, and is rarely painful, but preoperative examination, medication, and the right equipment will ensure a good experience for your patient. Ensure a negative pregnancy test. After introducing a vaginal speculum, the cervix is cleaned with chlorhexidine or povidone-iodine. Many women can tolerate IUD insertion, especially at the time of menses, without a paracervical block. For some women, however, insertion is less painful with local anesthetic and with administration of a nonsteroidal anti-inflammatory agent 30 minutes to 1 hour prior to the procedure.

A paracervical block can be placed by injecting 1 mL of local anesthetic (1% chlorprocaine) into the cervical lip (anterior if the uterus is anterior in the pelvis and posterior if it lies posteriorly). Inclusion of atropine, 0.4 mg, in the anesthetic will reduce the incidence of vasovagal reactions. After 1 minute, grasp the cervical lip with the tenaculum, ratcheting it only to the first position in a slow, deliberate fashion. Use the tenaculum to move the cervix to the patient's right, revealing the left lateral vaginal fornix. Place the needle tip in the cervical mucosa at 3 o'clock, 1–2 cm lateral to the cervical os, advance it about 1.5 inches (4 cm) under the mucosa, and inject about 4 mL of anesthetic, leaving an additional 1 mL behind under the mucosa as the needle is withdrawn. Now deflect the cervix to the patient's left and inject local anesthetic at 9 o'clock in similar fashion. **Wait 2–3 minutes before proceeding.** A very common mistake is to not allow sufficient time for anesthetic action (**Figure 23.8**).

## FIGURE 23.8

If a paracervical block is not used and a tenaculum is needed, having the patient cough just as the tenaculum is applied reduces pain and the chance of a vasovagal reaction. An alternative approach for pain relief is to apply benzocaine 20% gel first at the tenaculum site and then to leave a gel-soaked cotton-tipped applicator in the cervical canal for about 1 minute before inserting the IUD.<sup>496</sup>

Sound and measure the depth of the uterus (the insertion tube can be used for this purpose). The IUD is loaded into its insertion tube immediately prior to insertion. The arms of the TCu-380A must be folded manually, either with sterile gloves or through the sterile wrapper, and maneuvered into the end of the insertion tube, just enough to hold them in place during insertion. The insertion tube is advanced into the uterus to the correct depth as marked on the tube by a sliding plastic flange. The flange should be twisted to be in the same plane as the horizontal arms. When the insertion tube and IUD reach the fundus, withdraw a few millimeters. Check to make sure that the transverse arm of the IUD is in the horizontal plane so that the tips of the T will rest in the cornual regions of the endometrial cavity. Placement in the vertical plane increases the risk of expulsion and pregnancy.<sup>497</sup> To release the TCu-380A, advance the solid rod until the resistance of the IUD is felt, and withdraw the insertion tube no more than 1 cm while the solid insertion rod is held against the stem of the T, releasing the transverse arms into high fundal position. Then move the insertion tube back toward the fundus until slight resistance is felt. Remove the solid rod and finally the insertion tube taking care not to pull on the strings. Trim the strings to about 4 cm from the external os, and record their length in the chart. Shorter strings can cause unpleasant bristle-like sensations.

Patients with newly inserted IUDs should attempt to feel the strings before they leave the examining room. Giving them the cut ends of the strings as a sample of what to feel is helpful. Palpation should be performed monthly by the patient to verify continuing presence of the IUD after each menstrual flow. Caution the patient that the first two menses are typically heavier. As with all office procedures, patients should be provided a 24-hour phone number for urgent questions or concerns and especially to report unusual pain, bleeding, or vaginal discharge.

A 1-month follow-up visit is recommended to identify problems amenable to counseling and treatment. Women experiencing heavier menstrual flow or irregular bleeding in the 1st month after insertion are at increased risk for removals because of bleeding and pain.<sup>498</sup> Intensified support along with treatment with a nonsteroidal anti-inflammatory agent can maintain continuation of the method.

## Technique for the 52 mg Levonorgestrel IUD

Prepare for insertion as described above for the copper IUD with a negative pregnancy test, speculum placement, paracervical block or nonsteroidal anti-inflammatory agents, and cleansing the cervix with a surgical-grade solution. Place a tenaculum if necessary and sound the uterine depth. Open the sterile package. Make sure that the IUD arms are horizontal, and push the slider as far forward (toward the patient) as possible. Move the flange so that the forward surface is at the depth of the uterus as measured by the sound. Hold the slider firmly with a thumb or finger; move the inserter into the uterus until the flange is about 1.5–2.0 cm from the cervix (this allows space for the arms to open). Holding the inserter steady, release the arms by pulling the slider back until it reaches the mark (the raised horizontal line); wait for 10 seconds for the arms to completely open. Holding the slider in its new position, advance the inserter gently until the flange touches the cervix, placing the IUD high in the fundus (**Figure 23.9**). Release the IUD by pulling the slider down, making sure that the strings release from the notch. Remove the inserter and trim the strings.

**FIGURE 23.9**

Insertion against the anterior fundus is essential for maximal efficacy and low expulsion rates. Correct placement can be assessed with ultrasonography; this is especially useful when inserting IUDs in larger cavities (after a pregnancy or when myomas are present).

## Prophylactic Antibiotics

In women at low risk for STIs, the incidence of infection is so low that there is little benefit to be expected with prophylactic antibiotics, and they are not recommended.<sup>499</sup>

# IUD Removal

Removal of an IUD can usually be accomplished by grasping the string with a ring forceps or uterine dressing forceps and exerting firm traction. If strings cannot be seen, they can often be extracted from the cervical canal by rotating two cotton-tipped applicators or a Pap smear cytobrush in the endocervical canal. If further maneuvers are required, a paracervical block may be administered. Oral administration of a nonsteroidal anti-inflammatory drug beforehand will reduce uterine cramping.

If IUD strings cannot be identified or extracted from the endocervical canal, a light plastic uterine sound should be passed into the endometrial cavity. A standard metal sound is too heavy and insensitive for this purpose. The IUD can frequently be felt with the sound and localized against the anterior or posterior wall of the uterus. The device can then be removed using a Facit polyp or alligator-type forceps directed to where the device was felt, taking care to open the forceps widely immediately on passing it through the internal cervical os so that the IUD can be caught between the jaws. If removal is not easily accomplished using this forceps, direct visualization of the IUD with sonography or hysteroscopy can facilitate removal. Sonography is less painful and more convenient and should be tried first.

Fertility returns promptly, and pregnancies after removal of an IUD occur at a normal rate, sooner than after oral contraception.<sup>332,333,334,335,385</sup> Pregnancy outcome after IUD removal is associated with a normal incidence of spontaneous miscarriage and ectopic pregnancy.<sup>385</sup>

If a patient wishes to continue the use of an IUD, a new device can be placed immediately after removal of the old one. In this case, antibiotic prophylaxis is advised.

## Embedded IUDs

If removal is not easily accomplished, direct visualization of the IUD with sonography or hysteroscopy can be helpful. Sonography is safer and less expensive.<sup>461,500</sup> Transvaginal ultrasonography provides the best image to confirm the location of the IUD, but there is little room for the removal procedure. A better approach is to fill the bladder and use an abdominal sector transducer to image the uterine cavity as the forceps are introduced. One should open the forceps widely and see if the IUD moves when the forceps close on it. If it moves, one should close the forceps tightly and extract the IUD. If unsuccessful, the forceps is reintroduced in a different plane, keeping one jaw of the open forceps firmly against first the anterior and then the posterior uterine wall. If this approach is not successful, hysteroscopy is indicated.

## Finding a Displaced IUD

When an IUD cannot be found either by direct examination or ultrasound in the office, in addition to expulsion, one has to consider perforation of the uterus into the abdominal cavity (a very rare event) or embedment into the myometrium. All IUDs are radiopaque and should be able to be localized with abdominal x-rays using 2–3 views.

If the IUD is identified perforating the myometrium or in the abdominal cavity, it should be removed using operative laparoscopy, usually under general anesthesia. If the IUD is in the uterine cavity, but cannot be grasped with a forceps under sonographic guidance, hysteroscopy is the best approach. Both routes may be helpful if an IUD is partially perforated.

Copper in the abdominal cavity can lead to adhesion formation, making laparoscopic removal difficult.<sup>501</sup> Although inert perforated devices without closed loops were previously allowed to remain in the abdominal cavity, current practice is to remove any perforated IUD, including the levonorgestrel-releasing systems. Because IUD perforations usually occur at the time of insertion, it is important to check for correct position by identifying the string within a few weeks after insertion. Uterine perforation itself is unlikely to cause more than transient pain and bleeding and can go undetected at the time of IUD insertion. If you believe perforation has occurred, prompt sonography is indicated so that the device can be removed before adhesion formation can occur.

This problem should be put into perspective. With the new generation of IUDs (copper and levonorgestrel), adhesion formation appears to be an immediate reaction that does not progress and rarely leads to serious complications.<sup>502</sup> In appropriate situations (in which the risk of surgery is considerable), clinician and patient may elect not to remove the translocated IUD in the absence of concerning symptoms.<sup>503</sup> However, a case has been reported of sigmoid perforation occurring 5 years after insertion, and the general consensus continues to favor removal of a perforated IUD immediately on diagnosis.<sup>504</sup>

# The IUD for Older Women

The growing need for reversible contraception in older women would be well served by increased utilization of the IUD. The copper and levonorgestrel IUDs are among the most effective contraceptives, better than some sterilization operations. An older woman is more likely to be mutually monogamous and less likely to develop PID, and for those women who have already had their children, concern with fertility and problems with cramping and bleeding are both lesser issues. If protection from STIs is not a concern, insertion of a copper IUD can provide very effective contraception until the menopause without the need to do anything other than check the string occasionally. On the other hand, because alterations of bleeding patterns become more common in this age group, it may be necessary to remove an IUD to avoid misinterpreting bleeding that could be due to endometrial disease. The IUD is not a good choice when the uterine cavity is distorted by leiomyomas. There are epidemiologic data indicating that the copper reduces the risks of endometrial cancer and invasive cervical cancer,<sup>416,417,418,419,420</sup> presumably because of the induced biochemical alterations that affect cellular responses.

The levonorgestrel-releasing IUS (Mirena) is especially worth considering for older women. The levonorgestrel IUS lasts up to 7 years and reduces menstrual blood loss and pelvic infection rates.<sup>299,300,301</sup> Because of the favorable impact of locally released progestin on the endometrium, the levonorgestrel IUS is very effective for the treatment of menorrhagia, as effective as the administration of oral progestins (with less side effects), and compares favorably with surgical treatment (hysterectomy or endometrial ablation).<sup>339,340,341,342,343</sup> The use of the levonorgestrel-releasing IUS also reduces bleeding in women with uterine leiomyomas, and there is some evidence that this IUD reduces the prevalence of myomas, although not the volume of existing myomas.<sup>352,353,354,355,356</sup>

The 52 mg levonorgestrel IUS effectively protects the endometrium against hyperplasia in women using tamoxifen or postmenopausal estrogen therapy.<sup>304,307,308,309,310,311,372,373,374</sup> In addition, this IUD can be used to prevent and to treat endometrial hyperplasia.<sup>375,376,378</sup> But it is worth emphasizing again that although the 52 mg levonorgestrel IUD confidently provides good protection against endometrial hyperplasia, clinicians should maintain a high degree of suspicion of unusual bleeding and aggressively assess the endometrium.

# IUD MYTHS

---

We hope the information in this chapter lays to rest specific myths associated with IUDs. For emphasis, the following sentences provide the correct responses to what we believe are common misconceptions among clinicians:

1. IUDs are not abortifacients.
2. An increased risk of infection with the modern IUD is related only to the insertion.
3. IUD use does not increase the risk of PID or infertility.
4. IUDs do not increase the risk of ectopic pregnancy and CAN be used by women with a previous ectopic.
5. IUDs CAN be used by nulliparous women.
6. IUDs CAN be inserted immediately postpartum, including after first- and second-trimester abortions.
7. IUDs CAN be inserted in HIV-positive women.
8. The modern IUD HAS NOT exposed clinicians to litigation.

# Barrier Methods of Contraception and Withdrawal

Barrier methods of contraception are the oldest and the most widely used contraceptive techniques throughout recorded history. These are also the only contraceptive methods that protect against sexually transmitted infections (STIs). A need for sexual safety has brought new respect and modern developments to the condom, while other barrier methods continue to serve appropriate couples. Withdrawal is also an ancient method of contraception that deserves understanding and appreciation.

# HISTORY OF BARRIER METHODS

---

The use of vaginal contraceptives is probably as ancient as *Homo sapiens*. References to sponges and plugs appear in the earliest of writings. However, the diaphragm and the cervical cap were not invented until the late 1800s, the same time period that saw the beginning of investigations with spermicidal agents.

Intravaginal contraception was widespread in isolated cultures throughout the world. The Japanese used balls of bamboo paper, Islamic women used willow leaves, and women in the Pacific Islands used seaweed. References can be found throughout ancient writings to sticky plugs, made of gum-like substances, to be placed in the vagina prior to intercourse. In preliterate societies, an effective method had to have been the result of trial and error, with some good luck thrown in. Contraceptive knowledge is believed to have spread through communication of these traditions through these isolated societies. The social and technical circumstances of ancient times conspired to make communication of information very difficult. But even when knowledge was lacking, the desire to prevent conception was not, hence the widespread use of potions, body movements, and amulets, all of which can be best described as magic.

Egyptian papyri dating from 1850 B.C. refer to plugs of honey, gum, acacia, and crocodile dung. The descriptions of contraceptive techniques by Soranus are viewed as the best in history until modern times.<sup>1</sup> Soranus of Ephesus lived from 98 to 138 and has often been referred to as the greatest gynecologist of antiquity. He studied in Alexandria and practiced in Rome. His great text was lost for centuries and was not published until 1838. Soranus gave explicit directions regarding how to make concoctions that probably combined a barrier with spermicidal action. He favored making pulps from nuts and fruits (probably very acidic and spermicidal) and advocated the use of soft wool placed at the cervical os. He described up to 40 different combinations.

The earliest penis protectors were just that, intended to provide prophylaxis against infection. In 1564, Gabriello Fallopius, one of the early authorities on syphilis, described a linen condom that covered the glans penis. The linen condom of Fallopius was followed by full covering with animal skins and intestines, but use for contraception cannot be dated to earlier than the 1700s. By 1800, condoms were available at brothels throughout Europe. The vulcanization of rubber revolutionized contraception. Vulcanization of rubber dates to 1844, and, by 1850, rubber condoms were available in the United States. The introduction of liquid latex and automatic machinery ultimately made reliable condoms both plentiful and affordable.

Diaphragms first appeared in publications in Germany in the 1880s. A practicing German gynecologist C. Haase wrote extensively about his diaphragm, using the pseudonym Wilhelm P. J. Mensinga. The Mensinga diaphragm retained its original

design with little change until modern times.

The cervical cap was available for use before the diaphragm. A New York gynecologist E. B. Foote wrote a pamphlet describing its use around 1860. By the 1930s, the cervical cap was the most widely prescribed method of contraception in Europe. Its use was not as widespread in the United States; some blame the more restrictive attitude toward sexuality as an explanation for why American women had difficulty learning self-insertion techniques.

Scientific experimentation with chemical inhibitors of sperm began in the 1800s. By the 1950s, more than 90 different spermicidal products were being marketed, and some of them were used in the first efforts to control fertility in India.<sup>2</sup> With the availability of the intrauterine device and the development of oral contraception in the 1960s, interest in spermicidal agents waned, and the number of products declined.

In the last decades of the 1800s, condoms, diaphragms, pessaries, and douching syringes were widely advertised; however, they were not widely used. It is only since 1900 that the knowledge and application of contraception have been democratized, encouraged, and promoted. And it is only since 1960 that contraception teaching and practice became part of academic medicine but not without difficulty. In the 1960s, Duncan Reid, chair of obstetrics at Harvard Medical School, organized and cared for women in a clandestine clinic for contraception. In “Dr. Reid’s Clinic” at the Boston Lying-In Hospital, women were able to receive contraceptives not available elsewhere in the city ([Table 24.1](#)).

## **TABLE 24.1 Failure Rates During the First Year of Use, United States<sup>3,4,5</sup>**

Method	Percent of Women with Pregnancy	
	Lowest Expected	Typical
No method	85%	85%
Combination pill	0.3%	8.7%
Progestin only	0.5%	3.0%
IUDs		
Levonorgestrel IUD	0.1%	0.1%
Copper T 380A	0.6%	1.0%
Implant	0.05%	1.0%
Injectable		
3 month	0.3	0.3%
1 month	0.05	3.0%
Patch	0.3	8.0%
Vaginal ring	0.3	8.0%
Female sterilization	0.5%	0.7%
Male sterilization	0.1%	0.2%
Periodic abstinence		25.3%
Calendar	9.0%	
Ovulation method	3.0%	
Symptothermal	2.0%	
Postovulation	1.0%	
Spermicides	18.0%	29.0%
Cervical cap		
Parous women	26.0%	32.0%
Nulliparous women	9.0%	16.0%
Sponge		
Parous women	20.0%	32.0%
Nulliparous women	9.0%	16.0%
Diaphragm and spermicides	6.0%	16.0%
Condom		
Male	2.0%	17.4%
Female	5.0%	27.0%
Withdrawal	4.0%	18.4%

In 1961, C. Lee Buxton, chair of obstetrics and gynecology at Yale Medical School, and Estelle Griswold, the 61-year-old executive director of Connecticut Planned Parenthood, opened four Planned Parenthood clinics in New Haven, in a defiant move against the current Connecticut law. In an obvious test of the Connecticut law, Buxton and Griswold were arrested at the Orange Street clinic, in a prearranged scenario scripted by Buxton and Griswold at the invitation of the district attorney. They were found guilty and fined \$100, but imprisonment was deferred because the obvious goal was a decision by the United States Supreme Court. Buxton was forever rankled by the trivial amount of the fine. On June 7, 1965, the Supreme Court voted 7–2 to overturn the Connecticut law on the basis of a constitutional right of privacy. It was not until 1972 and 1973 that the last state laws prohibiting the distribution of contraceptives were overthrown.

# RISKS AND BENEFITS COMMON TO ALL BARRIER METHODS

---

Barrier methods (condoms and diaphragms) provide protection (about a 50% reduction) against STIs and pelvic inflammatory disease (PID).<sup>6,7,8,9,10</sup> This includes infections due to chlamydia, gonorrhea, trichomonas, herpes simplex, and cytomegalovirus. Only the condom has been proven to prevent human immunodeficiency virus (HIV) infection. STI protection has a beneficial impact on the risk of tubal infertility and ectopic pregnancy.<sup>8,11</sup> There have been no significant clinical studies on STIs and cervical caps or the female condom, but these methods seem to be at least as effective as male condom use in preventing STI transmission.<sup>12,13</sup> Women who have never used barrier methods of contraception are almost twice as likely to develop cancer of the cervix.<sup>11,14</sup> The risk of toxic shock syndrome is increased with female barrier methods, but the actual incidence is so rare that this is not a significant clinical consideration.<sup>15</sup> Women who have had toxic shock syndrome, however, should be advised to avoid barrier methods.

## **Barrier Methods and Preeclampsia**

An initial case-control study indicated that methods of contraception that prevented exposure to sperm were associated with an increased risk of preeclampsia.<sup>16</sup> This was not confirmed in a careful analysis of two large prospective pregnancy studies.<sup>17</sup> This latter conclusion was more compelling in that it was derived from a large, prospective, cohort database.

# THE DIAPHRAGM

---

The first effective contraceptive method under a woman's control was the vaginal diaphragm. Distribution of diaphragms led to Margaret Sanger's arrest in New York City in 1918. By 1940, one-third of contracepting American couples were using the diaphragm. This decreased to 10% by 1965 after the introduction of oral contraceptives and intrauterine devices and fell to about 1.9% in 1995, and today, diaphragm use has nearly disappeared in the United States.<sup>18</sup>

# Efficacy

Failure rates for diaphragm users vary from as low as 2% per year of use to a high of 23%. The typical use failure rate after 1 year of use is 16%.<sup>3,4,5</sup> Older, married women with longer use achieve the highest efficacy, but young women can use diaphragms very successfully if they are motivated and properly counseled. There have been no adequate studies to determine whether efficacy is different with and without spermicides.<sup>19</sup>

## Side Effects

The diaphragm is a safe method of contraception that rarely causes even minor side effects. Occasionally, women report vaginal irritation due to the latex rubber or the spermicidal jelly or cream used with the diaphragm. Less than 1% discontinue diaphragm use for these reasons. Urinary tract infections are two- to threefold more common among diaphragm users than among women using oral contraception.<sup>20,21</sup> Possibly, the rim of the diaphragm presses against the urethra and causes irritation that is perceived as infectious in origin, or true infection may result from touching the perineal area or from incomplete emptying of the bladder. It is more probable that spermicides used with the diaphragm can increase the risk of bacteriuria with *Escherichia coli*, perhaps due to an alteration in the normal vaginal flora.<sup>22</sup> Postcoital antibiotics can be prescribed for women with recurrent urinary tract infections that are associated with sexual activity. Postcoital prophylaxis is effective, using trimethoprim sulfamethoxazole (1 tablet postcoitus), nitrofurantoin (50 or 100 mg postcoitus), or cephalexin (250 mg postcoitus).

Improper fitting or prolonged retention (beyond 24 hours) can cause vaginal abrasion or mucosal irritation. There is no link between the normal use of diaphragms and the toxic shock syndrome.<sup>23</sup> It makes sense, however, to minimize the risk of toxic shock by removing the diaphragm after 24 hours and during menses.

# Benefits

Diaphragm use reduces the incidence of cervical gonorrhea, trichomonas, and chlamydia,<sup>24</sup> PID,<sup>8,25</sup> and tubal infertility.<sup>6,11</sup> There are no data, as of yet, regarding the effect of diaphragm use on the transmission of the acquired immunodeficiency syndrome (AIDS) virus HIV, but because the vagina remains exposed, the diaphragm is unlikely to protect against HIV. A clinical trial demonstrated no added benefit with a diaphragm against HIV when used with condoms.<sup>26</sup> An important advantage of the diaphragm is low cost. Diaphragms are durable and with proper care can last for several years.

# Choice and Use of the Diaphragm

There are three major types of latex diaphragms, and most manufacturers produce them in sizes ranging from 50 to 105 mm diameter, in increments of 2.5–5 mm. Most women use sizes between 65 and 80 mm. The latex diaphragm made with a flat metal spring or a coil spring remains in a straight line when pinched at the edges. This type is suitable for women with good vaginal muscle tone and an adequate recess behind the pubic arch. However, many women find it difficult to place the posterior edge of these flat diaphragms into the posterior cul-de-sac and over the cervix. Arcing diaphragms are easier to use for most women. They come in two types. The All-Flex type bends into an arc no matter where around the rim the edges are pinched together. The hinged type must be pinched between the hinges to form a symmetrical, narrow arc and may be easier for some women to insert. The arcing diaphragms allow the posterior edge of the diaphragm to slip more easily past the cervix and into the posterior cul-de-sac. Women with poor vaginal muscle tone, cystocele, rectocele, a long cervix, or an anterior cervix of a retroverted uterus use arcing diaphragms more successfully.

For women or their partners with latex allergies, the SILCS diaphragm is a silicone barrier used with a contraceptive gel.<sup>27</sup> It comes in one size that fits most women, and, therefore, interaction with a clinician and the requirement for fitting can be avoided. The Milex Wide-Seal diaphragm is also made of silicone and comes in eight sizes that require fitting.

## Fitting

Successful use of a diaphragm depends on proper fitting. The clinician must have aseptic fitting rings or the diaphragms themselves available in all diameters. These devices should be scrupulously disinfected by soaking in a bleach solution. At the time of the pelvic examination, the middle finger is placed against the vaginal wall and the posterior cul-de-sac, while the hand is lifted anteriorly until the pubic symphysis abuts the index finger. This point is marked with the examiner's thumb to approximate the diameter of the diaphragm. The corresponding fitting ring or diaphragm is inserted, and the fit is assessed by both clinician and patient.

If the diaphragm is too tightly pressed against the pubic symphysis, a smaller size is selected. If the diaphragm is too loose (comes out with a cough or bearing down), the next larger size is selected. After a good fit is obtained, the diaphragm is removed by hooking the index finger under the rim behind the symphysis and pulling. It is important to instruct the patient in these procedures during and after the fitting. The patient should then insert the diaphragm, practice checking for proper placement, and attempt removal.

## **Timing**

Diaphragm users need additional instruction about the timing of diaphragm use in relation to sexual intercourse and the use of spermicide. None of this advice has been rigorously assessed in clinical studies; therefore, these recommendations represent the consensus of clinical experience.

The diaphragm should be inserted no longer than 6 hours prior to sexual intercourse. About a tablespoonful of spermicidal cream or jelly should be placed in the dome of the diaphragm prior to insertion, and some of the spermicide should be spread around the rim with a finger. The diaphragm should be left in place for approximately 6 hours (but no more than 24 hours) after coitus. Additional spermicide should be placed in the vagina before each additional episode of sexual intercourse while the diaphragm is in place.

## **Reassessment**

Weight loss, weight gain, vaginal delivery, and even sexual intercourse can change vaginal caliber. The fit of a diaphragm should be assessed every year at the time of the regular examination.

## **Care of the Diaphragm**

After removal, the diaphragm should be washed with soap and water, rinsed, and dried. Powders of any sort should not be applied to the diaphragm. It is wise to use water to periodically check for leaks. Diaphragms should be stored in a cool and dark location.

# THE CERVICAL CAP

---

The cervical cap was popular in Europe long before its reintroduction into the United States. Currently, the only cervical cap available in the United States is the FemCap. The FemCap is made of nonallergenic silicone rubber and is shaped like a sailor's hat, a design that allows a snug fit over the cervix and in the vaginal fornices and provides a "brim" for easy removal.<sup>28</sup> There are three sizes, one for nulliparous women and larger sizes for women who have had a vaginal delivery. In a randomized trial, the pregnancy rate with FemCap was nearly twofold higher compared with a diaphragm.<sup>29</sup>

Other cervical caps available elsewhere, such as the latex Prentif cervical cap, have been shown in U.S. trials to be about as effective as the diaphragm but somewhat harder to fit and more difficult to insert (it must be placed precisely over the cervix).<sup>30,31</sup> Efficacy is significantly reduced in parous women.

Cervical caps have several advantages over the diaphragm. They can be left in place for a longer time (up to 48 hours), and they need not be used with a spermicide. However, a tablespoonful of spermicide placed in the cap before application is reported to increase efficacy (to a 6% failure rate in the first year) and to prolong wearing time by decreasing the incidence of foul-smelling discharge (a common complaint after 24 hours).<sup>31</sup>

The size of the cervix varies considerably from woman to woman, and the cervix changes in individual women in response to pregnancy or surgery. Proper fitting can be accomplished in about 80% of women. Women with a cervix that is too long or too short, or with a cervix that is far forward in the vagina, may not be suited for cap use. However, women with vaginal wall or pelvic relaxation, who cannot retain a diaphragm, may be able to use the cap.

Those women who can be fitted with a cervical cap must first learn how to identify the cervix and then how to slide the cap into the vagina, up the posterior vaginal wall and onto the cervix. After insertion and after each act of sexual intercourse, the cervix should be checked to make sure that it is covered.

The cervical cap must be left in place for at least 8 hours after sexual intercourse in order to ensure that no motile sperm are left in the vagina. To remove the cap, pressure must be exerted with a finger tip to break the seal. The finger is hooked over the cap rim to pull it out of the vagina. Bearing down or squatting or both can help to bring the cervix within reach of the finger.

The most common cause of failure is dislodgment of the cap from the cervix during sexual intercourse. There is no evidence that cervical caps cause toxic shock syndrome or dysplastic changes in the cervical mucosa.<sup>32</sup> It seems likely (although not yet

documented) that cervical caps would provide the same protection from STIs as the diaphragm.

Lea's Shield is a vaginal barrier contraceptive composed of silicone.<sup>33,34</sup> This soft, pliable device comes in one size and fits over the cervix, held in place by the pressure of the vaginal wall around it. There is a collapsible valve that communicates with a 9-mm opening in the bowl that fits over the cervix. This valve allows equalization of air pressure during insertion and drainage of cervical secretions and discharge, permitting a snug fit over the cervix. A thick U-shaped loop attached to the anterior side of the bowl is used to stabilize the device during insertion and for removal. The thicker part of the device is shaped to fill the posterior fornix, thus contributing to its placement and stability over the cervix. The addition of a spermicide, placed in the bowl, is recommended. Lea's Shield is designed to remain in place for 48 hours after intercourse. Pregnancy rates are similar to other barrier methods, and no serious adverse effects have been reported.<sup>35</sup>

Ovés is a silastic cervical cap that is available in three sizes, with a loop for insertion and removal. Studies are limited to very small numbers of women, and there are no meaningful data on efficacy.<sup>36</sup>

# THE CONTRACEPTIVE SPONGE

---

The vaginal contraceptive sponge is a sustained-release system for a spermicide. The sponge also absorbs semen and blocks the entrance to the cervical canal. The “Today” sponge is a dimpled polyurethane disc impregnated with 1 g of nonoxynol-9. Approximately 20% of the nonoxynol-9 is released over the 24 hours that the sponge is left in the vagina. “Protectaid” is a polyurethane sponge available in Canada and Hong Kong (it also can be purchased over the Internet) that contains three spermicides and a dispersing gel.<sup>37</sup> The spermicidal agents are sodium cholate, nonoxynol-9, and benzalkonium chloride. This combination exerts antiviral actions in vitro.<sup>38</sup> The dispersing agent, polydimethylsiloxane, forms a protective coating over the entire vagina, providing sustained protection.

To insert, the Today sponge is moistened with water (squeezing out the excess) and placed firmly against the cervix. There should always be a lapse of at least 6 hours after sexual intercourse before removal, even if the sponge has been in place for 24 hours before intercourse (maximal wear time, therefore, is 30 hours). It can be inserted immediately before sexual intercourse or up to 24 hours beforehand. It is removed by hooking a finger through the ribbon attached to the back of the sponge. The Protectaid sponge can be inserted up to 12 hours before intercourse, and it is easier to remove than the Today sponge. Obviously, the sponge is not a good choice for women with anatomic changes that make proper insertion and placement difficult.

In most studies, the effectiveness of the sponge exceeds that of foams, jellies, and tablets, but it is lower than that associated with diaphragm or condom use.<sup>5,39,40,41</sup> Some studies indicated failure rates that were twice as high in parous women, suggesting that one size may not fit all users.<sup>42</sup>

Discontinuation rates are generally higher among sponge users, compared with diaphragm and spermicide use. For some women, however, the sponge is preferred because it provides continuous protection for 24 hours regardless of the frequency of coitus. In addition, it is easier to use and less messy.

Side effects associated with the sponge include allergic reactions in about 4% of users. Another 8% complain of vaginal dryness, soreness, or itching. Some women find removal difficult. There is no risk of toxic shock syndrome, and, in fact, the nonoxynol-9 retards staphylococcal replication and toxin production. There has been some concern that the sponge may damage the vaginal mucosa and enhance HIV transmission.<sup>43</sup> Women using the sponge have lower rates of infection with gonorrhea, trichomonas, and chlamydia.<sup>8</sup>

# SPERMICIDES

---

Jellies, creams, foams, melting suppositories, foaming tablets, foaming suppositories, and soluble films are used as vehicles for chemical agents that inactivate sperm in the vagina before they can move into the upper genital tract. Some are used together with diaphragms, caps, and condoms, but even used alone, they can provide protection against pregnancy.

Various chemicals and a wide array of vehicles have been used vaginally as contraceptives for centuries. The first commercially available spermicidal pessaries were made in England in 1885 of cocoa butter and quinine sulfite. These or similar materials were used until the 1920s when effervescent tablets that released carbon dioxide and phenyl mercuric acetate were marketed. Modern spermicides, introduced in the 1950s, contain surface active agents that damage the sperm cell membranes. The agents currently used are nonoxynol-9, octoxynol-9, benzalkonium chloride, and menfegol. Most preparations contain 60–100 mg of these agents in each vaginal application, with concentrations ranging from 2% to 12.5% ([Table 24.2](#)).

## TABLE 24.2 Representative Products

---

Vaginal contraceptive film

---

- VCF (70 mg nonoxynol-9)

Foams

- Delfen (nonoxynol-9, 12.5%)
  - Emko (nonoxynol-9, 8%)
  - Koromex (nonoxynol-9, 12.5%)
- 

Jellies and creams

- Conceptrol (nonoxynol-9, 4%)
  - Delfen (nonoxynol-9, 12.5%)
  - Gynol II (nonoxynol-9, 3%)
  - Ramses (nonoxynol-9, 5%)
  - Koromex jelly (nonoxynol-9, 3%)
- 

**Suppositories**

- Encare (nonoxynol-9, 2.27%)
  - Koromex inserts (nonoxynol-9, 125 mg)
  - Semicid (nonoxynol-9, 100 mg)
- 

“Advantage 24” is a contraceptive gel that adheres to the vaginal mucosa and provides longer availability of nonoxynol-9; it is intended to be effective for 24 hours. Although available without prescription, adequate clinical trial data are not available. Allendale-N9 is a vaginal contraceptive film (VCF) that contains more nonoxynol-9 than VCF.<sup>44</sup> An Allendale film has also been developed that contains benzalkonium chloride instead of nonoxynol-9.<sup>45</sup> In addition to spermicidal activity, benzalkonium chloride is microbicidal and demonstrates activity against HIV.<sup>46</sup> Benzalkonium chloride is available for contraceptive use in the form of a suppository, in a sponge, or as a cream in several countries.

Although in vitro studies have demonstrated that spermicides kill or inactivate most STI pathogens, including HIV, it cannot be said that spermicides provide protection against STIs. Spermicides have been reported to prevent HIV seroconversion as well as

to have no effect; therefore, spermicides by themselves cannot be counted on for protection against HIV.<sup>45,46,47,48,49</sup> In a controlled, clinical trial in female sex workers, nonoxynol-9 failed to protect against HIV transmission.<sup>50</sup> Clinical studies have indicated reductions in the risk of gonorrhea,<sup>51,52,53</sup> pelvic infections,<sup>19</sup> and chlamydial infection.<sup>52,54</sup> However, these studies probably reflected condom use. In trials with a placebo, nonoxynol-9 provided no protection against gonorrhea or chlamydia.<sup>50,54,55,56</sup> Indeed, there is concern that frequent spermicide use may irritate the vagina and enhance HIV transmission.<sup>46</sup> Because of this concern, condom makers discontinued the production of condoms lubricated with nonoxynol-9. There is little difference in the incidence of trichomoniasis, candidiasis, or bacterial vaginosis among spermicide users.<sup>57</sup> **The best evidence indicates that spermicides do not provide additional protection against STIs over that associated with condoms; therefore, spermicides should not be used without condoms if a primary objective is to prevent infection with HIV, gonorrhea, or chlamydia.**

# Efficacy

Efficacy of spermicides in different studies ranges from less than 1% failure to nearly one-third in the first year of use. Failure rates of approximately 20–25% during a year's use are most typical.<sup>4,58</sup> A randomized trial comparing vaginal contraceptive film (72 mg nonoxynol-9) with Conceptrol foaming tablets (100 mg nonoxynol-9) recorded similar 6-month pregnancy rates (24.9% with the film and 28.0% with the tablet).<sup>58</sup> A randomized assessment of the various products concluded that a dose of 52.5 mg nonoxynol-9 was less effective (22% pregnancy rate in 6 months) than those containing 100 or 150 mg (about a 15% pregnancy rate in 6 months; intermediate doses were not tested).<sup>59</sup> These are very high rates, amounting to approximately 30–40% for 1 year of use. **Although better than no method, spermicides alone should not be recommended for contraception unless method failure and pregnancy are acceptable.**

Spermicides require application 10–30 minutes prior to sexual intercourse. Jellies, creams, and foams remain effective for as long as 8 hours, but tablets and suppositories are good for less than 1 hour. If ejaculation does not occur within the period of effectiveness, the spermicide should be reapplied. Reapplication should take place each coital episode.

**Vaginal postcoital douches are ineffective contraceptives even if they contain spermicidal agents. Postcoital douching is too late to prevent the rapid ascent of sperm (within seconds) to the fallopian tubes.**

# **Advantages**

Spermicides are relatively inexpensive and widely available in many retail outlets without prescription. This makes spermicides popular among adolescents and others who have infrequent or unpredictable sexual intercourse. In addition, spermicides are simple to use.

## Side Effects

No serious side effects or safety problems have arisen in all the years that spermicides have been used. The only serious question raised was that of a possible association between spermicide use and congenital abnormalities or spontaneous miscarriages. Epidemiologic analyses, including a meta-analysis, concluded that there is insufficient evidence to support these associations.<sup>60,61,62</sup> Spermicides are not absorbed through the vaginal mucosa in concentrations high enough to have systemic effects.<sup>63</sup> Vaginal and cervical mucosal damage (deepithelialization without inflammation) has been observed with nonoxynol-9, and the overall impact on HIV transmission, although unknown, is of concern.<sup>64,65</sup>

The principal minor problem is allergy that occurs in 1–5% of users, related to either the vehicle or the spermicidal agent. Using a different product often solves the problem. Spermicide users also have an altered vaginal flora promoting the colonization of *E. coli*, leading to a greater susceptibility to urinary tract infections as noted with diaphragm/spermicide users.<sup>22,66</sup>

# The Search for Contraceptives to Prevent STIs

For the last two decades, extensive research has been devoted to the development of contraceptive microbicides to prevent STIs, especially HIV. The ideal agent would be a topical microbicide that would prevent infection and be spermicidal. Any new agent must match the latex condom, which is nearly 100% effective in blocking bacteria and viruses. The road is long, extending from in vitro work to clinical application. An acceptable agent must avoid damage to vaginal epithelial cells and disruption of vaginal flora, and the delivery system must be user-friendly. Carraguard, a microbicide that contains carrageenan, a substance derived from seaweed, is a good example of the frustration in this area. After extensive development by the Population Council, a large, long-term phase 3 clinical trial in South Africa concluded that Carraguard did not prevent vaginal transmission of HIV.<sup>67</sup> Similarly, BufferGel, a microbicide designed to maintain vaginal acidity after ejaculation, and ProGel2000, a microbicide designed to block HIV entry into susceptible cells, were shown to be safe and effective in phase 1 clinical trials,<sup>68,69</sup> but were proven ineffective at preventing HIV transmission in a randomized controlled trial.<sup>70</sup> Acidform, a new spermicidal gel, is awaiting efficacy trials.<sup>71</sup>

# CONDOMS

---

Although awareness of condoms as an effective contraceptive method as well as a protector against STIs has increased tremendously in recent years, a great deal remains to be accomplished to reach the appropriate level of condom use. Contraceptive efficacy and STI prevention must be linked together and publicly promoted. The male condom is the only contraceptive proven to prevent HIV infection.

**There are three specific goals: correct use, consistent use, and affordable, easy availability.** Various types of condoms are available. Most are made of latex; polyurethane and silicone rubber condoms are also now manufactured. “Natural skin” (lamb’s intestine) condoms are still obtainable (about 1% of sales). Latex condoms are 0.3–0.8 mm thick. Sperm that are 0.003 mm in diameter cannot penetrate condoms. The organisms that cause STIs and AIDS also do not penetrate latex condoms, but they can penetrate condoms made from the intestine.<sup>72,73</sup> Evidence indicates that condom use (latex) also prevents transmission of human papillomavirus (HPV).<sup>74</sup> The use of spermicides or spermicide-coated condoms increases the incidence of E. coli bacteriuria and urinary tract infections due to either E. coli or Staphylococcus saprophyticus because of the spermicide-induced alteration in vaginal flora.<sup>22,75</sup> Consistent use of condoms when one partner is HIV seropositive is highly effective in preventing HIV transmission; there was no seroconversion in 124 couples who used condoms consistently compared with 12.7% conversion after 24 months in couples with inconsistent use.<sup>76,77</sup> Women who are partners of condom users are less likely to be HIV positive.<sup>78</sup> An evaluation of the world’s literature concluded that consistent use of condoms provides protection against HIV to a degree comparable to condom efficacy in preventing pregnancy (reflecting some inconsistent use and other routes of transmission).<sup>77</sup> In addition, condoms protect against transmission of the herpes simplex virus from infected men to women.<sup>79</sup>

Polyurethane condoms are expected to protect against STIs and HIV, based on in vitro efficacy as a barrier to bacteria and viruses. They are odorless, may have greater sensitivity, and are resistant to deterioration from storage and lubricants. Those individuals with latex allergy can use polyurethane condoms. Unfortunately, in a randomized, well-designed study, the polyurethane condom had a sixfold higher breakage rate than latex condoms, and another study comparing latex and polyurethane condoms found a higher pregnancy rate with the polyurethane condom.<sup>80,81</sup>

Condoms can be straight or tapered, smooth or ribbed, colored or clear, lubricated or nonlubricated. These are all marketing ventures aimed at attracting individual notions of pleasure and enjoyment.<sup>82</sup> An often repeated concern is the alleged reduction in

penile glans sensitivity that accompanies condom use.<sup>83</sup> This has never been objectively studied. A clinician can overcome this objection by advocating the use of thinner (and more esoteric) condoms, knowing that any difference is more of perception than reality.

As is true for most contraceptive methods, older, married couples experienced in using condoms and strongly motivated to avoid another pregnancy are much more effective users than young, unmarried couples with little contraceptive experience. This does not mean that condoms are not useful contraceptives for adolescents, who are likely to have sex unexpectedly or infrequently. Ninety-seven percent of female teenagers who are sexually active report at least occasional condom use.<sup>84</sup>

Prospective users need instructions to avoid pregnancy and STIs. A condom must be placed on the penis before it touches a partner. Uncircumcised men must pull the foreskin back. Prior to unrolling the condom to the base of the penis, air should be squeezed out of the reservoir tip with a thumb and forefinger. The tip of the condom should extend beyond the end of the penis to provide a reservoir to collect the ejaculate (a half-inch of pinched tip). If lubricants are used, they must be water based. Oil-based lubricants (such as Vaseline) will weaken the latex. Couples should be aware that any vaginal medication can compromise condom integrity. After intercourse, the condom should be held at the base as the still-erect penis is withdrawn. Semen must not be allowed to spill or leak. The condom should be handled gently because fingernails and rings can penetrate the latex and cause leakage. If there is evidence of spill or leakage, a spermicidal agent should be quickly inserted into the vagina, and treatment should be initiated within 72 hours—or 120 hours at most—with an emergency contraception method.

## Key Points: Maximal Condom Efficacy

- Use condoms for every act of coitus.
- Place the condom before vaginal contact.
- Create a reservoir at the tip.
- Withdraw while the penis is still erect.
- Hold the base of the condom during withdrawal.

These instructions should be provided to new users of condoms who are likely to be reluctant to ask questions. Most condoms are acquired without medical supervision; therefore, clinicians should use every opportunity to inform patients about their proper use.

Inconsistent use explains most condom failures. Incorrect use accounts for additional failures; also, condoms sometimes break. Breakage rates range from 1 to 8 per 100 episodes of vaginal intercourse (and somewhat higher for anal intercourse), and slippage rates range from 1% to 5%.<sup>83,85</sup> With experienced couples, condom failure due to breakage and slippage (sufficient to increase the risk of pregnancy or STIs) occurs at a rate of about 1%.<sup>86</sup> In a U.S. survey, one pregnancy resulted for every three condom breakages.<sup>87</sup> Concomitant use of spermicides lowers failure rates in case of breakage. In addition, even when there is slippage or breakage, the condom provides some protection against pregnancy and STIs because there is still a reduction in exposure to semen.<sup>88</sup>

Breakage is a greater problem for couples at risk for STIs. An infected man transmits gonorrhea to a susceptible woman approximately two-thirds of the time.<sup>89</sup> If the woman is infected, transmission to the man occurs one-third of the time.<sup>90</sup> The chances of HIV infection after a single sexual exposure ranges from 1 in 1,000 to 1 in 10, which is largely dependent on the HIV viral load.<sup>91,92,93,94</sup>

Condom breakage rates depend on sexual behavior and practices, experience with condom use, the condition of the condoms, and manufacturing quality. Condoms remain in good condition for up to 5 years unless exposed to ultraviolet light, excessive heat or humidity, ozone, or oils. Condom manufacturers regularly check samples of their products to make sure they meet national standards. These procedures limit the proportion of defects to less than 0.1% of all condoms distributed. Contraceptive failure is more likely to be due to nonuse or incorrect use.

**When a condom breaks, or if there is reason to believe spillage or leakage occurred, a woman should contact a clinician preferably within 72 hours and no later than 120 hours. Emergency contraception, as discussed in [Chapter 22](#), should be provided. Couples who rely on condoms for contraception should be educated regarding emergency contraception, and an appropriate method should be kept available for self-medication.**

For the immediate future, prevention of STIs, including the control of HIV, will require a great increase in the use of condoms. We must all be involved in the effort to promote condom use. Condom use must be portrayed in the positive light of STI prevention. An important area of concentration is the teaching of the social skills required to ensure use by a reluctant partner. Using scare tactics about STIs in order to encourage condom use is not sufficient. A more positive approach can yield better compliance. It is useful to emphasize that prevention of STIs will preserve future fertility. **For women not in a stable, monogamous relationship, a dual approach is recommended, combining the contraceptive efficacy and protection against PID**

**offered by estrogen-progestin contraception with the use of a barrier method for prevention of viral STIs.**

# THE FEMALE CONDOM

The female condom is a pouch made of polyurethane, which lines the vagina.<sup>95</sup> An internal ring in the closed end of the pouch covers the cervix and an external ring remains outside the vagina, partially covering the perineum. The female condom is prelubricated with silicone, and a spermicide need not be used. The female condom should be an effective barrier to STI infection. The female condom is impervious in vitro to cytomegalovirus and HIV<sup>96</sup>; however, high cost and acceptability are major problems. The integrity of the female condom is maintained with up to eight multiple uses with washing, drying, and relubricating.<sup>97</sup> The devices are more cumbersome than condoms, and studies have indicated relatively high rates of problems such as slippage.<sup>98</sup> Women who have successfully used barrier methods and who are strongly motivated to avoid STIs are more likely to choose the female condom. With careful use, the efficacy rate should be similar to that of the diaphragm and the cervical cap<sup>99,100,101</sup> (Table 24.3).

**TABLE 24.3 Appropriate Timing of Barrier Contraception Insertion and Removal**

	Diaphragm	Cap	Sponge	Female Condom
Insertion before coitus, no longer than	6 h	6 h	24 h	8 h
After coitus, should be left in place for	6 h	8 h	6 h	6 h
Maximal wear time	24 h	48 h	30 h	8 h

# WITHDRAWAL

---

Withdrawal as a contraceptive method, a method used for centuries and known historically as coitus interruptus, should not be ignored or underrated. The withdrawal method is intuitively learned, has no cost, and efficacy is surprisingly good. If withdrawal before ejaculation occurs with every instance of intercourse, a failure rate over a year of only 4% can be achieved.<sup>5</sup> Clinicians who scoff at this method lose sight of the fact that its typical failure rate of 18.4% during 1 year is very similar to that achieved with male condoms, which are a lowest expected failure rate of 2% and a 17.4% typical rate in 1 year.

A lack of respect for withdrawal as a contraceptive method can be attributed to two factors: an understandable preference for modern methods and the concern that preejaculate fluid contains sperm. Separating preejaculate fluid from the ejaculate in order to study the question has proven difficult and with mixed results. There is one small study of 5 men with a history of premature ejaculation and 3 men with excessive fluid during foreplay.<sup>102</sup> Not a single sperm was detected in preejaculatory fluid specimens collected at the tip of the urethra. In two other studies, no sperm was found in preejaculatory fluid from 16 men, and in 15 men, a few clumps of sperm were present in 5 men.<sup>103,104</sup> Most recently, a study of 27 men and 40 samples showed that 11 men repeatedly produced preejaculate samples with motile sperm in concentrations similar to ejaculate fluid.<sup>105</sup> This could certainly contribute to failures of the withdrawal method.

The modern use of this method (about 3% of contracepting women in the United States<sup>18</sup>) is difficult to accurately measure and is likely underreported because individuals very often combine withdrawal with another method, and the other method is the one reported in family planning surveys.<sup>106</sup> Indeed, many individuals do not classify withdrawal as a contraceptive method, saving that designation for modern methods. Nevertheless, it is not surprising that from 25% to 60% of adolescents report the use of withdrawal.<sup>107,108</sup>

We encourage clinicians to have a greater acceptance for this commonly used method, and it truly is a legitimate contraceptive method as evidenced by the substantial protection against pregnancy that is achievable. Of course, protection against STIs is not to be expected.

# Female Infertility

Infertility is defined as 1 year of regular unprotected intercourse without conception.<sup>1</sup> The term **subfertility** is used interchangeably to describe women or couples who may not be sterile but exhibit decreased reproductive efficiency. Approximately 85–90% of healthy young couples conceive within 1 year, most within 6 months.<sup>2,3</sup> Infertility therefore affects approximately 10–15% of couples and represents an important part of clinical practice.<sup>4</sup> Cycle **fecundability** is the probability that a cycle will result in pregnancy and **fecundity** is the probability that a cycle will result in a live birth.

Contrary to popular perception, the overall incidence of infertility does not seem to have increased over the past three decades.<sup>5</sup> However, the evaluation and treatment of infertility have changed dramatically during the same period. Three major developments have had the greatest impact. First was the introduction of in vitro fertilization (IVF) and other assisted reproductive technologies (ART). ART techniques have provided the means to study reproductive processes in new and more revealing ways and have markedly improved the prognosis for a great many infertile couples, particularly those whose infertility relates to severe tubal damage or male factors. Second, changes in population demographics have resulted in greater numbers of women attempting pregnancy at older ages when they are inherently less biologically fertile. Third, advances in ART and concerns about the age-related decline in fertility have combined to attract greater media attention and to raise public awareness of infertility and modern treatments. Consequently, infertile couples are now more likely to seek medical advice, evaluation, and treatment.

# THE EPIDEMIOLOGY OF INFERTILITY IN THE UNITED STATES

---

The first U.S. Census was in 1790. At that time, the crude birth rate was 55 per 1,000 total population; in 2015, it was 12.4 per 1,000,<sup>6</sup> representing a record low for the nation with nearly a 77% decline over the past 200-plus years and a 16% decline since 1990 (16.7 per 1,000 population). The general fertility rate (births per 1,000 women aged 15–44) in 2015 was 62.5, 8% lower than in 1990 (70.9/1,000), 25% lower than in 1970 (87.9/1,000), and 41% lower than in 1950 (106.2/1,000) during the postwar “baby boom.”<sup>6,7,8</sup>

**The overall long-term decline in the US birth and fertility rates has been attributed to several factors:**

- **Greater interest in advanced education and careers among women**
- **Later marriage and more frequent divorce**
- **Improvements in contraception and access to family planning services**
- **Delayed childbearing**
- **Decreased family size**

Attitudes toward women and among women in our society have changed dramatically in many ways over the past 50 years. Expanding opportunities have increased interests in advanced education and careers among women. The U.S. Census data indicate that in 1970, only 8.2% of women aged 25 and older had completed 4 or more years of college; by 2015, that proportion had quadrupled and reached the same rate as men (33%).<sup>9</sup> Women have represented the majority of college students in the United States since 1979. In recent years, the majority of bachelor’s and more advanced degrees have been awarded to women. The proportion of US women with infant children in the workforce has steadily increased, from 31% in 1976 to 59% in 2016.<sup>9</sup> In 2016, 82% of all women aged 25–44 years were in the labor force.<sup>10</sup>

Greater focus on education and careers among women triggered other trends in modern society. Less frequent and later marriage and more frequent divorce were among the most striking. First-marriage rates in the United States peaked after World War II, between 1945 and 1947 (143 per 1,000 single women aged 15–44), and declined about 15% every 10 years and approximately 50% overall over the next five decades.<sup>11</sup> The median age at first marriage for women has risen steadily since 1960 (20.3 years) and reached an all-time high in 2009 (26.5 years). The proportion of never-married women aged 25–29 has also steadily increased from 26.9% in 1986 to 46.8%

in 2009.<sup>12</sup> The probability of future marriage for women decreases as age increases: 84% at age 25, 72% at age 30, 52% at age 35, and 41% at age 40.<sup>13</sup> If and when women do marry, they also are more likely to divorce than in the past.<sup>11,13,14,15</sup> Divorce rates among women of reproductive age rose quickly after 1960 to more than double by 1980 (40 per 1,000 married women aged 15–44) and have declined only slightly over the last 30 years. The National Center for Health Statistics estimates that approximately one-third of new marriages among younger people will end in divorce within 10 years and 43% within 15 years. Once-married women also are increasingly less likely to remarry. Remarriage rates peaked in 1968 (166 per 1,000 divorces or widowed women aged 15–44) as divorce rates began to rise, but have since declined steadily by more than one-third, in parallel with first-marriage rates.<sup>11,13,14,15</sup>

The postwar “baby boom” generation, those born between 1946 and 1964, was the first to be afforded the means to safely and effectively control their fertility. Expanding contraceptive options and access to family planning and legalized abortion services over the past 5 decades definitely have contributed to declining US birth and fertility rates. Their effects have been direct, by reducing the number of unplanned pregnancies and births, and indirect, by helping women to avoid pregnancy until their education and career goals were met, and marriage and family become a priority.

The net result of all of these societal changes was a trend to delayed childbearing among American women. The mean age at first live birth has risen steadily, from 21.4 years in 1970 to an all-time high 26.4 years in 2015 (5 years and 24% higher). The percentage of first births occurring to women aged 30 or older increased drastically between 1970 and 2014.<sup>6,16</sup> The figure is increased by 26% between 2000 and 2014.

Between 1970 and 2015, birth rates fell for women aged 15–19 (68.3 vs. 22.3/1,000), 20–24 (167.8 vs. 76.8/1,000), and 25–29 (145.1 vs. 104.3/1,000) and increased for women aged 30–34 (73.3 vs. 101.5/1,000), 35–39 (31.7 vs. 51.8/1,000), and 40–44 (8.1 vs. 11.0/1,000).<sup>6,8</sup> Predictably, increasing age at first birth and declining fertility rates combined to result in fewer births per woman. At the height of the postwar baby boom, the US total fertility rate (births by age 45) reached a modern high of 3.7 births per woman (1957). Thereafter, the total fertility rate declined to a low of 1.8 in 1976 and has remained stable with some fluctuations.<sup>6</sup> In 2015, the total fertility rate was 1.8, under the population replacement rate, as has generally been since 1971. Likewise, the total fertility rates in most industrialized countries are inadequate even to ensure replacement of the population.<sup>17</sup>

Trends in the incidence of infertility among US women have been difficult to define confidently, partly due to confusion over the use of two different measures—impaired fecundity and infertility, which are defined differently, describe different populations,

and can yield conflicting data.<sup>18,19</sup> However, evidence indicates that the incidence of infertility in the United States now is declining.<sup>20</sup> The earliest national estimate of infertility, from the 1965 National Survey of Family Growth (NSFG), was 11.2%. In 1982, 8.5% of married American women were infertile, and in 2002, 7.4% were infertile, representing a 10% decrease over the intervening 20 years.<sup>20</sup> The latest figure from 2015 is 6.7%, demonstrating further decline.<sup>21</sup> A similar trend is observed worldwide. An analysis of 277 demographic and reproductive health surveys from 173 countries showed statistically similar prevalence of infertility in 1990 and 2010, while reduced child-seeking behavior resulted in a decrease in primary (1.6% to 1–0.5%) and secondary (3.9% to –3.0%) infertility, leading to unchanged overall prevalence due to increasing population.<sup>22</sup>

The array of infertility services, and their availability, has increased dramatically over the last 25 years. The public has a greater awareness of infertility and modern treatments, largely due to the increased media attention, good and bad, surrounding the advances and controversies relating to ART. As infertility has become more visible, and more socially acceptable, couples have become more comfortable to seek evaluation and treatment.

According to data derived from the NSFG conducted in 1995, 9.3 million women aged 15–44 (15%) had ever received infertility services, an increase from 6.6 million women (12%) in 1982.<sup>23</sup> These data indicated that the demand for infertility services increased during the 1980s and early 1990s, corresponding to the aging of baby boomers and the time when the availability of ART was rapidly expanding. Compared to the general population, women seeking infertility services were more likely to be older (aged 35–44 years; 43% vs. 36%), nulliparous (36% vs. 16%), married (79% vs. 64%), and relatively affluent (61% vs. 51%) and to have health care insurance (83% vs. 74%).<sup>23</sup> Among those who received infertility services, 35% had used ovulation-inducing drugs and 1.6% had undergone some form of ART. In the 2002 NSFG, 7.3 million women aged 15–44 reported ever having used infertility services, representing a significant decrease of approximately 20% since 1995.<sup>24</sup> The figure has remained unchanged in 2006–2010 and 2011–2015 at 7.4 and 7.3 million, respectively, representing 12% of women in this age bracket. Advice (38%), testing (36%), and medical help to prevent miscarriage (34%) were the most common types of services received. Thirty-two percent reported receiving drugs to improve ovulation and 19% intrauterine insemination (IUI).<sup>25</sup>

# AGING AND FERTILITY

---

The effects of aging on female fertility are perhaps best revealed by the results of studies in “natural” populations wherein couples reproduce without voluntary restrictions<sup>26</sup>; the Hutterites in North America are a classic example. Contraception is condemned in the sect, which emigrated originally from Switzerland in the 16th century and settled ultimately in communal colonies in South Dakota in the late 19th century. Studies of fertility in the Hutterites illustrate how fertility declines with advancing age.<sup>27</sup> Whereas only 2.4% of Hutterite women were infertile, 11% bore no children after age 34, 33% were infertile by age 40, and 87% were infertile at age 45. **Although revealing, these and other data derived from studies in natural populations may not reflect true biologic reproductive potential, for several reasons:**

- **Women who have children when young may be less inclined to conceive again in later life.**
- **Coital frequency often declines as age increases, reflecting decreasing desire or lack of a partner.**
- **The incidence of subclinical abortion is unknown.**
- **The cumulative impact of other diseases or conditions that can adversely affect fertility (e.g., pelvic infections, leiomyomata, endometriosis) is greater in older women.**

Taken together, data from studies in the Hutterites and other natural populations suggest that fertility in women peaks between the ages of 20 and 24, decreases relatively little until approximately age 30–32, and then declines progressively. **Overall, fertility rates are 4–8% lower in women aged 25–29 years, 15–19% lower in those aged 30–34, 26–46% lower in women aged 35–39, and as much as 95% lower for women aged 40–45 years.**<sup>28,29</sup>

Variations in fertility rates among natural populations could reflect differences in genetic factors or socioeconomic conditions at different times and in different places.

Other evidence for the adverse effect of aging on fertility derives from numerous studies of cumulative conception rates among women attempting pregnancy by artificial insemination with donor sperm. Since women in donor insemination programs are less likely to have other infertility factors and carefully timed inseminations eliminate the confounding effects of decreasing coital frequency with increasing age, donor insemination studies provide good estimates of female fertility. In a French study involving more than 2,000 women across up to 12 insemination cycles, conception rates were highest in those aged 25 or younger (73%) and aged 26–30 (74%), 16% lower

(62%) in women aged 31–35, and 27% lower in those over age 35 (54%).<sup>30</sup> An American donor insemination study yielded similar results, observing lower overall conception rates and a twofold higher number of inseminations per conception in women over age 35.<sup>31</sup> A Dutch study observed that the probability of a healthy live birth decreased by approximately 3.5% per year after age 30.<sup>29</sup> In a large British study of nearly 3,000 donor insemination cycles from a single center, cumulative conception rates in women over age 30 were 20–35% lower than in younger women after 3 (17% vs. 21%), 6 (26% vs. 40%), and 12 insemination cycles (44% vs. 62%).<sup>32</sup>

Success rates achieved with ART using nondonor eggs also decline as age increases. The numbers of oocytes retrieved and embryos available and implantation, pregnancy, and live birth rates are lower in older than in younger women.<sup>33</sup> Annual reports derived from registry data collected by the Centers for Disease Control and Prevention (CDC) in the United States since 1989 demonstrate consistently that age is the single most important factor affecting the probability of success with ART. Pregnancy and live birth rates for ART cycles using fresh, nondonor eggs or embryos vary little for women under age 32, but thereafter decrease steadily in an almost linear fashion as age increases. Regardless whether success rates are calculated per cycle, per oocyte retrieval, or per embryo transfer, the result is the same. In the 2015 US national summary, the live birth rate per embryo transfer was 46.5% for women under age 35, 38.4% for ages 35–37, 27.4% for ages 38–40, 15.5% for ages 41–42, and 6.6% for women aged 43–44 years, despite higher number of embryos being transferred to older women.<sup>33</sup>

The age-related decline in ART live birth rates reflects not only decreasing fertility but also increasing pregnancy wastage. Just as fertility decreases with increasing age, the incidence of clinically recognized miscarriage rises as age advances. **Miscarriage rates in natural conception cycles are generally low before age 30 (7–15%) and rise with age, only slightly for ages 30–34 (8–21%), but to a greater extent for ages 35–39 (17–28%) and ages 40 and older (34–52%).**<sup>28,34,35,36</sup> The same pattern is observed in pregnancies resulting from ART. In the 2015 US national summary of IVF outcomes, miscarriage rates were below 15% for women under age 35, almost 29% at age 40, and 65% for women aged 44 and older.<sup>33</sup> Longitudinal studies of healthy young women wherein daily urine samples were monitored for the appearance of human chorionic gonadotropin (hCG) have revealed that true spontaneous miscarriage rates (also including clinically unrecognized “biochemical” pregnancies) are substantially higher.<sup>37,38,39</sup> Up to 60% of all conceptions miscarry within the first 12 weeks of gestation and 20–40% of all early pregnancy losses go unrecognized. Whether the incidence of occult early pregnancy loss also is higher in older women than young women has not been determined. If so, the relationship between true spontaneous

miscarriage rates and age may be even more dramatic. Even if not, the overall miscarriage risk (recognized and unrecognized) in women over age 40 approaches or exceeds 75% (Figure 25.1).<sup>38,40</sup>

**FIGURE 25.1**

# Physiology of Reproductive Aging

The age-related decrease in female fertility and the societal trends toward delayed childbearing have focused a great deal of attention on the physiology of reproductive aging. Consequently, our understanding of the mechanisms that govern the pace of follicular depletion, the endocrinology of reproductive aging, the age-related changes in follicular dynamics and oocyte quality, and the genetic determinants of ovarian aging has advanced greatly over the past 30 years. We long ago recognized the changes in menstrual cycle characteristics that accompany advancing age, but now much better understand the mechanisms responsible for those changes. We long ago recognized that fertility declines as age increases, but now have measures of reproductive aging that help to guide our efforts to overcome its limitations. We may not be able to prevent aging, but now we can better help women to set and to realize their reproductive goals.

## Follicular Depletion

In humans, the number of oocytes peaks around the 20th week of gestation when approximately 6–7 million oocytes arrested at the first meiotic prophase are found in the ovarian cortex.<sup>41,42,43</sup> Afterward, regulated apoptosis starts an irreversible decline in the germ cell population.<sup>44</sup> The number of oocytes declines to 1–2 million at birth<sup>45</sup> and to 300,000–400,000 by puberty.<sup>42,46</sup> Over the next 35–40 years of reproductive life, only about 400 oocytes will ovulate, the rest being lost through atresia. By age 40, the number of follicles shrinks to approximately 25,000, and at menopause, there remains less than 1,000 follicles.<sup>47,48,49,50</sup>

Accurate modeling of the pattern of follicle depletion in the human ovary is important because the ability to measure reproductive aging or to predict the number of remaining follicles—to tell time on the biologic clock—would help women make informed decisions about their reproductive plans.<sup>51</sup> However, for obvious reasons, accurate measures of the numbers of primordial follicles across a human female reproductive life span are difficult to obtain.

The first attempt to define the age-related pattern of follicular depletion was based on an analysis of combined data from older morphometric studies and yielded a biexponential model of ovarian aging, describing a biphasic pattern of oocyte depletion, with a distinct increase in the rate of decline beginning at approximately age 37.5 years.<sup>41,47,52,53</sup> The biphasic model was widely accepted, despite the biologic implausibility of an abrupt, population-wide, physiologic shift in the rate of follicular depletion.<sup>54,55</sup> The model still is cited frequently,<sup>56,57</sup> but subsequent work has demonstrated that a simpler, more biologically plausible, exponential<sup>48,58</sup> or power

function<sup>59</sup> conforms best with available human data and current concepts regarding the mechanisms that govern the rate of follicular depletion.<sup>51,60</sup> **The current working model describes a gradually increasing rate of follicular depletion in which the pace of decline increases as the number of follicles remaining decreases, supported by evidence that paracrine factors secreted by primordial follicles inhibit recruitment and regulate the size of the resting follicular pool.**<sup>51,60,61,62</sup> The model describes the mean trajectory of follicular depletion, but a great deal of population variation remains unexplained. Some of the variation among individuals doubtless relates to differences in the size of the initial follicular pool, which could be random but likely is genetically determined, and on lifestyle factors. The current model of reproductive aging still is evolving and does not yet have any real clinical utility because it cannot predict the reproductive life span for an individual woman.<sup>51,59</sup>

## **Endocrinology of Reproductive Aging**

Toward the end of the reproductive period, serum follicle-stimulating hormone (FSH) levels begin to rise, while luteinizing hormone (LH) concentrations remain unchanged. This occurs before any discernible change in menstrual regularity. The subtle “monotropic” rise in circulating FSH concentrations is most apparent during the intercycle transition, when the corpus luteum regresses and menses begins, and could result from age-related changes in the pattern of pulsatile kisspeptin and gonadotropin-releasing hormone (GnRH) secretion or from progressive follicular depletion and decreased inhibitory feedback by ovarian hormones. The weight of available evidence supports the second explanation.<sup>63,64</sup>

A variety of studies in animals and women have identified changes in the patterns of hypothalamo-pituitary hormone secretion across the menopausal transition. In rodents, an age-related decrease in pulsatile GnRH and LH secretion and a loss of positive estrogen feedback have been observed, before the follicular pool is exhausted.<sup>65,66,67,68</sup> In nonhuman primates, pulsatile GnRH release increases during the perimenopause and the positive feedback response remains intact.<sup>69</sup> Studies in perimenopausal and postmenopausal women have yielded conflicting results. Whereas some have observed changes in sensitivity to estrogen feedback signals<sup>70,71</sup> or in LH pulse amplitude or frequency,<sup>72,73,74,75,76,77</sup> others have not.<sup>78,79,80</sup> The response to exogenous GnRH stimulation also is inconsistent.<sup>76,81,82</sup> On balance, these data suggest strongly that age-related changes in pulsatile LH secretion and gonadotropin concentrations merely reflect changes in ovarian feedback signals and do not result from aging of the hypothalamo-pituitary axis.

**The bulk of available evidence indicates that the progressive increase in FSH**

**concentrations associated with reproductive aging results from a progressive decrease in the levels of feedback inhibition from the smaller cohorts of follicles recruited from a shrinking follicular pool.** Circulating follicular phase inhibin B levels (derived primarily from smaller antral follicles) decrease as or even before FSH concentrations begin to increase.<sup>63,83,84,85,86,87,88,89,90</sup> Inhibin A levels also decline, but only in the later stages of reproductive aging, after the onset of menstrual irregularity.<sup>87,91,92,93,94</sup> Both inhibins selectively inhibit pituitary FSH secretion. Consequently, FSH levels rise progressively as inhibin production from smaller cohorts of aging follicles decreases, most noticeably in the early follicular phase. Whereas declining inhibin production also could reflect a decrease in the functional capacity of older follicles,<sup>95</sup> the observation that preovulatory follicular fluid inhibin concentrations are similar in young and older cycling women suggests that the number of remaining follicles is more important.<sup>83</sup> Ovarian steroid hormones do not play a major role. The initial rise in FSH levels precedes any measurable decrease in estradiol levels, by several years.<sup>64,96</sup> Follicular phase estradiol levels in older cycling women generally are similar to those in younger women and often even higher.<sup>83,97</sup> Luteal phase estrogen and progesterone levels also do not seem to change consistently with advancing age.<sup>63,85,87,98,99,100,101</sup> Moreover, in sporadic ovulatory cycles in aging women, serum concentrations of estradiol and progesterone are comparable to those observed in younger women.<sup>102</sup>

As age and FSH levels increase, the follicular phase becomes shorter<sup>103,104,105</sup>; LH levels and luteal phase duration remain unchanged. As the follicular phase shortens, estradiol levels rise earlier, suggesting that higher FSH levels stimulate more rapid follicular development.<sup>63</sup> **However, careful studies have shown that the earlier rise in estradiol levels results not from accelerated follicle growth, but from advanced follicular development at the beginning of the cycle and earlier selection of the dominant follicle.**<sup>98,104,106</sup> The earlier increase in follicular phase FSH level also frequently results in more than one dominant follicle,<sup>107,108,109</sup> explaining the higher prevalence of dizygotic twinning in older cycling women.<sup>98,107,110</sup>

Reproductive aging already is quite advanced when the first clinical sign appears. Cycles remain regular, but overall cycle length and variability decrease gradually, reaching a nadir at an average age of 42 years,<sup>103,111</sup> when fertility is at or near an end. However, women generally take notice only when cycles become irregular, marking the beginning of the menopausal transition.<sup>112</sup> The menopausal transition begins at an average age of 46 years, but can arrive as early as age 34 and as late as age 54 years.<sup>103,111,113,114,115</sup> Thereafter, average cycle length and variability increase steadily as ovulations become less regular and frequent.<sup>111</sup> Regardless of age, the interval from

loss of menstrual regularity to menopause is relatively fixed, spanning approximately 5–6 years.<sup>46,113,116</sup> The age of menopause, recognized only in retrospect, averages 51 years, but ranges widely between ages 40 and 60 years.<sup>115,117,118,119,120,121,122</sup> The variation in menopausal age is very similar across populations and generally follows a normal distribution that is slightly skewed to younger ages.<sup>122,123,124</sup>

## Genetics of Reproductive Aging

Barring any disease that destroys or causes the removal of ovarian tissue and any important environmental insults, the total number of follicles at birth, and the age when the supply is exhausted, is genetically determined.<sup>46,122,125,126,127,128,129,130,131,132</sup>

There is good correlation between menopausal age in mothers and daughters and between sisters, suggesting that genetic factors play an important role in determining menopausal age.<sup>133,134,135</sup> **Approximately 10% of women become menopausal by the age of 45,<sup>115,122</sup> probably because they were endowed with a smaller than average ovarian follicular pool that is functionally depleted at an earlier age.** Pedigree analysis has revealed that the genetic features of early menopause (age 40–45) and premature ovarian failure (POF) are similar, suggesting a dominant pattern of inheritance through maternal or paternal relatives.<sup>136,137</sup> The same genetic factors that determine the age at menopause also likely determine the age of reproductive milestones preceding the menopause.<sup>138</sup> In natural populations, the age at the last birth varies as widely as the age at menopause, but occurs on average 10 years earlier.<sup>46</sup> Moreover, women who repeatedly respond poorly to exogenous gonadotropin stimulation also tend to have an earlier menopausal transition,<sup>138,139,140,141</sup> suggesting their poor response reflects an advanced stage of follicular depletion, beginning years sooner than would be anticipated normally.<sup>138</sup>

Genes affecting reproductive hormones (FSH, FSHR, LH, LHR, CYP17, CYP19) or involved in the initial growth of follicles (GDF9, BMP15, GPR3) impact follicular function; mutations are rare in humans, but polymorphisms could influence the rate of follicular recruitment and depletion and thereby affect the length of reproductive life.<sup>142</sup> Variations in other genes encoding DNA-binding proteins and transcription factors (NOBOX, LHX8) and RNA-binding proteins (EPAB, CPEB, NANOS) expressed during oogenesis could affect germ cell formation; mutations causing POF have been identified in a few women.<sup>143,144,145</sup> Variations in other genes with links to POF also might affect the rate of follicular depletion in normal women (ADAMTs9, FOXL2).<sup>146,147</sup> In a Dutch cohort study, common polymorphisms in the gene encoding the receptor for antimüllerian hormone (AMHR2) were associated with menopausal age,<sup>148</sup> implicating a decrease in AMH signaling that would weaken its paracrine

inhibition of primordial follicle recruitment, leading to more rapid follicular depletion.

Candidate gene approaches are based on hypotheses regarding the genes or pathways that are most likely to be associated with a certain phenotype. This approach is limited by our incomplete knowledge of the biology of reproductive aging and its genetic regulation. Genome-wide association studies (GWAS), on the other hand, aim to discover novel susceptibility loci for any disease as well as traits like age at menopause, without the limitation of a preconceived hypothesis. The first GWAS performed to identify loci involved in reproductive aging enrolled approximately 17,000 women and identified 13 loci clustered at chromosomes 5, 6, 19, and 20, associated with age at natural menopause.<sup>149</sup> A subsequent GWAS also identified the loci on chromosomes 19 and 20 and, in addition, another locus at chromosome 13, associated with the age at natural menopause.<sup>150</sup> Studies with similar approaches in 6,500 women with African ancestry and 3,500 Chinese women were consistent with the findings of earlier reports, suggesting that the timing of menopause is largely regulated in a similar fashion in different ethnic populations.<sup>151,152</sup> Subsequently, some of the genetic variants identified by these GWAS were found to be associated with early menopause in an independent cohort, suggesting that common genetic variants influencing natural menopause constitute also risk factors for early onset of menopause.<sup>153</sup> A more recent meta-analysis of age at natural menopause in nearly 40,000 women of European ancestry from 22 studies with replication in an additional 14,000 women confirmed 4 of the previously reported loci and identified 13 novel loci. The identified genes were not implicated in follicle development; instead, they were primarily associated with DNA repair and maintenance and immune function.<sup>154</sup> It is noteworthy that recent studies using whole exome sequencing identified mutations in homologous recombination and dsDNA break repair genes MCM8 and MCM9 in women with POF.<sup>155,156</sup> Careful examinations of these and other candidate genes yet to be identified likely will yield new insights and further our understanding of the mechanisms that govern reproductive aging.

## **The Aging Follicle and Oocyte**

Whereas the number of remaining ovarian follicles steadily declines with increasing age, observations in stimulated cycles suggest that aging follicles also become progressively less sensitive to gonadotropin stimulation. As age increases, the total dose and duration of treatment required to stimulate multiple follicular development increase. The rate of rise and the peak in estradiol levels decrease, reflecting the smaller cohorts of follicles that can be recruited. However, the amount of estradiol secreted by the follicles that do emerge and grow to maturity appears comparable to that in younger women.<sup>157</sup> Although a decrease in exogenous hCG-induced ovarian androgen

production can be demonstrated before the age of 30, circulating estradiol levels remain normal throughout and beyond the reproductive years, probably because rising FSH levels are able to compensate.<sup>158</sup> Studies of ovarian follicular development and preovulatory follicular fluid hormones in older and younger cycling women do not suggest any age-related decline in follicular function, once growth and development begin. Preovulatory follicles in older and younger women are similar in size and inhibin content, and follicular fluid progesterone levels and estrogen/androgen ratios are even higher in older than in younger women.<sup>83</sup>

Older cycling women ovulate as regularly and more frequently than younger women. Their rising FSH levels apparently compensate quite effectively for any decrease in follicular sensitivity to gonadotropin stimulation. Preovulatory follicles in older cycling women get an earlier start, but grow at a normal pace and reach a normal size; their follicular fluid characteristics suggest they also are quite healthy. Why then does fertility in women decline progressively with age? **The available evidence indicates that both the age-related decline in female fertility and the increase in risk of miscarriage can be attributed to an increase in the proportion of abnormal oocytes in an aging and shrinking follicular pool.**

As the number of follicles decreases, oocyte quality also declines, primarily because of an increase in meiotic nondisjunction, resulting in an increasing rate of oocyte and embryo aneuploidy in aging women.<sup>49,159,160,161</sup> A wide variety of techniques has been used to study the chromosomal composition of human oocytes. The best available evidence, derived from a detailed cytogenetic analysis of oocytes retrieved for IVF that failed to fertilize, suggests that the global rate of oocyte aneuploidy increases with advancing maternal age.<sup>162,163</sup>

As previously discussed ([Chapter 2](#)), meiosis involves a single round of DNA replication (in the premeiotic S phase), followed by two cell divisions to form gametes each with a half (or haploid) set of chromosomes. In the first meiotic division (meiosis I), duplicated chromosomes, consisting of pairs of sister chromatids, pair up with their homologues, and a synaptonemal complex is formed between them; recombination then occurs between nonsister homologous chromatids. At anaphase I, the two homologue chromosomes migrate to opposite poles. The second meiotic division (meiosis II) then follows without additional DNA replication. The pairs of sister chromatids align on the metaphase II spindle, and at anaphase II, the two sister chromatids finally separate to opposite poles resulting in daughter cells with a haploid set of chromosomes. Oocyte aneuploidy results primarily from premature separation of sister chromatids during meiosis I or from whole chromosome nondisjunction during meiosis II.<sup>163</sup> The prevalence of both types of meiotic segregation errors increases progressively with age and makes the greatest contribution to the age-dependent increase in the prevalence of

aneuploidy in human embryos.<sup>162,163,164,165,166</sup>

The European Society for Human Reproduction and Embryology (ESHRE) set up a pilot study of polar body biopsy and aneuploidy analysis in women of advanced maternal age (mean age 40.0).<sup>167</sup> Intracytoplasmic sperm microinjection was performed, and both polar bodies were biopsied and assessed simultaneously to identify errors in meiotic divisions. If aneuploidy was detected in one or both polar bodies, the corresponding presumed aneuploid fertilized oocyte or zygote was tested independently to confirm concordance with the polar body testing. This study revealed a high incidence of aneuploidies (72%), often multiple aneuploidies per zygote, resulting from an approximately equal proportion of errors in both meiotic divisions. While all chromosomes (except chromosome 3) had errors, the incidence of aneuploidy was higher for those with shorter and acrocentric chromosomes, particularly in chromosomes 11–22.

The pattern of copy number changes demonstrated that most meiosis I errors resulted from premature separation of sister chromatids as originally observed 2 decades ago,<sup>164</sup> and only 3% were caused by classical nondisjunction. In about half of cases where there had been an error in meiosis I, this error was balanced in meiosis II. Therefore, in the zygote, there were more aneuploidies resulting from errors in meiosis II than meiosis I. This pattern of multiple meiotic errors caused by premature separation of sister chromatids, and a net excess of meiosis II errors in zygotes following assisted conception, is in contrast with the low incidence of multiple aneuploidies detected in pregnancies following natural conception and the predominance of female meiosis I errors in trisomies.<sup>35,160</sup> This could suggest that the use of high doses of exogenous hormones for ovarian stimulation in older patients perturbs the process of meiosis.

An analysis of trophoctoderm biopsies from more than 15,000 human blastocysts also showed that aneuploidy rate increases with age.<sup>166</sup> This is true for all chromosomes and highest for chromosomes 15, 16, 18, 19, 21, and 22.<sup>168</sup> The age-related increase in aneuploidy was most pronounced for acrocentric chromosomes (where centromere is located near one end of the chromosome, e.g., chromosome 21).<sup>168</sup>

The age-related decrease in the proportion of normal oocytes (23,X) and the corresponding increase in the proportion of aneuploid oocytes and embryos bear striking similarity to the age-related decrease in fertility and increase in the incidence of spontaneous miscarriage in women. Fertility and the prevalence of euploid oocytes decrease progressively with age. Miscarriage risk and the prevalence of aneuploid oocytes are relatively low and change little until approximately age 35, and then increase progressively, reaching 70% at age 40 and virtually 100% after age 45.<sup>162,167</sup> These observations offer a logical explanation for the age-related increase in the prevalence of aneuploidy in spontaneous abortuses. Whereas at least half of all

clinically recognized miscarriages exhibit an abnormal karyotype and the frequency of both euploid (normal) and aneuploid (abnormal) abortuses increases with maternal age, the probability that an abortus will be chromosomally abnormal increases with age, from less than 35% at age 20 to nearly 80% over age 42.<sup>35</sup> Trisomies are by far the most common abnormality observed, followed by polyploidies and monosomy X (45,X).

Studies of meiotic segregation have revealed that factors predisposing to nondisjunction relate to the disruption of chromosomal pairing and recombination.<sup>169,170</sup> Various mechanisms have been implicated, but all involve an age-dependent deterioration in cellular factors required for proper spindle formation and function.<sup>171</sup> Molecular investigations of chromatid cohesion and separation have implicated cohesins, a specific class of proteins that maintain cohesion between sister chromatids and oppose the splitting forces mediated by the microtubules of the meiotic spindle.<sup>172,173,174,175</sup> An age-related premature degradation or deficiency of cohesins may result in unstable bivalent chromatid structures and predispose to premature separation of sister chromatids before they align on the meiotic spindle. The smaller chromosomes appear more prone to premature chromatid separation, possibly because they have fewer of the chiasma that help to prevent such dissociation.<sup>164,176,177</sup> Other studies using high-resolution confocal microscopy to examine the meiotic spindle in human oocytes have revealed that abnormalities of the cleavage spindle microtubular matrix or chromosome alignment during meiosis II are 4 to 5 times more common in older cycling women (age 40–45) than in younger women (age 20–25).<sup>49</sup> These and other observations of cultured human oocytes collected from unstimulated ovaries further indicate that the meiotic competence of oocytes declines with age.<sup>178</sup> **In sum, accumulated evidence strongly suggests that the primary cause of the age-dependent decrease in fecundability and increase in the incidence of miscarriage is an increasing prevalence of aneuploidy in aging oocytes resulting at least in part from disordered regulatory mechanisms governing meiotic spindle formation and function (Figure 25.2).**

## Aging and the Uterus

Aging does not appear to have any significant adverse effect on the uterus. Even though benign uterine pathology (leiomyomata, endometrial polyps, adenomyosis) is more common in older women,<sup>179,180,181</sup> there is limited evidence to suggest that uterine age itself has a major impact on fertility.<sup>182,183,184,185</sup> Age also does not appear to adversely affect endometrial development or function in response to steroid stimulation.<sup>186</sup> The most reliable evidence comes from comparing outcomes in nondonor and donor oocyte IVF cycles. Whereas early studies suggested that donor oocyte IVF pregnancy and delivery rates decreased modestly with the age of the recipient,<sup>187,188,189</sup> the bulk of more recent experience refutes those conclusions.<sup>190,191</sup> In the national summary of ART success rates for the year 2015, live birth rates declined progressively with increasing age for nondonor egg cycles, as expected. In contrast, the overall live birth per transfer rate in donor egg IVF cycles was over 50% and did not vary significantly with the age of the recipient.<sup>33</sup> **Live birth rates in donor egg IVF cycles relate to the age of the donor, not the age of the recipient.** In one large series, miscarriage rates increased from 14% in women matched with egg donors aged 20–24 to 44% for women whose donors were over age 35.<sup>192</sup> However, perinatal outcomes are improved when a gestational carrier is used rather than transfer of donor embryos to an infertile patient's own uterus, even when adjusted for age.<sup>193,194</sup> There are defects in the infertile uterus as suggested above that may impact fertility and tend to accumulate with age, but aging itself is not thought to be a significant factor influencing uterine receptivity.

## Aging and Male Fertility

The relationship between age and fertility in men is discussed in detail in [Chapter 26](#) and summarized here. Several studies have shown that semen volume, sperm motility, progressive motility, and morphologically normal sperm significantly decrease with male age.<sup>195,196,197,198</sup> The data also suggest a decrease in sperm concentration and count.<sup>196</sup> However, semen characteristics generally do not accurately predict fertilizing capacity<sup>199,200,201,202</sup>; nor do endocrine parameters.<sup>203,204</sup> When the effect of male partner age on pregnancy rates is investigated, obvious confounders are female partner age and lower coital frequency due to aging. Among the few studies that have controlled for female age, pregnancy rates for men over 50 have been 23–38% lower than for men under age 30.<sup>195</sup> A British study that examined the effect of men's age on the time to conception (adjusting for the confounding effects of both partner's age and coital frequency) found that increasing men's age was associated with increasing time to conception and declining overall pregnancy rates; the time to conception was fivefold greater for men over age 45 than for men under age 25, and restricting the analysis to men with young partners yielded similar results.<sup>205</sup> Results of two studies that controlled for female partner age have suggested that male fertility may start to decline earlier, beginning in the late 30s.<sup>206,207</sup> Studies on the effect of male age on the outcome of ART cycles using donor oocytes yielded conflicting results.<sup>198,208</sup>

There are several possible biologic mechanisms that might explain an age-related decline in male fertility. Sperm chromosomal abnormalities may increase in frequency with age and adversely affect early embryonic development.<sup>209</sup> There is at least some evidence to suggest that increasing male age may raise the risk of miscarriage in young women.<sup>210</sup> In addition, there are epigenetic changes resulting in altered sperm DNA methylome in aging men.<sup>211</sup> Average FSH levels in men increase during their 30s,<sup>212</sup> suggesting that age-related changes in the hypothalamo-pituitary-gonadal axis may begin during midlife.<sup>213</sup> The testes and prostate also exhibit morphologic changes with aging that might adversely affect both sperm production and the biochemical properties of semen.<sup>214</sup> Whatever the mechanism, decreasing fertility with increasing male age in healthy couples suggests that normal sperm overproduction may not fully buffer the effects of increasing age.

**Overall, the available evidence suggests a negative correlation between male age and pregnancy rates. The time to conception increases with male age. However, because there is little or no overall measurable decline in male fertility before age 45–50, male factors generally contribute relatively little to the overall age-related decline in fertility.**

# Ovarian Reserve and Its Assessment

The term ovarian reserve refers to (1) the size and quality of the remaining ovarian follicular pool and (2) the ability of the ovaries to respond to exogenous gonadotropin stimulation, which are related concepts. Since the major effect of aging on a woman's reproductive potential is through declining oocyte number and increased oocyte aneuploidy, the concept of ovarian reserve is relevant for female reproductive aging.

There are two intentions for ovarian reserve testing: (1) to predict fecundity and (2) to gain prognostic information regarding the likelihood of successful response to ovarian stimulation in women undergoing infertility treatment.

Like all screening tests, ovarian reserve tests are aimed at identifying individuals at risk for a disease, in this case "diminished ovarian reserve" (DOR). **It is important to emphasize that such tests cannot and do not establish a diagnosis of DOR; they only identify women more likely to exhibit a poor response to gonadotropin stimulation and potentially have a lower likelihood of achieving pregnancy with treatment.** The value of a screening test depends on its validity, describing its ability to correctly categorize individuals as affected (sensitivity) or unaffected (specificity). The sensitivity and specificity of a screening test will vary with the chosen threshold value. A choice intended to maximize sensitivity minimizes the number of false-negative results (patients with DOR categorized as normal), but increases the number of false-positive results (patients with a normal ovarian reserve categorized as having DOR). Conversely, a threshold value that maximizes specificity minimizes false positives, but increases false-negative results. **For measures of ovarian reserve, test threshold values should have high specificity for DOR, so as to decrease false-positive results (incorrectly categorizing a patient with a normal ovarian reserve as having DOR), thereby avoiding overly aggressive treatment or inappropriate recommendations to abandon treatment or pursue adoption or oocyte donation in women with a normal ovarian reserve. Treating women with unrecognized DOR (the consequence of maximizing specificity) is undesirable, but a less serious error.**

The most important test characteristics of a screening test are its positive predictive value (PPV) and negative predictive value (NPV), which vary with the prevalence of the disease of interest, i.e. DOR, in the test population. PPV describes the probability that a woman with a positive test truly has DOR, and NPV is the probability that a woman with a negative test truly has a normal ovarian reserve. If the prevalence of DOR is low, as in young women, the PPV will be low, even if sensitivity and specificity are high. Conversely, if the prevalence of DOR is high, as in older women, the PPV will be high if a highly specific threshold value is chosen. **If the purpose of ovarian reserve testing is to correctly identify women with DOR, it will be most useful in**

**women at high risk for DOR. When applied in a low prevalence population, many women with a normal ovarian reserve will have a false-positive result and be categorized as having DOR.**

Ovarian reserve tests include both biochemical and ultrasonographic measures of the size and (by inference) the quality of the ovarian follicular pool. Biochemical tests include both basal measurements, such as FSH, estradiol, inhibin B, and antimüllerian hormone (AMH), and provocative tests, such as the clomiphene citrate challenge test (CCCT). Ultrasonographic measures of ovarian reserve include the antral follicle count (AFC) and ovarian volume.

It should be noted that both biochemical and ultrasonographic markers of ovarian reserve have poor predictive value for conception. Women should not be told that they cannot conceive spontaneously or should not be denied fertility-promoting treatments, including ART, based solely on finding of decreased ovarian reserve.

## **Basal FSH and Estradiol Concentrations**

Serum FSH concentration was one of the earliest and commonly used tests of ovarian reserve. Since an isolated increase in FSH levels is one of the earliest indications of reproductive aging in women, it was an obvious choice for identifying women with diminished ovarian reserve (DOR). As a marker of ovarian reserve, serum FSH concentration is best obtained during the early follicular phase (cycle days 2–4).

However, serum FSH concentration has wide intra- and intercycle variation, limiting its value as a screening test. Moreover, FSH values vary with the assay method; although values obtained with different assays correlate very well, absolute values can differ significantly. Values also vary with the reference standard, previously an International Reference Preparation of Human Menopausal Gonadotropin (IRP-HMG) and now the World Health Organization Second International Reference Preparation (IRP 78/549).

Numerous studies have investigated the relationship between cycle day 3 FSH concentrations or FSH/LH ratios and IVF cycle outcomes, all observing that these measures correlate with the ovarian response to exogenous gonadotropin stimulation and, to a lesser extent, with the likelihood for success. As FSH values increase, the peak in estradiol levels, the number of oocytes retrieved, and the probability for pregnancy or live birth steadily decline.<sup>215,216,217,218,219,220,221</sup> **With current assays (using IRP 78/549), FSH levels greater than 10 IU/L (10–20 IU/L) have high specificity (80–100%) for predicting poor response to stimulation, but their sensitivity for identifying such women is generally low (10–30%) and decreases with the threshold value.**<sup>222</sup> Although most women who are tested (including those

with DOR) will have a normal result, the test is still useful because those with abnormal results are very likely to have DOR.

Because FSH levels can vary significantly, many clinicians prefer to repeat the test. Not surprisingly, consistently high values are associated with a poor prognosis, but a single elevated FSH concentration (>10 IU/L) does not have high specificity for predicting poor response to stimulation or failure to achieve pregnancy.<sup>223</sup> Serial testing in efforts to select the ideal cycle for treatment does not improve outcomes in women with fluctuating FSH concentrations.<sup>224,225</sup>

**The basal serum estradiol concentration, by itself, has little value as an ovarian reserve test,<sup>226,227,228,229</sup> but can provide additional information that helps in the interpretation of the basal FSH level.** An early elevation in serum estradiol reflects advanced follicular development and early selection of a dominant follicle (as classically observed in women with advanced reproductive aging) and will suppress FSH concentrations, thereby possibly masking an otherwise obviously high FSH level indicating DOR. When the basal FSH is normal and the estradiol concentration is elevated (>60–80 pg/mL), the likelihood of poor response to stimulation is increased and the chance for pregnancy is decreased.<sup>230,231,232,233</sup> When both FSH and estradiol are elevated, ovarian response to stimulation is likely to be very poor.

Due to their low diagnostic performance, basal FSH and estradiol measurements are being increasingly replaced with serum AMH and AFC in daily practice.

## Clomiphene Citrate Challenge Test

The CCCT is a provocative and possibly more sensitive test of ovarian reserve that probes the endocrine dynamics of the cycle under both basal and stimulated conditions, before (cycle day 3 FSH and estradiol) and after (cycle day 10 FSH) treatment with clomiphene citrate (100 mg/day, cycle days 5–9).<sup>234</sup>

The smaller follicular cohorts in aging women produce less inhibin B and estradiol, resulting in less negative feedback inhibition on clomiphene-induced pituitary FSH release, causing an exaggerated increase in FSH concentrations.<sup>84,235</sup> Consequently, a frankly elevated cycle day 10 FSH concentration can identify women with DOR who might otherwise go unrecognized if evaluated with basal cycle day 3 FSH and estradiol levels alone.<sup>236,237</sup>

In studies evaluating CCCT results, stimulated concentrations of FSH, estradiol, and inhibin B have varied widely, limiting the value of the test.<sup>238,239,240</sup> A 2006 systematic review of the predictive value of the CCCT over a range of day 10 FSH concentrations (10–22 IU/L) in women at low, average, and high probability of DOR concluded the test

had 47–98% specificity and 35–93% sensitivity for predicting poor response to stimulation and 67–100% specificity and 13–66% sensitivity for predicting treatment failure.<sup>241</sup> **Overall, the additional value of CCCT over basal FSH and AFC is marginal, and it is being used less often in daily practice.**

## **Inhibin B**

Inhibin B is secreted primarily during the follicular phase by the granulosa cells of smaller antral follicles. Its concentrations increase in response to exogenous GnRH or FSH stimulation and show wide intra- and intercycle variation.<sup>228,242</sup> Thus, **inhibin B is generally not regarded as a reliable measure of ovarian reserve.**

Although inhibin B levels are generally lower in women who respond poorly to exogenous gonadotropin stimulation than in those who respond normally,<sup>243,244</sup> even low threshold values (40–45 pg/mL) have only 64–90% specificity and 40–80% sensitivity for predicting poor response. Inhibin B has a relatively low PPV (19–22%) but a relatively high NPV for detecting DOR in a general IVF population<sup>242,245</sup>; in a high prevalence population, the PPV of inhibin B can exceed 80%.<sup>228</sup> In most studies, inhibin B has had poor PPV for failed treatment.<sup>227,228,246,247,248</sup>

## **Antimüllerian Hormone**

Antimüllerian hormone (AMH) is produced by the granulosa cells of preantral and small antral follicles, beginning when primordial follicles start developing into primary follicles and ending when early antral follicles reach a diameter of 2–6 mm.<sup>249,250,251,252,253</sup> Small antral follicles are likely the primary source because they contain larger numbers of granulosa cells and a more developed microvasculature.<sup>254,255</sup> Although it functions primarily as an autocrine and paracrine regulator of follicle development, AMH appears in measurable amounts in the serum.<sup>256</sup> The number of small antral follicles correlates with the size of the residual follicular pool and AMH levels decline progressively, becoming undetectable near the menopause.<sup>257,258,259,260</sup>

**Because AMH derives from preantral and small antral follicles, levels were thought to be gonadotropin-independent and exhibit little variation within and between cycles.**<sup>261,262,263</sup> However, recent studies suggest AMH levels decrease with the use of oral contraceptives and GnRH agonists.<sup>264</sup> In early clinical studies, AMH has been assayed using two different commercial assay kits, and although the results were highly correlated, their standard curves were not parallel and there was no applicable conversion factor; one comparative study observed that concentrations measured with one kit were more than fourfold lower than those measured with the other.<sup>265</sup> Even

though the two manufacturers of AMH assays merged to form a third company and a new two-step, sandwich-type enzymatic microplate assay that uses a more stable antibody was introduced, the assay was calibrated to the standards of one manufacturer, and results remained systematically different, that is, 40% higher, than the previous version of the other manufacturer. Moreover, AMH readings are affected by the storage and handling conditions of the samples. Consequently, when applying results in clinical practice, it is important to know which assay method was used to measure AMH. Current commercial assay kits yield consistent results with low interassay variation (<10%).<sup>266</sup>

The performance of AMH as a screening test of ovarian reserve has been examined in the general IVF population and in populations of women at low or high risk for DOR. Overall, lower AMH levels have been associated with poor response to ovarian stimulation and low oocyte yield, embryo quality, and pregnancy rates,<sup>242,243,267,268,269</sup> but studies correlating mean AMH levels with IVF outcomes have not yielded threshold values that can be applied confidently in clinical care,<sup>226,243,245,267</sup> and more recent studies failed to show an effect of low AMH levels on pregnancy rate, when corrected for age.<sup>270,271</sup> **In the general IVF population, low AMH threshold values (0.2–0.7 ng/mL) have had 40–97% sensitivity, 78–92% specificity, 22–88% PPV, and 97–100% NPV for predicting poor response to stimulation ( $\leq 3$  follicles or  $\leq 2$ –4 oocytes), but have proven neither sensitive nor specific for predicting pregnancy.**<sup>242,272,273,274</sup>

**AMH is a very promising screening test for DOR but is likely to be more useful in a general IVF population or in women at high risk for DOR than in women at low risk for DOR. Low threshold values have good specificity for poor response to ovarian stimulation, but not for predicting pregnancy.**

## Antral Follicle Count

Reproductive-aged women have an estimated 20–150 growing follicles in the ovaries at any one time, although only those large enough to be imaged (>2 mm) can be visualized by transvaginal ultrasonography (TVUS).<sup>275,276,277</sup> Antral follicles are FSH sensitive and can progress to more advanced stages of development when stimulated with exogenous FSH. **Histologic studies have revealed that the number of small antral follicles in the ovaries is proportional to the number of primordial follicles remaining.**<sup>278</sup> **Therefore, as the supply of primordial follicles decreases, the number of visible small antral follicles also declines.** The antral follicle count (AFC; total number of antral follicles measuring 2–10 mm in both ovaries) thus provides an indirect but useful measure of ovarian reserve.<sup>276,279,280,281,282</sup>

AFC correlates with onset of the menopausal transition, indicating that it relates to the number of follicles remaining.<sup>258</sup> Some, perhaps as much as half, of the antral follicles that can be imaged are probably in the process of atresia, but there is no way other than observing their response to FSH stimulation to distinguish them from viable growing follicles.<sup>283</sup> However, AFC correlates well with oocyte yield in IVF cycles,<sup>284</sup> suggesting that gonadotropin stimulation can still rescue follicles that may be in the early stages of atresia.<sup>285</sup> Several studies have observed a relationship between the AFC and response to ovarian stimulation in IVF cycles. In the general IVF population, including women at low and high risk for DOR, an AFC threshold value of three to four follicles has high specificity (73–100%) for predicting poor response to ovarian stimulation and failure to conceive (64–100%), but relatively low sensitivity for both endpoints (9–73% for poor response, 8–33% for failure to conceive).<sup>228,284,286,287,288,289,290,291</sup> The PPV and NPV of AFC have varied widely in studies.

**A low AFC has high specificity for predicting poor response to ovarian stimulation and treatment failure, making it a useful test, but low sensitivity limits its overall clinical utility.**

## Ovarian Volume

Not surprisingly, ovarian volume decreases with progressive follicular depletion.<sup>292,293</sup> However, the measure has high intercycle and interobserver variability,<sup>228,294,295,296</sup> and because most studies of ovarian volume have excluded women with ovarian pathology such as endometriomas and polycystic ovary syndrome, results have limited generalizability.<sup>293,297</sup>

Ovarian volume (length × width × depth × 0.52 = volume) generally correlates with the number of oocytes retrieved, but poorly with pregnancy.<sup>286,291,298,299,300</sup> A low ovarian volume (<3 mL) has high specificity (80–90%) and widely ranging sensitivity (11–80%) for predicting poor response to ovarian stimulation.<sup>222</sup> The PPV for poor response can be as low as 17% among women at low risk for DOR and as high as 53% in women at high risk.<sup>228</sup> **Overall, ovarian volume has very limited clinical utility as an ovarian reserve test.**

## Other Tests of Ovarian Reserve

Numerous other provocative tests of ovarian reserve have been investigated, including exogenous FSH-stimulated estradiol, inhibin B or AMH levels,<sup>267,301,302,303,304,305</sup> and GnRH agonist-stimulated FSH, estradiol, inhibin B, or AMH

concentrations.<sup>267,301,306,307,308</sup> In theory, the ovarian and endocrine response to FSH or GnRH agonist stimulation should provide the best estimate of the number of responsive follicles. **However, the available evidence does not justify the complexity and higher costs of these tests since they are not found to be better predictors of response to ovarian stimulation or pregnancy than basal FSH, AMH, and AFC.**<sup>222</sup>

## Combined Tests of Ovarian Reserve

Since none of the ovarian reserve tests alone has 100% sensitivity and specificity, varying combinations of ovarian reserve tests have been tried to improve diagnostic performance. However, as different tests of ovarian reserve are highly correlated, using more than one measure in a prediction model does not necessarily improve its performance.<sup>228,244,286</sup> The use of combined tests will not only increase the cost of testing but also complicate clinical decision-making. A combination of AMH, inhibin B, AFC, and ovarian volume was not found to be a better predictor of response to stimulation than only AFC and AMH alone.<sup>289</sup> A meta-analysis of cohort studies investigating the performance of various combinations of tests concluded that models combining tests do not perform significantly better than individual tests such as the AFC.<sup>309</sup>

## Summary

Currently, there is no ovarian reserve test that predicts the likelihood of spontaneous conception for a regularly menstruating woman. For the purpose of predicting response to ovarian stimulation, the lack of a uniformly accepted definition of diminished ovarian reserve despite a number of attempts remains a problem. In order to predict success of ART, the ideal ovarian reserve test should yield consistent results and be highly specific, to minimize the risk for incorrectly categorizing normal women as having a diminished ovarian reserve. Currently, AFC and antimüllerian hormone are replacing basal FSH levels as the most commonly used ovarian reserve test in clinical practice.

Although ovarian reserve tests are capable of predicting response to exogenous gonadotropin stimulation reasonably well, whether the information gained truly affects outcomes is less certain. Individualized FSH dosing based on ovarian reserve testing does not seem to improve live birth rates or decrease cost of treatment.<sup>310,311,312</sup> **Moreover, increasing gonadotropin dosage does not improve response predictably in women with diminished ovarian reserve, probably because the small cohort of responsive antral follicles is the limiting factor and no amount of stimulation can increase that number appreciably.**<sup>313,314,315</sup> Even in women who previously exhibited a poor response to stimulation, changes in treatment regimens generally have not

improved response or pregnancy rates in subsequent cycles.<sup>314,316,317,318</sup>

**None of the ovarian reserve tests currently in use is an accurate predictor of pregnancy in IVF cycles, with the possible exception of when extreme abnormal threshold values are applied, which results in very low sensitivity for identifying women having a poor prognosis.**<sup>319</sup> The tests are adequate for predicting poor response, which does have prognostic value, although not as much in young women as in older women.<sup>320,321,322</sup> Although ovarian reserve tests have become a routine element of pretreatment evaluation for couples planning IVF, it can be argued that routine testing has limited clinical utility in the large majority of patients and can be misleading, especially in women at low risk for having a diminished ovarian reserve.<sup>283</sup>

Ovarian reserve tests also have become a routine element of the diagnostic evaluation for infertility. Advocates for the liberal application of ovarian reserve tests argue that abnormal tests can help to persuade older women to abandon plans to pursue aggressive, costly, and likely futile treatment and can help to convince young women to do just the opposite, to take fullest advantage of a rapidly closing window of opportunity. Others more circumspect emphasize correctly that few young women will have an abnormal test, and some of those who do inevitably will be categorized incorrectly, leading to inappropriate counseling and treatment. **The best overall strategy would seem to limit ovarian reserve testing to women at increased risk for having a diminished ovarian reserve and to apply highly specific threshold values to minimize the risk for a false-positive result.** In this context, ovarian reserve testing can best be justified for women with any of the following characteristics<sup>138,323,324,325,326</sup>

- Age over 35
- Unexplained infertility to identify unsuspected loss of ovarian reserve
- Family history of early menopause
- Previous ovarian surgery (ovarian cystectomy or drilling, unilateral oophorectomy), chemotherapy, or radiation
- Smoking
- Demonstrated poor response to exogenous gonadotropin stimulation

**Ovarian reserve tests always should be interpreted with caution. Rigid application of test results risks inappropriate recommendations for treatment, or for no treatment, and both must be avoided. An abnormal test result does not preclude the possibility of pregnancy. Except perhaps when grossly abnormal, test results should not be used to deny treatment, but only to obtain prognostic information that may help to guide the choice of treatment and best use of available resources. Although the probability of pregnancy may be low, many with abnormal test results**

**will achieve pregnancy if afforded the chance. Ultimately, regardless of the prognosis, the success rate for any individual woman will be 0% or 100%.**

# GUIDING PRINCIPLES FOR EVALUATION AND TREATMENT OF INFERTILITY

---

From the beginning, the evaluation of infertility should focus on the couple and not on one or the other partner, regardless of past reproductive performance. Ideally, both partners should be present during office visits. This enables the flow of information between the physician and both partners, as well as between the partners. It is equally important to allow each partner to express her or his own opinion and be able to ask questions directly. This can help increase patient compliance, which is very often a challenging aspect of the management of infertile couples.

**The four basic goals of management of infertility are:**

- **To identify and to correct specific causes of infertility, when possible. With proper evaluation and treatment, the majority of women will achieve pregnancy.**
- **To provide accurate information and to dispel the misinformation commonly gained from friends, mass media, and the Internet.**
- **To provide emotional support during a trying time.**

In many couples, the inability to conceive results in feelings they have lost control over an important and very personal part of their lives. The process of evaluation and the associated uncertainty significantly adds to that burden. Infertile couples often need the opportunity to express their concerns, frustrations, and fears, and support groups can help to meet that need. Group meetings can help couples to realize that their problem is not unique and to learn how others cope with similar problems. Whereas severe anxieties can have adverse effects on ovulatory function and coital frequency, there is no substantial evidence that the usual anxieties of couples trying to conceive cause or contribute to their infertility.

- **To guide couples failing to conceive with other forms of treatment to alternatives, including IVF, the use of donor gametes (oocytes or sperm), and adoption, and to help those who reject or fail treatment to come to closure.**

Counseling must be an ongoing process during both evaluation and treatment. Regular visits to review and critique results and to outline recommendations for further evaluation and treatment help to ensure that all of the couple's medical, emotional, and financial needs and concerns are addressed effectively in a timely fashion.

# Lifestyle and Environmental Factors

Understandably, all infertile couples are very interested in learning anything they might do to maximize the likelihood of achieving a successful pregnancy. Lifestyle choices and environmental factors influence fertility and deserve consideration and discussion when they are relevant. The United States has the highest obesity rate in the world. Over 40% of American women are obese and another 30% are overweight.<sup>327</sup> Obesity is defined as a body mass index (BMI) greater than 30 kg/m<sup>2</sup> and overweight is defined as a BMI between 25 kg/m<sup>2</sup> and 30 kg/m<sup>2</sup>. In women, obesity is associated with menstrual dysfunction, decreased fertility, and increased risks of miscarriage and obstetric and neonatal complications. In men, obesity is associated with abnormal semen parameters and can adversely affect fertility.<sup>328</sup>

Substance abuse is one of the few things over which the couple may have specific control, smoking being the most important. Many are not aware of the adverse effects smoking has on fertility and pregnancy outcome.<sup>329</sup> The couple's motivation to maximize their fertility presents a golden opportunity to educate those who smoke and to establish a smoking cessation strategy. Smoking has well-known adverse impact on pregnancy outcome, and evidence strongly suggests that fertility is lower in both men and women who smoke.<sup>330,331,332,333,334</sup> The prevalence of infertility is higher, fecundability is lower, and the time to conception is longer in smoking than in nonsmoking women, and the effects of passive smoke exposure are only slightly less than those of active smoking by either partner.<sup>335</sup> The available data suggest that the adverse effects of smoking on fertility are dose-dependent.<sup>331,336,337,338</sup> The mechanisms involved may include accelerated follicular depletion,<sup>339,340,341</sup> menstrual cycle abnormalities,<sup>342</sup> or gamete or embryo mutagenesis induced by toxins in cigarette smoke.<sup>343,344,345,346,347</sup> A causal relationship between cigarette smoking and female infertility has not been established. However, based on the results of a meta-analysis including 12 studies (overall OR for risk of infertility in women smokers versus nonsmokers 1.60),<sup>333</sup> and assuming a 22.5% prevalence of smoking in women of reproductive age, up to 12% of female infertility could be related to smoking.<sup>348,349</sup> Consequently, an active approach to prevention of infertility is justified, discouraging smoking and helping those who smoke to quit.<sup>350</sup>

Other forms of substance abuse also can adversely affect fertility. Marijuana inhibits the secretion of GnRH and can suppress reproductive function in both women and men.<sup>351</sup> In women, marijuana use can interfere with ovulatory function.<sup>352</sup> Cocaine use can impair spermatogenesis in men<sup>351,353</sup> and has been associated with a greatly increased risk of tubal disease in women.<sup>352</sup> Heavy alcohol consumption in women may decrease fertility<sup>354,355,356</sup>; in men, it has been associated with decreased semen quality

and impotence.<sup>357</sup> Conflicting evidence suggests that moderate alcohol intake can reduce fecundability.<sup>358,359</sup> In both women and men, even modest amounts of alcohol consumption have been associated with lower pregnancy rates in IVF cycles.<sup>360</sup> Although moderate caffeine ingestion (200 mg daily, which is equal to about one 12-ounce cup of coffee) appears not to have any adverse effects on fertility, higher levels of consumption may delay conception<sup>334,361,362</sup> or increase the risk of pregnancy loss.<sup>363,364</sup>

Other potentially harmful occupational and environmental exposures, although uncommon, may be identified. Exposures to perchlorethylene in the dry-cleaning industry, toluene in the printing business, ethylene oxide, and mixed solvents have been associated with decreased fecundity. Semen abnormalities have been described in men exposed to radiant heat or heavy metals. Environmental exposure to herbicides or fungicides has been associated with decreased fertility in women<sup>356</sup> and exposure to pesticides and other chlorinated hydrocarbons with an increased risk of miscarriage.<sup>365</sup>

**For couples attempting to conceive, there is fair evidence to support recommendations for smoking cessation and efforts to achieve a BMI between 20 and 25 kg/m<sup>2</sup>. Recommendations to limit alcohol consumption to four or fewer drinks per week and to limit caffeine intake to less than 200 mg/day also are reasonable and consistent with available evidence. However, there have been no randomized controlled trials demonstrating that such lifestyle modifications improve fertility.**

# Normal Reproductive Efficiency

Explaining normal human reproductive process helps to provide perspective for infertile couples. Understanding the relative inefficiency of human reproduction can help decrease the couple's stress and set realistic expectations regarding the assessment and treatment process. **In normally fertile couples, cycle fecundity averages 20% and does not exceed approximately 35% even when coitus is carefully timed.**<sup>207,366,367</sup>

This information is particularly helpful when discussing and comparing the efficacy of different treatment options, typically viewed in terms of cycle fecundability. It is important to ensure that couples realize that the benchmark for comparison is 20–30%, and not 100%.

Given the average 20% cycle fecundability, the cumulative pregnancy rates observed over time in normal fertile couples are easy to understand. The data in [Table 25.1](#) have been a standard since 1956 and have been confirmed by more recent studies.<sup>3,368,369</sup>

Data from **Guttmacher AF**, Factors affecting normal expectancy of conception, JAMA 161:855, 1956.

**A normal sperm can survive in the female reproductive tract and retain the ability to fertilize an egg for at least 3 and up to 5 days, but an oocyte can be fertilized successfully for only approximately 12–24 hours after ovulation.<sup>370</sup> Consequently, virtually all pregnancies result from intercourse occurring sometime within the 6-day interval ending on the day of ovulation.<sup>207,367,371</sup>** Estimates of when fertility peaks vary with the method used to determine the time of ovulation. When ovulation is assumed to occur on the day before the midcycle rise in basal body temperature (BBT), the day of peak fertility falls 2 days prior to ovulation<sup>207</sup>; ovulation generally occurs within 1 day of that predicted.<sup>371</sup> When the time of ovulation is based on daily urine estrogen concentrations, the probability of conception increases steadily as ovulation nears and peaks on the day before and day of ovulation,<sup>367,371</sup> ranging from about 10% at its low to approximately 33% at its peak. When daily urinary LH excretion is monitored to detect the midcycle surge that triggers ovulation, follicular collapse (as determined by serial TVUS) and, presumably, ovum release generally follow within 14–26 hours, and almost always within 48 hours.<sup>372,373</sup> Regardless of the method used, all studies indicate that fertility plummets almost immediately thereafter, declining to near zero within 24 hours after ovulation.

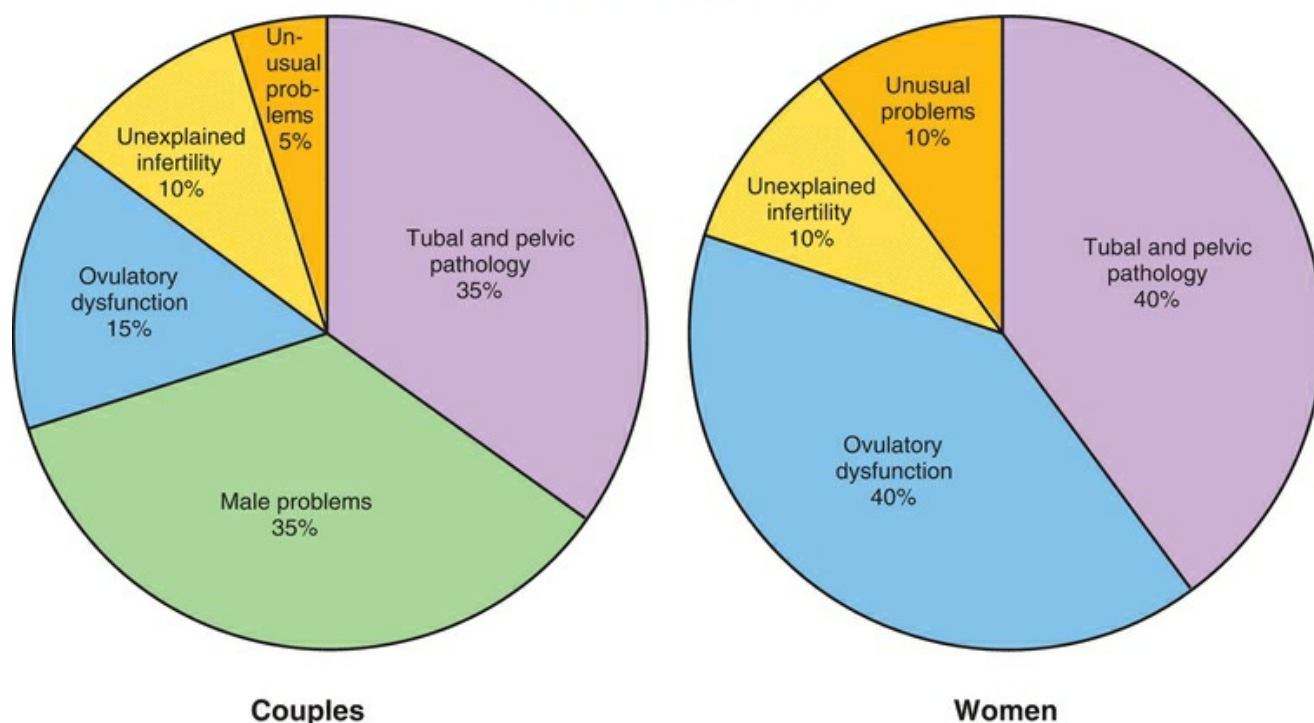

Even though timing coitus to coincide with the most fertile period seems straightforward and is frequently recommended to infertile couples as a means to increase the likelihood of pregnancy, there is very low-quality evidence to support the recommendation.<sup>374</sup> Although BBT and ovulation predictor kits (that measure elevations in urinary LH) can help define the time of ovulation, they should be used only when

necessary. Scheduled intercourse clearly adds to the already significant stress of infertility. Moreover, much of the interval of peak fertility during the menstrual cycle may be inadvertently excluded while awaiting the appropriate “signal.” **For most couples, the simple recommendation for intercourse approximately once every 2–3 days can avoid an unnecessary source of stress while also helping to ensure that coitus occurs during the interval of highest fertility.**<sup>375</sup> However, timed coitus may be a reasonable recommendation for couples having infrequent intercourse, by preference or because of circumstance.

# Causes of Infertility

Before any formal investigation begins, the major causes of infertility and the basic components of the infertility evaluation should be outlined for the couple. **The major causes of infertility include ovulatory dysfunction (20–40%), tubal and peritoneal pathology (30–40%), and male factors (30–40%); uterine pathology is relatively uncommon, and the remainder is largely unexplained.** Many couples suffer from multiple etiologies. The prevalence of each cause of infertility varies with age. Ovulatory dysfunction is more common in younger than in older couples, tubal and peritoneal factors have a similar prevalence, and male factors and unexplained infertility are observed somewhat more often in older couples.<sup>376,377</sup> The distribution of causes also varies with the duration of infertility and the level of care.<sup>378,379,380</sup> Most couples seeking evaluation have been trying to conceive for 2 or more years, so few will be normally fertile (**Figure 25.3**). Those with longer durations of infertility generally have more severe or multiple problems and tend to congregate in tertiary care centers. The average duration of infertility for couples seen in tertiary care centers (42 months)<sup>380</sup> is twice that for couples seen in the primary care setting (21 months).<sup>378</sup> Predictably, the proportion of couples with easily treatable ovulatory dysfunction decreases from primary to tertiary care, and that with more severe tubal/peritoneal or male factors increases.

Causes of Infertility

## FIGURE 25.3

The human reproductive process is complex, but for purposes of evaluation, it can be dissected into its most important and basic components.

### Key Points: Human Reproductive Process

- Sperm must be deposited at or near the cervix at or near the time of ovulation, ascend into the fallopian tubes, and have the capacity to fertilize the oocyte (male factor).
- Ovulation of a mature oocyte must occur, ideally on a regular and predictable basis (ovarian factor).
- The fallopian tubes must capture ovulated ova and effectively transport sperm and embryos (tubal factor).
- The uterus must be receptive to embryo implantation and capable of supporting subsequent normal growth and development (uterine factor).

The infertility evaluation is designed to isolate and test the integrity of each component, insofar as that is possible, and to identify any abnormalities that might impair or prevent conception. The pace and extent of evaluation should be based on the couple's age, duration of infertility, medical history, physical examination, and preferences.

Some infertility problems once considered insurmountable are now amenable to modern treatments. IVF can effectively bypass irreparable tubal occlusive disease, and intracytoplasmic sperm injection (ICSI) can overcome even severe abnormalities of semen quality. Treatments aimed at increasing gamete density—bringing together more than the usual numbers of oocytes and sperm in the right place at the right time—can increase cycle fecundability for couples with age-related or otherwise unexplained infertility and include ovarian stimulation with IUI or IVF. In women with POF, women beyond normal reproductive age, and women without ovaries, IVF using donor oocytes is highly successful.

A substantial proportion of subfertile couples suffer from unexplained infertility (i.e., have normal semen analysis, at least one patent tube, macroscopically normal-appearing uterus and endometrium, and regular menstrual cycle); similarly, a rational treatment does not exist for some common causes of infertility (i.e., advanced female age, severe tubal damage, idiopathic oligoasthenospermia).<sup>6</sup> **The scope and sequence of the modern infertility evaluation have shifted focus, from always making a**

**specific diagnosis to using the most efficient and cost-effective tests. Likewise, the focus of treatment for infertility also has shifted, from systematic correction of each identified factor to applying the most efficient and cost-effective therapy, which often is ART.**

# Indications for Evaluation

When should a formal evaluation for infertility begin? After all, most infertile couples are only subfertile, not truly sterile, and many will conceive, eventually, without treatment. Infertility has a significant spontaneous cure rate that varies with female partner age, duration, past conception history, and the cause(s). **The probability for achieving a live birth without treatment decreases with increasing age and duration of infertility.**<sup>378,379,380,381,382,383</sup> Overall, the likelihood of pregnancy without treatment declines by about 5% for each additional year of female partner age and by 15–25% for each added year of infertility.<sup>380</sup> **The largest majority of spontaneous pregnancies occur within 3 years; thereafter, the prognosis for success without treatment is relatively poor.** Couples that have conceived before generally have a better prognosis than those who have never achieved pregnancy. The cause of infertility also affects the prognosis for success without treatment but, of course, cannot be determined without evaluation. Predictably, the diagnoses of anovulation and unexplained infertility have the best prognosis. The likelihood for success without treatment for couples with male factors, tubal disease, and endometriosis varies widely with the severity of disease; the prognosis is reasonably good for mild oligospermia, tubal adhesions, and mild endometriosis and quite poor for severe male factors, tubal obstruction, and severe endometriosis.

**Evaluation should be offered to all couples who have failed to conceive after a year or more of regular unprotected intercourse, but a year of infertility is not a prerequisite for evaluation. Earlier evaluation is justified in the presence of obvious risk factors, such as irregular or infrequent menses, history of pelvic infection, surgery or endometriosis, or having a male partner with known or suspected poor semen quality, and also is warranted after 6 months of unsuccessful effort for women over the age of 35 years.**<sup>1,384</sup>

Education should be offered to any couple who seeks it, regardless whether they have made any active effort to conceive. It is always helpful to explain the reproductive process, to inform couples that normal cycle fecundability is approximately 20% (far lower than most realize), and to discuss the relationship between age and fertility, when it is relevant. In concerned couples who have not yet truly tested their fertility and have no obvious problems, some basic preliminary evaluation is reasonable to perform, if requested. A complete medical history helps in identifying or ruling out obvious risk factors, and tests to confirm ovulation and semen analysis are easy, inexpensive, and minimally invasive and quickly can identify some of the most common reproductive problems. In women at risk for diminished ovarian reserve, an ovarian reserve test is also reasonable, because results may help to determine when and how further evaluation

and treatment should be recommended.

# PRELIMINARY EVALUATION OF THE INFERTILE COUPLE

---

Any evaluation of infertility must begin with a careful history and physical examination, which often will identify symptoms or signs that suggest a specific cause and help to focus evaluation on the factor(s) most likely responsible. In the female partner, relevant medical history and physical findings are noted in [Table 25.2](#).<sup>384</sup>

## **TABLE 25.2 History and Examination of the Female Partner**

## History

- Obstetric history including gravidity, parity, pregnancy outcomes, and associated complications.
  - Menstrual history including cycle length and characteristics and onset and severity of dysmenorrhea.
  - Coital frequency and sexual dysfunction.
  - Duration of infertility and results of any previous evaluation and treatment.
  - Medical and surgical history, including episodes of pelvic inflammatory disease or exposure to sexually transmitted infections.
  - Previous abnormal cervical cancer screening results and subsequent treatment.
  - Current medications and allergies.
  - Occupation and use of tobacco, alcohol, and other drugs.
  - Family history of birth defects, mental retardation, early menopause, or reproductive failure.
  - Symptoms of thyroid disease, pelvic or abdominal pain, galactorrhea, hirsutism, or dyspareunia.
- 

## Physical Examination

- Weight and BMI.
  - Thyroid enlargement, nodule, or tenderness.
  - Breast secretions and their characteristics.
  - Signs of androgen excess.
  - Pelvic or abdominal tenderness, organ enlargement, or mass.
  - Uterine size, contour, position, and mobility.
  - Vaginal or cervical abnormality, secretions, or discharge.
  - Mass, tenderness, or nodularity in the adnexa or cul-de-sac.
-

Irregular or infrequent menses indicate ovulatory dysfunction. Previous treatment for cervical intraepithelial neoplasia or observation of a mucopurulent cervicitis or cervical stenosis helps to identify unusual women in whom the cervix may present an obstacle. A history of previous hysteroscopic or reconstructive uterine surgery or recently developing symptoms of menorrhagia suggest an abnormality of the uterine cavity; previous uncomplicated first- and second-trimester pregnancy terminations generally do not adversely affect subsequent fertility.<sup>385,386</sup> Worsening dysmenorrhea, new onset of dyspareunia, or physical findings of focal tenderness or cul-de-sac nodularity suggest endometriosis. A history of pelvic infection, septic abortion, ruptured appendix, ectopic pregnancy, abdominal myomectomy, or adnexal surgery should raise suspicion for tubal or peritoneal disease.

# Screening Tests

**Cervical cancer** screening is recommended for all sexually active women of reproductive age who have a cervix. The date and results of the most recent screening should be documented and a new one performed, if needed. The optimal method of screening depends on previous history and age.<sup>387</sup> A blood type, Rh factor, and antibody screening (in Rh-negative women) also is recommended, if not already known.

The American College of Obstetricians and Gynecologists recommend that all women considering pregnancy should be offered carrier screening for cystic fibrosis and spinal muscular atrophy, as well as a complete blood count and screening for thalassemias and hemoglobinopathies.<sup>388</sup> Women with a family history of fragile X-related disorders or intellectual disability suggestive of fragile X syndrome or women with premature ovarian insufficiency should be offered fragile X permutation carrier screening.<sup>388</sup> Additional screening also may be indicated based on family history or specific ethnicity; an example is the Ashkenazi Jewish population where an expanded carrier screening for a number of recessive disorders is indicated. Couples with consanguinity should be offered genetic counseling to discuss the increased risk of recessive conditions being expressed in their offspring and the limitations and benefits of carrier screening. When a woman is found to be a carrier for a specific condition, her reproductive partner should be offered screening to provide accurate genetic counseling regarding risk of an affected child if he tests positive and reproductive options (e.g., donor gametes, preimplantation genetic diagnosis, prenatal diagnosis).<sup>388</sup>

All women attempting pregnancy with undocumented previous rubella infection or vaccination should be tested for immunity and vaccinated if seronegative.<sup>389</sup> As there has never been a documented case of congenital rubella syndrome attributed to vaccine, the CDC has determined that women need not avoid pregnancy for more than 1 month after vaccination.<sup>390</sup> The CDC also recommends that all women without history of previous infection or evidence of immunity or vaccination against varicella (chicken pox) receive two doses of vaccine and avoid pregnancy for 1 month after each dose.<sup>389</sup>

Screening for **sexually transmitted infections** (STIs) is recommended for all women at moderate to high risk for infection. Decisions regarding STI screening should consider that current recommendations from the CDC include screening all pregnant women for syphilis (rapid plasma reagin, RPR), hepatitis B (hepatitis B surface antigen, HBSAg), and human immunodeficiency virus type 1 (HIV-1), unless the woman declines the latter, at the first prenatal visit.<sup>391</sup> Chlamydia and gonorrhea screening (nucleic acid-based tests) is recommended for all pregnant women younger than 25 years or older women at increased risk of infection.<sup>391</sup> For women receiving inseminations of donor sperm, the American Society for Reproductive Medicine (ASRM) considers

syphilis, hepatitis B and C, HIV-1, HIV-2, chlamydia, gonorrhea, and cytomegalovirus (CMV) screening mandatory and recommends screening for human T-cell lymphotropic virus (HTLV) types I and II at the discretion of the physician.<sup>392</sup> For male partners of women receiving inseminations of donor sperm, the ASRM strongly recommends HIV-1 and HIV-2 and recommends other STI screening similar to the female partner. For recipients of donor oocytes or embryos and their male partners, the ASRM recommends screening for syphilis, hepatitis B and C, HIV-1, HIV-2, chlamydia, gonorrhea, and CMV.<sup>392</sup> Any additional screening laboratory tests should be directed by the medical history and clinical judgment.

# MALE FACTOR: ABNORMALITIES OF SEMEN QUALITY

---

The evaluation and treatment of male infertility are the focus of [Chapter 26](#), but must be addressed briefly here because male factors explain or contribute significantly to infertility in up to 35% of couples. Semen analysis is therefore always an appropriate and important initial step in the evaluation of the infertile couple. In the absence of any known genital abnormality, trauma, surgery, or sexual dysfunction, physical examination of the male partner can be deferred pending the results of the initial semen analysis.

When semen analysis yields equivocal results, additional analyses are required to better define a suspected abnormality. A frankly abnormal semen analysis is an indication for additional evaluation that may be conducted by a gynecologist having the necessary training and experience, but most often is performed by a urologist or other specialist in male reproduction.<sup>393</sup> Invasive diagnostic procedures, including hysterosalpingography (HSG), in the female partner generally can be deferred until evaluation of the male is completed. The range of effective treatment options for couples with severe male factor infertility is limited and often will direct or even dictate what additional evaluation may be relevant in the female partner. When semen quality is normal, attention naturally turns to the female partner.

# OVARIAN FACTOR: OVULATORY DYSFUNCTION

---

Overall, disorders of ovulation account for approximately 15% of the problems identified in infertile couples. Ovulatory dysfunction can be severe enough to prevent conception (anovulation), or only a contributing factor (oligo-ovulation). However, because cycle fecundability averages only approximately 20% even in normally fertile couples, the distinction is moot.

A number of methods can be used to determine if and when ovulation occurs. Directly or indirectly, all are based on one or another of the hormonal events that characterize the normal ovulatory cycle ([Chapter 5](#)). Each of the available tests is useful and no one test is necessarily best. Some are simple, noninvasive, and inexpensive, and others are more complicated, invasive, and costly. A few can predict when ovulation is likely, with varying accuracy. However, no test, regardless how sophisticated, can prove that ovulation has actually occurred; the only positive proof that assures the occurrence of ovulation is pregnancy. The most appropriate test to use varies with the information required. The same tests used to diagnose anovulation can be used to assess the effectiveness of treatment.

# Menstrual History

Menstrual history alone often is sufficient to establish a diagnosis of oligo-/anovulation. Ovulatory women generally have regular, predictable menstrual cycles between 21 and 35 days, with menstrual flow that is consistent in volume and duration, and typically accompanied by a recognizable pattern of premenstrual and menstrual symptoms. Conversely, menstrual cycles in anovulatory women generally are irregular, unpredictable, or infrequent, vary in flow characteristics, and exhibit no consistent pattern of menses. **Women with regular menses are almost always ovulatory. Women with irregular or infrequent menses may ovulate, but not consistently, and do not require specific diagnostic tests to prove what is already obvious.**

# Basal Body Temperature

BBT is body temperature under basal conditions, at rest. For practical purposes, BBT is measured each morning, upon awakening and before arising. Traditionally, BBT is measured with an oral glass-mercury thermometer having an expanded scale, typically ranging from 96.0 to 100.0 degrees Fahrenheit and marked in tenths of one degree; modern electronic thermometers are a suitable alternative, but only if they have the necessary accuracy and precision. As a test of ovulation, daily BBT recordings are based on the thermogenic properties of progesterone; as levels rise after ovulation, BBT also increases. The effects are more qualitative than quantitative, are subtle but nonetheless distinct, and generally easy to detect when daily BBT recordings are plotted on graph paper.<sup>394</sup> **Synthetic progestins commonly used to induce menses in amenorrheic women (medroxyprogesterone acetate, norethindrone acetate) have similar thermogenic properties and also raise BBT.** A BBT rise in a woman taking a progestin should not be confused with ovulation.

BBT is typically low and fluctuates between 97.0 and 98.0 degrees during the follicular phase of the cycle, modestly but distinctly higher (0.4–0.8 degrees) during the luteal phase, and falls again to baseline levels just before or after the onset of menses. In ovulatory women, a “biphasic” pattern usually is readily evident. **The ideal BBT recording is distinctly biphasic and reveals a cycle between 25 and 35 days in length, with menses beginning 12 days or more after the rise in temperature.** When pregnancy occurs in a monitored cycle, the onset of menses is delayed and BBT remains elevated, reflecting the sustained production of progesterone by the corpus luteum stimulated by hCG.

BBT recordings provide objective evidence of ovulation and also reveal the approximate time of ovulation. Unfortunately, the temporal relationship between the thermogenic shift in BBT and ovulation frequently is misunderstood. BBT generally falls to its lowest level on the day before or day of ovulation, but the nadir in BBT cannot be reliably identified until after the temperature rises and remains elevated.<sup>395</sup> The shift in BBT occurs when progesterone concentrations rise above approximately 3–5 ng/mL, 1–5 days after the midcycle LH surge and up to 4 days after ovulation.<sup>396</sup> The temperature rise usually is somewhat abrupt, but may be gradual and difficult to define, and once apparent (2 or more days of temperature elevation), the most fertile interval has passed. **In cycles monitored with BBT, the interval of highest fertility spans the 7-day interval immediately before the midcycle rise in BBT.** Much of the uncertainty in predicting the time of ovulation can be avoided by reviewing a series of recordings, noting the earliest and latest days of the cycle on which the temperature shift occurred. **Coital timing can be optimized by suggesting intercourse on alternate days**

**beginning 7 days before the earliest observed rise in BBT and ending on the latest day it has been observed.**

The principal advantage that BBT has over other tests of ovulation is low cost. However, some find it stressful, serving as a daily reminder of unsuccessful efforts to conceive, each day beginning with thoughts of a family not yet realized. Since BBT cannot reliably define the time of ovulation and can become tedious, it is not the method of choice for evaluating ovulatory function for most infertile women.<sup>384</sup>

# Serum Progesterone Concentration

**A serum progesterone measurement is the simplest, most common, objective, and reliable test of ovulatory function, as long as it is appropriately timed.** Progesterone levels generally remain below 1 ng/mL during the follicular phase, rise slightly on the day of the LH surge (1–2 ng/mL) and steadily thereafter, peak 7–8 days after ovulation, and decline again over the days preceding menses. **A progesterone concentration less than 3 ng/mL implies anovulation, except when drawn immediately after ovulation or just before the onset of menses, when lower levels naturally might be expected.**<sup>397,398</sup>

When is the best time to measure the serum progesterone concentration to document ovulation? **Ideally, the serum progesterone level should be drawn approximately 1 week before the expected onset of menses, when the concentration is at or near its peak. Contrary to popular belief and practice, cycle day 21 is not always the best time to measure the serum progesterone concentration.** Cycle day 21 is a good choice for women with cycles lasting approximately 28 days, but a poor choice for women with 35-day cycles. The normal ovulatory cycle is 25–35 days long and exhibits a 13–15-day luteal phase. At the extremes of normal, ovulation may occur as early as cycle day 10 (in a 25-day cycle) and as late as day 22 (in a 35-day cycle). If ovulation occurs on cycle day 10, day 21 falls 11 days after ovulation, well after progesterone concentrations peak and when they are again nearing basal levels. If ovulation occurs on cycle day 22, day 21 falls 1 day **before** ovulation, when progesterone levels have not yet started to rise. **The best time to test will vary with the overall length of the menstrual cycle, aiming for approximately 1 week before the expected menses. If the menses does not commence 7 days after a serum progesterone reading of less than 3 ng/mL, it may be reasonable to repeat the test.**

Serum progesterone levels also have been used to evaluate the quality of luteal function. Whereas the amount and duration of progesterone production certainly do reflect the functional capacity of the corpus luteum, a truly accurate measure requires frequent serum progesterone determinations that are costly and impractical.<sup>399,400,401</sup> Judgments based on limited sampling, regardless how well timed, have numerous pitfalls and cannot define the quality of luteal function reliably.<sup>399,402,403,404,405,406</sup> **There is no consensus on minimum serum progesterone concentration that defines normal luteal function.** A midluteal serum progesterone level greater than 10 ng/mL is a popular standard,<sup>407</sup> but the concentrations observed in normal and abnormal cycles and in conception and nonconception cycles in both fertile and infertile women vary widely and overlap greatly.<sup>408</sup> One reason is that progesterone is secreted by the corpus luteum in distinct pulses, temporally linked to pulsatile LH secretion<sup>409,410</sup>; levels ranging from

as low as 4 ng/mL to as high as 40 ng/mL can be observed within brief intervals of time.<sup>410</sup> **A midluteal serum progesterone concentration cannot define the quality of luteal function and has little value beyond documenting ovulation.**

# Urinary LH Excretion

A wide variety of different commercial products allow women to determine not only if they ovulate, but when, in advance of the actual event. Generally known as “ovulation prediction kits” or “LH kits,” the products are all designed to detect the midcycle LH surge in urine.

The midcycle LH surge is a relatively brief event, typically lasting between 48 and 50 hours from start to finish. LH has a short half-life and is rapidly cleared via the urine. Ovulation predictor kits turn positive when the urinary LH concentration exceeds a threshold level normally seen only during the LH surge. In most cycles, the test is positive on a single day, occasionally on 2 consecutive days. To detect the LH surge reliably, testing must be done on a daily basis, generally beginning 2 or 3 days before the surge is expected, based on the overall length of the cycle. The first positive test provides all relevant information; there is no value in continued testing.

Test results are sensitive to both the volume of fluid intake and time of day. There is no need to restrict fluid intake, but patients should be advised to avoid drinking large volumes of fluid a short time before they plan to test. Logically, the first morning void would seem an ideal specimen to test because it is usually the most concentrated. However, results correlate best with the serum LH peak when testing is performed in the late afternoon or early evening hours (4:00–10:00 P.M.),<sup>396</sup> probably because LH surges often begin in the early morning hours and are not detected in urine for several hours. Twice-daily testing decreases the frequency of false-negative results (failure to detect the LH surge in an ovulatory cycle), but generally is unnecessary. When performed daily and properly timed, testing will detect the LH surge in most ovulatory cycles. True false-positive tests (detection of an LH surge in an anovulatory cycle) occur in approximately 7% of cycles<sup>411</sup>; equivocal or “borderline” results also are common and can be both confusing and frustrating.

The accuracy of ovulation predictor kits varies. All are useful and reasonably reliable, but some are better and easier to use than others.<sup>373,412,413</sup> The best products predict ovulation within the subsequent 24–48 hours, with greater than 90% probability.<sup>372,373</sup> **Ovulation generally occurs 14–26 hours after detection of the LH surge and almost always within 48 hours.**<sup>372</sup> **Consequently, the interval of greatest fertility includes the day the surge is detected and the following 2 days. The day after the first positive test generally is the one best day for timed intercourse or insemination.**<sup>372,414,415</sup> Ovulation predictor kits are noninvasive, are widely available, require relatively little time and effort, and invite women to become actively involved in their care without increasing their stress levels.<sup>416,417</sup> Their greatest advantage over other methods is their ability to predict when ovulation will occur. Accurate

identification of the midcycle LH surge also defines the length of the follicular and luteal phases, which may reveal subtle and otherwise unrecognized cycle abnormalities warranting treatment. Women who cannot detect an LH surge using the ovulation predictor kits are often anovulatory, but may assume the kit is not functioning properly; patients should be advised that failure to detect an LH surge may reveal an important diagnostic component of their infertility. After establishing ovulation, repeated urinary LH monitoring is perhaps best reserved for women who ovulate (based on menstrual history, LH monitoring, or an appropriately timed serum progesterone concentration), but have infrequent intercourse or require insemination (**Figure 25.4**).

**FIGURE 25.4**

# Endometrial Biopsy and Luteal Phase Deficiency

Endometrial biopsy can be used as a test of ovulation, based on the characteristic histologic changes induced by progesterone. During the follicular phase of the cycle, the endometrium exhibits a proliferative pattern, reflecting the growth stimulated by rising levels of estrogen derived primarily from the dominant ovarian follicle. During the luteal phase, progesterone secreted by the corpus luteum induces the “secretory” transformation of the endometrium. Anovulatory women are always in the follicular phase; their endometrium is always proliferative and even may become hyperplastic with extended exposure to a constant estrogen growth stimulus. **In the absence of treatment with exogenous progesterone or a synthetic progestin, a secretory endometrium implies recent ovulation.**

Endometrial biopsy is a relatively simple office procedure, usually performed with a disposable plastic aspiration cannula, and complications are few. Pretreatment with a nonsteroidal anti-inflammatory drug (NSAID) helps to reduce pain or cramping associated with the procedure. Sedation or anesthetic (paracervical block) is helpful when the biopsy is technically difficult and in women who are very anxious. When properly timed, in the same way and for the same reasons as a serum progesterone concentration, endometrial biopsy is an effective test of ovulation. However, it is also invasive, uncomfortable, and costly and provides little more information than can be obtained from BBT recordings, a serum progesterone concentration, or monitoring urine LH excretion. Therefore, endometrial biopsy has rather limited and specific indications in the evaluation of infertile women. For women with chronic anovulation of long duration, biopsy can identify or exclude endometrial hyperplasia that requires specific treatment. In those few individuals suspected of harboring a chronic endometritis, biopsy is diagnostic. **In the past, endometrial biopsy for diagnosis of luteal phase deficiency was considered a basic element of the infertility evaluation, but no longer.**

Inadequate corpus luteum progesterone production or “luteal phase deficiency” (LPD) was long considered an important cause of both infertility and early pregnancy loss.<sup>418,419</sup> The proposed mechanisms were different but related, representing only different points on a pathophysiologic continuum. In theory, because the human implantation window is relatively narrow (spanning the interval from approximately 6 to 10 days after ovulation),<sup>420,421,422</sup> low circulating progesterone levels could be expected to result in delayed endometrial maturation, causing a shift in the implantation window and failed or late implantation. A long delay would threaten embryo viability or prevent implantation. A shorter delay would allow implantation but result in a tardy or low-amplitude hCG rescue signal that could not stimulate normal amounts of progesterone from an already regressing corpus luteum, or maintain production for the

requisite duration,<sup>423,424,425</sup> with either causing a premature luteal-placental shift and pregnancy loss.<sup>426</sup> In this context, endometrial biopsy was viewed as a bioassay of luteal function because it would reflect both the functional capacity of the corpus luteum and the end-organ response.

The classic histologic features of secretory endometrial development were described by Noyes, Hertig, and Rock, in the lead article of the inaugural issue of **Fertility and Sterility**.<sup>427</sup> The pattern was considered sufficiently predictable to allow experienced pathologists to “date” the endometrium, assigning a histologic day that could be compared to the actual day of sampling, estimated by counting backward from the onset of the next menstrual period (assuming menses began on the 14th postovulatory day), or defined by the number of days elapsed since detection of the LH surge or observation of follicular collapse by serial ultrasonography.<sup>428</sup> Historically, histologic and sampling dates that agreed, within a 2-day interval, were considered normal, whereas a date more than 2 days “out of phase” was the gold standard criterion for the diagnosis of LPD.<sup>429,430,431</sup> Traditionally, diagnosis of LPD required abnormal results in two (preferably consecutive) cycles, reasoning that reproductive failure could only be attributed to LPD if it was consistent or recurring and acknowledging that LPD also could occur in normal fertile women, at least occasionally.<sup>432,433,434,435,436,437,438</sup> Endometrial dating was accepted widely by clinicians and pathologists and the practice endured, despite numerous challenges to its validity.

The first and most fundamental criticism of the traditional histologic dating criteria was that the normal standard was based on analysis of tissue specimens obtained from infertile women<sup>427</sup>; the reference population was abnormal, by definition, and also likely heterogeneous because infertility has many different causes. Second, the sampling date was estimated retrospectively, after the onset of menses, assuming a uniform 14-day luteal phase, despite numerous studies demonstrating that luteal phase duration varied significantly, even in normal women.<sup>103,108,111,439,440</sup> Moreover, retrospective estimates of the sampling date correlated poorly with the time of ovulation as defined by the LH surge or observations of follicular collapse,<sup>407,428,441</sup> and ignored any effect that biopsy might have on the onset of menses, or when it was perceived to start.<sup>428,437,442</sup> Third, the traditional histologic dating criteria were inherently subjective, and numerous studies had observed significant intraobserver and interobserver variations in histologic interpretation that were great enough to affect diagnosis and management in 20–40% of individual women.<sup>431,443,444,445,446</sup>

The standard practice of endometrial biopsy and histologic dating for diagnosis of LPD was proven invalid in 2004, for all intents and purposes. A systematic reanalysis of the histologic features used for endometrial dating confirmed the classically

described sequence, but revealed the patterns were much less temporally discrete than originally described, and demonstrated that normal variations among individuals, between cycles in individuals, and among different observers were too great to reliably define any specific luteal day or even a narrow interval of days.<sup>447</sup> Soon thereafter, a large multicenter trial demonstrated conclusively that abnormal histologic dating could not discriminate infertile from proven fertile women.<sup>448</sup> The second study invalidated the practice of endometrial dating, and the first explained why the method failed.

Recent evidence challenges even the basic premise on which the concept of LPD is founded: that abnormally low circulating progesterone concentrations result in delayed endometrial maturation. In normal women treated with a fixed physiologic dose of estrogen after downregulation with a GnRH agonist, and then randomized to receive physiologic (mean progesterone level 19 ng/mL) or grossly low levels of exogenous progesterone treatment (mean progesterone level 5.5 ng/mL), there was no discernible difference in endometrial histology.<sup>449</sup> These observations suggest the histologic features of secretory endometrium relate more to the duration of progesterone exposure than to the concentration. Studies using a similar design have demonstrated that widely ranging concentrations of estradiol also have no discernible impact on secretory endometrial maturation.<sup>450</sup> Altogether, these data indicate that secretory endometrial development can progress normally despite widely varying concentrations of estradiol and progesterone, challenging the traditional paradigm, and served to further invalidate the use of endometrial histologic dating as a diagnostic tool. **In sum, histologic endometrial dating cannot guide the clinical management of women with reproductive failure and has no place in the diagnostic evaluation of infertility.**

The lack of any valid method for diagnosis of LPD does not refute its existence or its potential importance in the pathophysiology of reproductive failure. The pathogenic mechanisms outlined above are still viable. Evidence supports the notion of a finite implantation window<sup>420,421,422</sup> that progesterone is essential for embryo implantation<sup>451</sup> and that delayed implantation might adversely affect corpus luteum function,<sup>423,424,425</sup> predisposing to reproductive failure.<sup>426</sup> It is entirely possible, if not likely, that abnormally low levels of progesterone might have important functional consequences with no morphologic correlate. Biochemical or molecular markers of endometrial function provide the means to further explore the possibility. The pattern of endometrial gene expression defines distinct functional phases of the cycle.<sup>452</sup> A number of endometrial proteins exhibit patterns of expression or gene regulation during the putative implantation window, suggesting they might serve as markers of endometrial receptivity, including cytokines (leukemia inhibitory factor, colony-stimulating factor-1, and interleukin-1), cell adhesion molecules (the avb3 integrin), transcription factors (HOXA10 and HOXA11),<sup>453,454,455,456</sup> glycodelin, and the polymorphic mucin 1,<sup>457,458</sup>

osteopontin,<sup>459,460,461</sup> N-acetylglucosamine-6-O-sulfotransferase (important in the synthesis of L-selectin ligands),<sup>462</sup> and the L-selectin ligand itself.<sup>463</sup>

Analysis of the transcriptomic signature of 134 genes in endometrial biopsies revealed high specificity for endometrial dating and has been applied clinically to improve pregnancy success in women with recurrent implantation failure in assisted reproduction, by increasing likelihood of transfer during the window of implantation.<sup>464,465</sup> However, it is unlikely that all recurrent implantation failures would be due to asynchronous endometrial response to progesterone, and more recently, another study reported a transcriptomic signature involving 303 genes in women who have failed multiple IVF treatment cycles.<sup>466</sup> Genes involved in cell cycle regulation and cell division, general proliferative processes, and cytoskeleton and cilia formation were found to be downregulated in the endometrium transcriptome of women with multiple IVF failures, suggesting a more disrupted rather than an asynchronous pattern.<sup>466</sup>

None of these findings has been adequately validated as a reliable measure of endometrial function or receptivity, but if and when that occurs, a functional marker may become the basis for diagnosis of LPD, and endometrial biopsy again may be viewed as offering valuable information beyond that provided by other tests of ovulation.

# Transvaginal Ultrasonography

The last and most complicated test of ovulation involves serial TVUS, which permits direct observation of events in the ovary just before and immediately after ovum release. Although still not providing positive proof that ovulation actually occurred, serial TVUS provides detailed information about the size and number of preovulatory follicles and the most accurate estimate of when ovulation occurs.

In its final stages of development, the preovulatory follicle grows at a predictable pace, approximately 2 mm per day (range: 1–3 mm/day). After ovulation, the follicle collapses, margins become less distinct, the density of internal echoes increases, and the volume of cul-de-sac fluid increases.<sup>467,468</sup> Abnormal patterns of follicle development also can be observed. The follicle may grow at an abnormal pace, collapse when still relatively small, or continue to grow but fail to rupture and persist as a cyst for days after the LH surge—the luteinized unruptured follicle.<sup>469,470</sup> Such subtle forms of ovulatory dysfunction cannot be detected otherwise, but also are rare. **Because treatment with prostaglandin synthase inhibitors (NSAIDs) can disrupt the ovulatory process and predispose to a luteinized unruptured follicle,<sup>471,472</sup> their use is best limited to the menstrual phase of the cycle in women attempting to conceive.**

Serial TVUS to monitor the size and number of developing follicles is essential to the safety and effectiveness of ovulation induction with exogenous gonadotropins ([Chapter 27](#)), but the costs and logistical demands involved are otherwise difficult to justify. Consequently, the method generally should be reserved for the few in whom the safety or effectiveness of treatment truly hinges on the detailed information it offers.

## Summary: Assessment of Ovulation

The evaluation of ovulation is a core component of the evaluation for infertility. All of the different methods are useful and no one method is necessarily best. Whereas some are very simple, noninvasive, and inexpensive, others are more complicated, invasive, and costly. A few provide the means to determine not only if ovulation occurs, but when, with varying accuracy. The best choice among methods varies with the information required. In women with oligomenorrhea or amenorrhea, no formal evaluation is needed to establish a diagnosis of ovulatory dysfunction, but endometrial biopsy to exclude hyperplasia may be prudent, depending on duration. When the only objective is to confirm ovulatory function, as in those with regular monthly menses, a properly timed serum progesterone concentration is the simplest and most reliable method. When circumstances require accurate prediction of ovulation, as in couples having infrequent intercourse or those requiring insemination, urinary LH monitoring generally is the most cost-effective and appropriate choice. In the few who require insemination but consistently fail to detect a midcycle LH surge, serial TVUS can provide the necessary information; however, an ovulatory defect should be suspected. Ultimately, the method chosen should be tailored to the needs of the individual patient.

Infertile women with ovulatory dysfunction are obvious candidates for ovulation induction. In general, only limited additional evaluation is needed to define the initial treatment of choice, and most women will respond promptly to one of the simpler treatment strategies ([Chapter 27](#)). In the majority of cases, it is reasonable and appropriate to begin treatment immediately, even before other potential causes of infertility have been investigated. If anovulation is the only obstacle to overcome, most couples will conceive promptly without further interventions. Women with amenorrhea or hyperandrogenic anovulation deserve additional preliminary evaluation, applying the principles described in [Chapters 10, 11, and 12](#).

# CERVICAL FACTOR: ABNORMALITIES OF SPERM-MUCUS INTERACTION

---

The cervix participates in the reproductive process in several ways. Cervical mucus accepts or captures sperm from the ejaculate and the vagina, excludes the seminal plasma and morphologically abnormal sperm,<sup>473</sup> nurtures sperm biochemically, and serves as a reservoir, thereby prolonging sperm survival and the fertile interval between intercourse and ovulation. Mucus is a glycoprotein gel with solid and liquid phases and has a mosaic ultrastructure with interstitial channels between mucin strands that expand and contract in response to cyclic changes in the steroid hormone environment across the menstrual cycle to facilitate or inhibit the passage of sperm.<sup>474,475,476,477,478</sup> Estrogen stimulates cervical mucus production, and as levels rise during the follicular phase, mucus becomes more abundant and watery, less cellular, and more easily penetrated by sperm.<sup>479</sup> Progesterone inhibits cervical mucus production and renders it opaque, viscid, and impenetrable. The cyclic changes in cervical mucus characteristics help to explain why the cycle day-specific probability of conception rises steadily as ovulation nears and plummets immediately thereafter.

For most of the past century, the postcoital test for diagnosis of cervical factor infertility was considered a basic element of the infertility evaluation. The test involved collection of cervical mucus (by aspiration or with nasal polyp forceps) shortly before the expected time of ovulation (as determined by BBT or urinary LH monitoring in previous cycles) a few to several hours (typically 2–12 hours) after intercourse.<sup>480</sup> The mucus specimen was evaluated for pH, clarity, cellularity, viscosity (the length to which a column of mucus can be stretched in centimeters, known as “spinnbarkeit”), and salinity (evaluated according to the complexity of the network of crystals that forms when mucus is dried on a glass slide, also known as “ferning”) and for the number and motility of surviving sperm. The presence of motile sperm confirmed effective coital technique and sperm survival, and the number of sperm (per high-power field) was used to predict semen quality (sperm density and motility) and cycle fecundability (inverse correlation with time to conception or cumulative conception rates).<sup>481,482,483,484,485,486</sup> Most considered even a single motile sperm in most fields a normal test result.<sup>486,487,488</sup>

Abnormal postcoital test results were common, usually due to improper timing, either too early in the cycle when mucus was relatively scant or after ovulation when mucus quality was poor.<sup>489</sup> Timing was optimized by performing the test within 2 days before the LH surge or when TVUS demonstrated a preovulatory follicle.<sup>490</sup> Other explanations for poor-quality mucus were cervicitis, previous treatment for cervical intraepithelial neoplasia (e.g., cryotherapy), and treatment with clomiphene citrate.

Potential explanations for the absence of motile sperm in good-quality mucus included ineffective intercourse, failed ejaculation (frequently resulting from performance anxiety), poor semen quality, and use of spermicidal coital lubricants. Observations of degenerating, immotile, “shaking,” or agglutinated sperm were considered reason for antisperm antibody testing.<sup>484</sup> An abnormal result was confirmed by repeat testing to establish the diagnosis of cervical factor infertility,<sup>480,486,491</sup> prompting further evaluation with a nucleic acid test for chlamydia and cultures for ureaplasma and mycoplasma (or empirical treatment with antibiotics),<sup>492,493,494</sup> and semen analysis. Normal semen quality and absence of sperm in good-quality mucus were regarded as evidence of “hostile” cervical mucus or a sperm function abnormality, differentiated by comparisons of partner and donor sperm survival and motility in bovine cervical mucus in vitro and antisperm antibody testing.<sup>495,496,497</sup> Strategies for correcting or overcoming cervical factor infertility included treatment with exogenous estrogens (to stimulate mucus production)<sup>498</sup> or mucolytic agents (guaifenesin),<sup>499</sup> precoital douching with a sodium bicarbonate solution,<sup>500</sup> and IUI.<sup>484,501,502,503</sup>

Advocates of routine postcoital testing argued that the postcoital test could identify couples who might benefit from a simple treatment and had prognostic value for predicting the probability of pregnancy without treatment.<sup>382,485</sup> Critics reasoned that results achieved even with IUI suggested only a modest benefit at best,<sup>504</sup> that any prognostic value the test might have was limited to young couples with unexplained infertility of short duration because the test surely had no predictive value in women with infertility due to anovulation or tubal occlusive disease, and that male infertility amenable to treatment with IUI could be more accurately defined by the results of semen analysis. The argument for expectant management in couples with unexplained infertility and a normal postcoital test was dismissed as moot, because few couples seeking evaluation and treatment accepted the recommendation.

**The postcoital test for diagnosis of cervical factor is no longer recommended.**<sup>384</sup> Abnormalities of cervical mucus production or sperm/mucus interaction are rarely, if ever, the sole or principal cause of infertility. Chronic cervicitis or cervical stenosis resulting from conization or other treatment for cervical disease that might impair sperm-mucus interaction can be identified by speculum examination, and in the absence of such findings, the likelihood that cervical mucus represents an important obstacle is remote. Semen analysis identifies couples with significant male factor infertility. The test has no standard methodology or interpretation<sup>480,488</sup> and has poor reproducibility even among trained observers.<sup>505</sup> The only randomized trial comparing outcomes in women with normal and abnormal postcoital tests found the test invalid because neither test results nor treatment for abnormal tests affected the outcome.<sup>506,507,508</sup> Office examination after scheduled

intercourse is an inconvenient and unwelcome intrusion for most couples, adding further to their burden of stress. Finally, postcoital test results seldom change clinical management, because contemporary treatments for unexplained infertility include IUI (with ovarian stimulation) or IVF, both of which negate any contributing cervical factor.

# UTERINE FACTOR: ANATOMIC AND FUNCTIONAL ABNORMALITIES

---

Abnormalities of the uterus are a relatively uncommon cause of infertility, but should always be considered. If for no other reason, they may adversely affect the outcome of pregnancies achieved by successful treatment of more common male, ovarian, and tubal factors. The anatomic uterine abnormalities that can adversely affect fertility include congenital malformations, leiomyomas, and intrauterine adhesions; endometrial polyps also have been implicated, but their reproductive implications are less clear. The only functional uterine abnormality of specific interest in the evaluation of infertility is chronic endometritis. Whereas abnormalities of endometrial receptivity (including LPD) might be viewed as another, they can have no practical significance until there is conclusive evidence that infertility can result from intrinsic endometrial dysfunction that impairs or prevents implantation and a method for diagnosis has been validated.

Anatomic and functional uterine abnormalities that can impair fertility also can adversely affect pregnancy outcome. They are discussed here as a cause of infertility and elsewhere ([Chapter 30](#)) as a cause of recurrent pregnancy loss. The embryology or pathogenesis and obstetric consequences of uterine malformations and of leiomyomas are considered at length in [Chapter 3](#). Discussion here is focused on their diagnosis, their impact on fertility, and how they influence evaluation and treatment.

There are three basic methods for evaluation of the uterine cavity: HSG, TVUS or saline sonohysterography, and hysteroscopy. Each has advantages and disadvantages and the choice among them should be tailored to the needs of the individual patient. HSG is the traditional method and most often still the best initial test because it also evaluates tubal patency. However, in women with no risk factors for tubal disease and those whose tubal status is already known (from earlier surgery for other indications) or is largely irrelevant (as in women who require IVF for severe male factor infertility), ultrasonography offers a simpler and better tolerated alternative that also may reveal unsuspected ovarian pathology (cyst, endometrioma), with no radiation exposure. When symptoms suggest an anatomic lesion of the uterine cavity (menorrhagia, intermenstrual spotting), sonohysterography is the most sensitive and logical diagnostic test. Hysteroscopy is definitive but has few diagnostic advantages over sonohysterography and generally can be safely reserved for treatment of abnormalities already identified by less invasive and costly methods.

# Hysterosalpingography

HSG accurately defines the size and shape of the uterine cavity, provides clear images of most uterine developmental anomalies (unicornuate, septate, bicornuate, and didelphys), and, with exceptions, also identifies submucous myomas and intrauterine adhesions that can have important reproductive implications. Although HSG also may reveal endometrial polyps, sonohysterography is a more sensitive method for their detection. A slow injection of contrast medium helps to minimize the risk that a cavity lesion will be obscured and go undetected.

The normal uterine cavity is symmetrical, roughly triangular in shape, widest at the level of the cornual orifices near the fundus, and relatively smooth in its contours. The various developmental uterine anomalies generally have a fairly characteristic appearance on HSG. A unicornuate uterus is typically somewhat tubular, deviates to the left or right, and has one fallopian tube. Both septate and bicornuate uteri typically exhibit a common lower segment that divides into two distinct horns to yield a Y-shaped configuration with varying distance between the upper arms.<sup>509,510</sup> The two anomalies cannot be differentiated by HSG alone; additional evaluation is required to establish an accurate diagnosis (standard or three-dimensional ultrasonography, sonohysterography, magnetic resonance imaging [MRI], or laparoscopy).<sup>511</sup> Either anomaly also can be confused with a unicornuate uterus if only one of the two horns is imaged because they divide near or below the tip of the cannula or catheter inserted into the cervix or uterus. To properly study a uterus didelphys or complete septate uterus, the two hemiuteri must be imaged via their separate cervical openings, often found on opposite sides of the two hemivaginas of varying length. Myomas and larger polyps generally produce curvilinear filling defects of various sizes and shapes. HSG in women with intrauterine adhesions usually reveals grossly irregular cavity contours and filling defects and, in many with severe disease, no cavity at all.

The accuracy of HSG for detecting intrauterine pathology in infertile women varies with the nature of the abnormality. A large study involving over 300 women comparing HSG to hysteroscopy (the gold standard) observed that HSG had an overall 98% sensitivity, 35% specificity, 70% PPV, and 92% NPV, with a 30% false-positive rate and 8% false-negative rate; misdiagnoses are almost entirely related to distinguishing submucous myomas from polyps and were, therefore, relatively unimportant<sup>512</sup>; either requires surgical intervention for correction. In another study of similar design, HSG had 75% sensitivity for detection of intrauterine adhesions and only 50% sensitivity for detection of endometrial polyps.<sup>513</sup>

Specific issues concerning the scheduling and preparation for HSG and details regarding technique and interpretation as they relate to the evaluation of tubal factor

infertility are addressed in the following section (see “Tubal Factor,” below).

# Transvaginal Ultrasonography and Saline Sonohysterography

TVUS is another method for evaluation of uterine factors in infertile women. Saline sonohysterography, involving TVUS during or after introduction of sterile saline through a catheter designed for the purpose, crisply defines cavity contours and readily demonstrates even small, but potentially important, intrauterine lesions.<sup>514</sup>

In all phases of the cycle, the interface between the endometrium and the myometrium is well defined. The interface between the two layers of the endometrium itself (bordering the uterine cavity) can be difficult to identify very early in the cycle and during the secretory phase, but is visible during the latter half of the proliferative phase. Together, the two layers of the endometrium comprise the “endometrial stripe,” which changes in appearance and thickness across the cycle. During the proliferative phase, the endometrium is relatively hypoechoic and grows in thickness to yield a prominent “triple line” or trilaminar pattern. During the secretory phase, the endometrium grows little more, or not at all, and increases in echodensity, possibly because the developing network of coiled basilar vessels presents a great many more reflective surfaces. Cycle-dependent changes in uterine artery blood flow parameters (velocity and pulsatility index) measured using color and pulsed Doppler ultrasonography also have been described,<sup>515,516</sup> but diurnal variations and differences between the two uterine arteries (ipsilateral or contralateral to the dominant ovarian follicle) complicate interpretation. In efforts to define a receptive endometrium, several studies have examined the correlation between endometrial stripe thickness and pattern or uterine artery blood flow parameters with implantation or pregnancy rates in IVF cycles,<sup>517,518,519,520,521,522</sup> but results are conflicting. Whereas some have found correlations between one or more parameters and treatment outcomes, others have not. The few studies examining the endometrium in unstimulated cycles in infertile women have not demonstrated any important correlation between endometrial thickness, pattern, or blood flow and the cause of infertility or prognosis.<sup>523,524,525</sup> **In the diagnostic evaluation of infertile women, transvaginal ultrasonography can identify important uterine pathology but provides no useful measure of endometrial function or receptivity.**

For identification of congenital malformations, standard two-dimensional TVUS complements HSG and improves diagnostic accuracy for differentiating septate and bicornuate uteri by revealing the shape of the fundal contour. The septate uterus presents a single unified fundus that often is somewhat broader than normal and sometimes slightly concave; the bicornuate uterus has two entirely separate fundi divided by a distinct midline cleft of varying depth.<sup>509,511</sup> The accuracy of saline sonohysterography

exceeds that of HSG, by revealing both the double uterine cavity and the shape of the fundal contour. Three-dimensional (3D) ultrasonography has the advantage of obtaining a coronal view and providing accurate and reproducible information about external and internal contours of the uterus, ideally when the endometrium is 5 mm or thicker.<sup>510,511,526,527</sup> Three-dimensional ultrasonography showed 100% specificity and sensitivity for diagnosing congenital uterine anomalies in two studies, and its concordance with specificity and sensitivity of laparoscopy and hysteroscopy was reported to be 100% and 96%, respectively.<sup>528,529</sup> Another study reported 87% sensitivity and 97% specificity for 3D ultrasonography after evaluating 214 women with infertility who underwent laparoscopy and hysteroscopy.<sup>530</sup>

Results of studies evaluating the accuracy of TVUS for detection of submucous myomas and endometrial polyps have varied, but in general, both two-dimensional and 3D TVUS are more sensitive than HSG and approach the accuracy of hysteroscopy.<sup>531,532,533,534</sup> In a study of 3,850 infertile women with 74 histologically diagnosed endometrial polyps, 3D TVUS had sensitivity, specificity, PPV, and NPV of 100%, 99.7%, 98.6%, and 100%, respectively.<sup>535</sup> Other studies yielded similar results for the diagnostic accuracy of 3D ultrasonography, comparable to that of hysteroscopy.<sup>531,536</sup> Three-dimensional ultrasonography can successfully illustrate the endometrial cavity and map the location of the fibroids, even when they are multiple.<sup>535</sup> Yet, it should be kept in mind that MRI may produce more accurate results than 3D ultrasonography (USG) in some extreme cases. Accuracy for diagnosing fibroids dropped from 98% to 89% for 3D ultrasonography and from 100% to 94% for MRI, when five or more fibroids were present.<sup>537</sup> It is noteworthy that whereas the detection of an overall or focal increase in endometrial thickness or asymmetry between the two layers in two-dimensional or 3D TVUS suggests a polyp or myoma, saline sonohysterography reveals a polypoid projection into the fluid-filled cavity.

For diagnosis of intrauterine adhesions, standard TVUS is reasonably specific, but rather insensitive<sup>513,538</sup>; a focally narrowed or discontinuous endometrial stripe suggests the diagnosis. Saline sonohysterography compares with HSG, having relatively high sensitivity (75%) and specificity (over 90%), modest PPV (approximately 50%), and excellent NPV (over 95%) for detection of adhesions.<sup>513,539</sup> Women with mild disease exhibit mobile thin, echogenic bands bridging a normally distensible endometrial cavity. Those with severe disease have more broadly based bands or no cavity at all.<sup>540</sup>

# Hysteroscopy

Hysteroscopy is the gold standard method for both diagnosis and treatment of intrauterine pathology that may adversely affect fertility. Traditionally, hysteroscopy was reserved for treatment of disease identified by other less invasive methods, but modern operative hysteroscopes with an outer diameter measuring 2–3 mm now permit diagnostic and minor operative procedures to be performed safely in the office setting.<sup>541</sup> Major intrauterine pathology generally requires more traditional operative hysteroscopy using instruments having larger caliber and greater capabilities.

# Congenital Uterine Anomalies

**Developmental uterine anomalies have long been associated with pregnancy loss and obstetric complications, but affected women generally are not infertile.** The prevalence of uterine anomalies in infertile women and fertile women with normal reproductive outcomes is similar, approximately 2–4%.<sup>542,543,544,545,546,547</sup> The prevalence is higher among women with poor pregnancy outcomes, such as miscarriage (13%), and in those with a history of infertility and recurrent miscarriage (24.5%).<sup>548</sup> Consequently, when discovered during an infertility evaluation, anomalies cannot be regarded as the likely cause or even as an important contributing cause of infertility, but only as another obstacle that must be considered when planning treatment after evaluation is completed. For example, treatments associated with substantial risk for multifetal gestation (ovarian stimulation/IUI, IVF) present even greater risks to women with uterine malformations.

In a recent systematic review, septate uterus was the most common anomaly among infertile women (3%), followed by arcuate (2%), bicornuate (1.1%), unicornuate (0.5%), and didelphys (0.3%).<sup>547,548</sup> However, arcuate uterus is considered as a variant of the normal without any reproductive or obstetric consequences.<sup>549</sup> The prevalence of only unicornuate and bicornuate uteri was found to be significantly higher in infertile women than in unselected population of women.<sup>548</sup>

Septate uterus is the anomaly most highly associated with reproductive failure and obstetrical complications, including first- and second-trimester miscarriage, preterm delivery, fetal malpresentation, intrauterine growth restriction, and infertility.<sup>511,547,550</sup> The mechanisms responsible are poorly understood, but poor septal blood supply, resulting in poor implantation efficiency and embryo growth, and cervical incompetence are the usual suspects.<sup>551,552,553,554</sup>

Although diagnosis of septate uterus is not an automatic indication for metroplasty, the overall reproductive performance of women with a septum in situ (at least those who are recognized) is rather poor, with term delivery rates of approximately 40%. Most losses occur in the first trimester (approximately 60%). A methodologically robust meta-analysis of 19 studies assessing the effect of septum incision in a mixed population of women with infertility, miscarriage, and/or recurrent pregnancy loss found an overall pregnancy rate of 64% and live birth rate of 50% after septum incision.<sup>555</sup> In the past, surgical correction of a septate uterus required abdominal metroplasty, risking postoperative adhesions that might impair fertility, and committed all future successful pregnancies to cesarean birth. Surgical treatment was reserved for women in whom the benefits of surgery more clearly outweighed the risks, but modern hysteroscopic surgery has changed the equation. Today, hysteroscopic septum resection is a relatively

straightforward and brief outpatient procedure associated with low morbidity, no risk of adnexal adhesions or obligation to cesarean delivery, and a prompt and uneventful recovery; surgical indications now are appropriately more liberal.

Inevitably, systematic infertility evaluations will identify nulligravid women with a uterine septum who present a management dilemma. Given the high probability of successful hysteroscopic surgery and its low morbidity, we believe it is reasonable and appropriate to consider pre-emptive surgical correction of a septate uterus, especially in women over age 35, women with infertility of long duration, women with other indications for surgical treatment, and women who require IVF or other treatments associated with increased risk of multifetal gestation and pregnancy loss.<sup>511,547,549,556</sup> Careful discussion of the relative risks and benefits of surgery is always important, but especially so when the indications for surgery are less clear.

# Uterine Myomas

Myomas can be identified up to 70% of all reproductive-aged women and in 5–10% of infertile women<sup>557,558</sup>; myomas are the only abnormal finding in 1–2% of women with infertility. Although they are an established cause of abnormal bleeding, pain, and symptoms relating to pressure on adjacent organs, the impact of myomas on fertility has been more difficult to define, with the bulk of evidence coming from observational studies comparing the prevalence of myomas in fertile and infertile women or the reproductive performance of women with otherwise unexplained infertility before and after myomectomy.<sup>182,183</sup> Most studies are methodologically limited, such as small heterogeneous populations, with inconsistent definitions of myomas with regard to their size, location, and number, and often failing to report relevant outcome measures.<sup>559</sup> **Infertility relating to myomas has been attributed to all of the following mechanisms<sup>560</sup>:**

- **Displacement of the cervix, decreasing exposure to sperm**
- **Enlargement or deformity of the uterine cavity, interfering with sperm transport**
- **Obstruction of the interstitial segment of the fallopian tubes**
- **Distorted adnexal anatomy, interfering with ovum capture**
- **Distortion of the uterine cavity or increased or abnormal myometrial contractions, inhibiting sperm or embryo transport**
- **Impaired uterine blood flow, chronic endometritis, or decreased endometrial receptivity, interfering with implantation**

Whereas there is relatively little evidence to support the majority of these mechanisms, a number of observations lend credence to the notion that myomas may impair fertility by interfering with implantation. Glandular atrophy is commonly observed in the endometrium overlying myomas, depending on their proximity, and also can be seen in the opposing endometrium, suggesting it results from mechanical pressure.<sup>561,562,563</sup> Molecular studies indicate that submucous and intramural myomas may induce a local decrease in HOX gene expression, which has been implicated in the cascade of molecular events involved in implantation.<sup>564,565</sup>

The effects of myomas on fertility are best assessed by studies comparing IVF outcomes in infertile women with and without myomas, because IVF effectively controls for the confounding effects of other fertility factors. Numerous studies have examined the effects of myomas of varying size and location.<sup>566,567,568,569,570,571,572</sup> Altogether, these observations permit some conclusions regarding the effects of myomas on IVF

outcomes and, by inference, on overall fertility.

There is a clear consensus that submucous myomas have significant adverse effect on clinical pregnancy rates (OR = 0.3, CI = 0.1–0.7) and delivery rates (OR = 0.3, CI = 0.1–0.8).<sup>183,560,573,574,575,576,577</sup> Available data also support the conclusion that submucous myomas increase risk for miscarriage by more than threefold,<sup>576,577</sup> while the effect of intramural myomas that do not distort the cavity on the risk of miscarriage is less clear.<sup>578</sup> Results of early studies examining the effect of intramural myomas on IVF outcomes were inconsistent, with some finding adverse effects,<sup>567,568,569,570,579</sup> and others not.<sup>566,576,580,581,582,583,584</sup> Large-scale prospective studies report significantly lower implantation, pregnancy, ongoing pregnancy, and live birth rates.<sup>569,570</sup> A 2010 systematic review of the effect of intramural myomas without uterine cavity involvement on IVF outcome included 19 observational studies comprising 6,087 IVF cycles.<sup>585</sup> Live birth rate was significantly decreased (RR = 0.79, 95% CI = 0.70–0.88). It is noteworthy that when results from the only two prospective studies reporting live birth rate were pooled, the relative reduction in live birth was 40% (RR = 0.60, 95% CI = 0.41–0.87). Likewise, clinical pregnancy rate was decreased by 21% (RR = 0.79, 95% CI = 0.70–0.88), and implantation rate was decreased by a relative 13% (RR = 0.87, 95% CI = 0.73–1.03).<sup>585</sup> All of the evidence concerning the effects of subserosal myomas is consistent in finding no evidence of adverse effects on IVF outcomes. **In sum, the accumulated body of evidence indicates that submucous myomas reduce IVF success rates by approximately 70% and intramural myomas by approximately 20–40%, and subserosal myomas have no adverse impact on outcomes. Submucous myomas increase risk for miscarriage after successful IVF at least threefold and intramural myomas by more than half.**

Logically, decisions regarding the management of infertile women with myomas should be guided by the evidence concerning their likely importance and the outcomes of surgical intervention. It seems clear that submucous myomas (distorting the uterine cavity) have important adverse effects on fertility and pregnancy outcomes and that myomectomy improves both. A 2009 systematic review of studies examining outcomes after submucous myomectomy concluded that clinical pregnancy rates achieved with IVF were twofold higher after surgery than in women with submucous myomas in situ and comparable to those observed in women without myomas.<sup>577</sup> A randomized trial comparing the effects of myomectomy and expectant management on fertility in 181 women with a combination of submucous, intramural, and subserosal myomas observed that myomectomy significantly improved pregnancy rates among women with submucous myomas (43% vs. 27%) and those with both submucous and intramural myomas (26% vs. 15%), without other interventions.<sup>586</sup> Younger women having a single small submucous myoma and otherwise unexplained infertility have the best prognosis.

Results are less encouraging for older women and those with multiple or large submucous myomas. Although complications of hysteroscopic myomectomy are relatively few, the risk of postoperative intrauterine adhesions increases with the size, number, and extent of intramural extension of submucous myomas.

Evidence for the benefits of myomectomy in women with intramural myomas (not distorting the uterine cavity) is less compelling, probably because their impact on fertility is not as great. A randomized trial observed a clinically significant trend toward improved fertility in women with intramural myomas after myomectomy (56% vs. 41%).<sup>586</sup> A prospective, nonrandomized cohort study involved 318 women with recurrent pregnancy loss or unexplained infertility and compared women undergoing laparoscopic myomectomy, those with conservatively followed myomas, and a control group of unexplained infertility without myomas.<sup>587</sup> Women undergoing laparoscopic myomectomy had higher live birth rates compared to those with in situ myomas (42% [44/106] vs. 11% [12/106], respectively) and those with unexplained infertility without myomas (25% [27/106]). The observations were limited by differences in age between groups, and selection bias is a potential threat to the validity of nonrandomized studies, that is, women who underwent surgery could have different types of myomas than women who did not have surgery.

It is noteworthy that the single existing randomized controlled trial (RCT) found no significant effect of myomectomy on clinical pregnancy rates based on the type of fibroid removed (intramural, odds ratio [OR] 1.88, confidence interval [CI] 0.57–6.14, 45 women; submucosal, OR 2.04, CI 0.62–6.66, 52 women; intramural-subserosal, OR 2.0, CI 0.40–10.09, 31 women; intramural-submucosal, OR 3.24, CI 0.72–14.57, 42 women).<sup>586</sup> Similarly, a cohort study involved 63 infertile women with intramural myomas and 100 age-matched controls without myomas undergoing ART with the same stimulation protocol. Nineteen of the 63 women with myomas underwent myomectomy prior to ART.<sup>588</sup> Clinical pregnancy rates were similar between groups (36% myomectomy vs. 29% in situ intramural myoma vs. 36% controls). Similar results were found in a retrospective cohort study of 58 women undergoing ART with a history of prior myomectomy or myomas in situ.<sup>589</sup>

In contrast to these studies, a trial of 168 women with non-cavity-distorting intramural myomas compared ART outcomes between those who underwent laparoscopy before ART and no surgery prior to ART.<sup>590</sup> Cumulative pregnancy rate (34% [28/84] vs. 15% [13/84]) and live birth rate (25% [21/84] vs. 12% [10/84]) were significantly higher in the laparoscopy group compared with the nonsurgical group.<sup>590</sup> Benefit of myomectomy was observed in the surgical group of women who had at least one fibroid with a diameter greater than 5 cm. However, many of these studies are underpowered, and the inclusion/exclusion criteria of the size and location

of myomas in study subjects are inconsistent. Age differences between groups were not reported or taken into consideration during analyses; fibroid size and number between groups and potential selection bias limit the validity of these findings. Thus, these data do not clearly demonstrate an improvement or deterioration in outcomes after myomectomy compared with no surgery.

**Decisions regarding the management of infertile women with asymptomatic intramural myomas are among the most difficult clinical judgments. They must consider not only the size, number, and location of myomas and the risks and benefits of the procedure but also age, duration of infertility, ovarian reserve, other infertility factors, and the treatments they require.** In most cases, the benefits of myomectomy are modest or uncertain, and the procedure is not without significant potential risks. Myomectomy commonly results in postoperative pelvic and adnexal adhesions, which can decrease fertility if severe,<sup>591,592</sup> but are less concerning in women who require IVF for other reasons. Myomectomy generally commits the patient to cesarean delivery to avoid the risk of uterine rupture during labor, which has been reported after myomectomy.<sup>593,594,595,596</sup> Whereas excision of large, deep intramural myomas that abut or displace the uterine cavity might reasonably be expected to improve fertility, removal of smaller myomas having no direct anatomical relationship with the cavity probably will not. Whereas excision of anterior and fundal myomas is not likely to result in serious adnexal adhesions, posterior uterine incisions invite the complication. Arguably, excision of any intramural myomas large enough or deep enough to warrant myomectomy also likely warrants recommendation for cesarean delivery. Whereas myomectomy offers limited, if any, benefits to young women with infertility of short duration and other infertility factors amenable to nonsurgical treatments, it is less difficult to justify in older women with unexplained infertility of long-duration planning to pursue IVF.<sup>597</sup>

Adherence to basic microsurgical principles—gentle tissue handling, meticulous hemostasis, and minimal exposed suture—helps to ensure best surgical results. Adjuvants such as local injection of aqueous Pitressin, tourniquets to compress the uterine arteries, and surgical adhesion barriers aim at those goals. Laparoscopic and robotic myomectomy, performed by those having the requisite training and experience, may offer the same benefits as traditional open or minilaparotomy myomectomy for infertile women with intramural myomas and have the added advantage of lower morbidity (decreased blood loss and shorter recovery time).<sup>598,599,600,601,602</sup> A multicenter, randomized trial comparing reproductive outcomes after laparoscopic and minilaparotomy myomectomy in women with unexplained infertility observed no differences in cumulative pregnancy, live birth, and miscarriage rates between the two procedures.<sup>599</sup> There are concerns regarding myoma morcellation and the risk of

dissemination of malignant tissue, if the tumor turns out to be a sarcoma. The U.S. Food and Drug Administration has provided guidance that limits the use of power morcellation of uterine tissue. These risks should be reviewed with women who consider laparoscopic myomectomy with morcellation.

**The careful selection of patients most likely to benefit from myomectomy is far more important than the choice of surgical technique. If the procedure has little or no likely benefit, the choice of technique is irrelevant.**

# Intrauterine Adhesions (Asherman Syndrome)

Intrauterine adhesions develop as a result of trauma.<sup>603,604,605,606</sup> Any insult severe enough to remove or destroy the endometrium can cause adhesions. The gravid uterus is particularly susceptible to injury, especially between the second and fourth weeks postpartum.<sup>607</sup> Inflammation or infection also may predispose to adhesions.<sup>608,609,610</sup> In approximately 90% of cases, intrauterine adhesions relate to curettage for pregnancy complications, such as missed or incomplete abortion or retained products of conception.<sup>611</sup> Adhesions also can develop after abdominal or hysteroscopic myomectomy, septum resection, or other uterine surgery. In the developing world, genital tuberculosis is an important cause of intrauterine adhesions; although rare in the United States, the possibility must be considered in women emigrated from regions where the disease is prevalent.<sup>612</sup>

Intrauterine adhesions can be asymptomatic or cause menstrual disorders (hypomenorrhea, amenorrhea, dysmenorrhea), pain, recurrent miscarriage, or infertility.<sup>605,606</sup> The overall incidence of intrauterine adhesions is uncertain, but may be increasing.<sup>611,613</sup> The risk of intrauterine adhesions associated with elective termination of pregnancy is generally low, but the prevalence and severity of adhesions may increase with the number of procedures.<sup>614</sup> A temporal relationship between symptoms and a predisposing event, the inability to pass a uterine sound, or a negative progestin challenge in amenorrheic women suggest the diagnosis. When suspected, HSG and saline sonohysterography confirm the presence of intrauterine adhesions. Compared to hysteroscopy (the gold standard), HSG has approximately 80% sensitivity and specificity for diagnosis of adhesions.<sup>615</sup> A study comparing HSG and sonohysterography with hysteroscopy concluded the two methods of imaging were equally sensitive for detection of adhesions,<sup>513</sup> but hysteroscopy is required to define the location and extent of disease.

Hysteroscopy can reveal a variety of findings.<sup>603,610,616</sup> Central adhesive bands can appear as columns or bridges between the opposing walls of the cavity, dividing it into smaller irregular chambers of varying size and shape. Adhesions at the margins of the cavity often appear as half-drawn curtains that may obscure one or both cornual orifices. Depending on their composition (mucosal, fibromuscular, connective tissue), adhesions may or may not have a surface of the endometrium; dense connective tissue adhesions typically do not. Whereas mucosal adhesions generally appear similar to the surrounding normal tissue and are easy to lyse, fibromuscular and connective tissue adhesions are thicker, are typically pale, and must be mechanically divided or dissected. Numerous classification systems have been proposed, but no system has gained wide acceptance or has prognostic value validated by prospective studies.<sup>605,606</sup>

Consequently, outcome studies are difficult to interpret and compare.

Hysteroscopy is the method of choice for treatment of intrauterine adhesions and is both safer and more effective than blind curettage. Sometimes, the pressure provided by continuous infusion of distension media can lyse mild adhesions, or pushing the tip of the hysteroscope may suffice. When needed, an assortment of mechanical, electrosurgical, and laser-based instruments allows adhesions to be lysed or cut under direct vision. Indirect evidence suggests cold scissors are safer than electrosurgery regarding the risk of further endometrial damage.<sup>617</sup> In the case of severe adhesions, an HSG can serve as a roadmap for planning surgery. When possible, identification of anatomic landmarks as the tubal ostia helps proper dissection. Transabdominal ultrasound-guided office hysteroscopy enable orientation in an endometrial cavity obliterated by severe adhesions. Even though simultaneous laparoscopy is suggested as an aid to guide hysteroscopic adhesiolysis, it has several limitations. First and foremost, laparoscope does not allow the surgeon to understand the location of the hysteroscope in the orthogonal planes until the myometrium is too thinned to allow visualization of the light from the hysteroscope through uterine serosa with the laparoscope. A retrospective study suggests uterine perforation rates are lower with transabdominal ultrasound guidance than with laparoscopic guidance.<sup>618</sup> Increased cost and potential morbidity associated with laparoscopy should also be considered in the absence of another indication for laparoscopy.

Various methods have been used to facilitate hysteroscopic surgery or to improve outcomes. When available, office hysteroscope could be preferred for adhesiolysis since the smaller instruments can allow fine movements and does not require cervical dilation for the majority of women. Vaginal administration of misoprostol (200–400 µg) for cervical softening before operative hysteroscopy can reduce or eliminate the need for mechanical dilation and the incidence of operative complications.<sup>619</sup> However, routine use of vaginal misoprostol before office hysteroscopy can lead to leakage of distention medium through a softened cervix and render the procedure more difficult. Various physical barriers, including both unmedicated intrauterine device (IUDs) and balloon catheters, are commonly used as a means to maintain separation between the opposing layers of the endometrium during the immediate postoperative interval. Despite the absence of data on their effect on fertility, solid barriers reduce the rate of adhesion reformation. Balloon catheters shaped to mimic the uterine cavity are available specifically for this purpose. An IUD with a large surface area, such as the Lippes loop, which does not contain copper or progestin, should be preferred. Semisolid barriers such as hyaluronic acid gel also reduce adhesion formation. The absence of the need for removal and better conforming the contours of endometrial cavity can be regarded as advantages of hyaluronic acid gel over solid barriers; however, there are no comparative studies reporting pregnancy rates following the use

of solid or semisolid barriers.<sup>617</sup> Postoperative treatment with exogenous estrogens to promote rapid re-epithelialization and reduce risks of recurrent adhesions is frequently used, but its efficacy has not been established,<sup>617</sup> a typical regimen involves treatment with 2–6-mg estradiol daily for 4 weeks, adding a progestin (e.g., medroxyprogesterone acetate 10 mg daily) during the last week.

Complications of hysteroscopic adhesiolysis are the same as with any operative hysteroscopic procedure and are relatively uncommon. Acute complications include uterine perforation, fluid overload and electrolyte imbalance, hemorrhage, and infection; late complications include recurrent adhesions and uterine rupture in a subsequent pregnancy.<sup>620</sup>

Surgical results should be evaluated by HSG or saline sonohysterography after menses.<sup>621</sup> A second operation to lyse persistent or recurrent adhesions may be required when disease is severe. Alternatively, pressure lavage with normal saline under guidance of TVUS can be used to hydrodissect recurrent adhesions that are not particularly dense or extensive.<sup>622</sup> Lysis using a balloon catheter under fluoroscopic control and local anesthesia or intravenous sedation also has been described.<sup>623</sup> Normal cyclic menses can be restored in from 70% to 90% of women with intrauterine adhesions, depending on severity.<sup>603</sup> Conception and term delivery rates after successful hysteroscopic lysis of intrauterine adhesions have ranged between 25% and 75%<sup>603,610,624,625,626,627,628,629,630</sup>; predictably, the prognosis is better for women with mild disease.

# Endometrial Polyps

Endometrial polyps are hyperplastic endometrial growths with a vascular center and a sessile or pedunculated shape extending into the uterine cavity. They are generally rare in young women and increase in incidence with age. The true prevalence of polyps among infertile women is unknown and varying figures are reported.<sup>631</sup> While one study reported a prevalence of 15.6% among women with unexplained infertility, the figure ranged between 1.4 and 8% among women undergoing ART.<sup>632,633</sup> A number of molecular mechanisms have been implicated in their pathogenesis, including endometrial hyperplasia,<sup>634</sup> overexpression of endometrial aromatase,<sup>603,635</sup> and gene mutations.<sup>636</sup> Saline sonohysterography is the most useful method of imaging for detection of endometrial polyps,<sup>533,637,638</sup> although false-positive results due to blood clots, mucus, and shearing of normal endometrium are not uncommon.

Careful, systematic evaluation inevitably will identify polypoid cavitory lesions in some infertile women. Differentiation of small submucous myomas and endometrial polyps can be difficult by any means other than hysteroscopy.<sup>512</sup> Whereas symptomatic women (abnormal bleeding) certainly merit hysteroscopic evaluation and treatment, whether surgery has benefits for asymptomatic infertile women with polyps is less clear. The observation that polyps are resistant to the actions of progesterone suggests they might interfere with implantation<sup>639</sup>; local inflammatory changes and distortion of the uterine cavity also have been implicated.<sup>640</sup>

Evidence from studies examining reproductive performance after hysteroscopic polypectomy is rather weak and conflicting.<sup>184,185,640,641</sup> In a study of infertile women with documented but unresected endometrial polyps (<2 cm), IVF outcomes in treated (preliminary hysteroscopic polypectomy) and untreated women were not different.<sup>185</sup> In two studies examining outcomes in women with polyps (<1.5–2 cm) identified by ultrasonography during ovarian stimulation for IVF, pregnancy rates in women who proceeded to oocyte retrieval and embryo transfer or had hysteroscopic polypectomy after retrieval and later frozen embryo transfer were not different from those in women without polyps having fresh or frozen embryo transfers.<sup>632,642</sup> The evidence indicating that polyps adversely affect fertility derives from two randomized controlled trials comparing outcomes after up to four cycles of IUI in infertile women with polyps who underwent preliminary polypectomy or no treatment.<sup>641,643</sup> Two hundred thirty and 120 women were randomized in these trials, and both showed significantly higher pregnancy rates following polypectomy (63.4% vs. 28.2% and 41.7% vs. 20%).<sup>641,643</sup> Overall, hysteroscopic polypectomy results in a greater than twofold increase in clinical pregnancy among subfertile or infertile women who subsequently undergo IUI.<sup>644</sup>

Similarly, a retrospective study reported higher natural conception rates among infertile women who had hysteroscopic polypectomy compared with those who had hysteroscopy with a normal cavity (78% vs. 42.1%).<sup>184</sup> A recent US cost analysis study suggests that pretreatment office or operative hysteroscopic polypectomy is cost-effective when performed prior to both IUI and IVF over a range of plausible pregnancy rates and procedural costs.<sup>645</sup>

**Taken together, the available evidence suggests that polypectomy may improve reproductive performance in infertile women. Treatment must be individualized, depending on the size of a polyp, associated symptoms, and circumstances leading to its discovery.**<sup>646,647</sup>

# Chronic Endometritis

Chronic endometritis has been regarded traditionally as a distinct but uncommon cause of reproductive failure, but its true prevalence in infertile women is unknown.<sup>648</sup> Available evidence suggests that chronic subclinical endometritis is relatively common in women with symptomatic lower genital tract infections, including cervicitis and recurrent bacterial vaginosis.<sup>649,650,651,652</sup> Mucopurulent cervicitis is highly associated with chlamydia (*Chlamydia trachomatis*) and mycoplasma (*Mycoplasma genitalium*) infection, and both organisms, in turn, are associated with chronic endometritis, which likely plays a role in the pathogenesis of tubal factor infertility.<sup>494,652,653,654,655,656</sup> However, the data regarding the true prevalence and importance of chronic endometritis in asymptomatic infertile women are contradictory. While some retrospective studies suggest that up to 57–66% of women with unexplained infertility or unexplained recurrent implantation failure are diagnosed with chronic endometritis, in a prospective study involving 678 asymptomatic women who would undergo their first ART cycle, the prevalence of chronic endometritis diagnosed by hysteroscopic biopsy was 2.8%.<sup>657,658,659</sup> In addition, women with and without chronic endometritis had similar cumulative live birth rates (76% vs. 54%, in women with and without chronic endometritis, respectively), and clinical pregnancy rate per embryo transferred was similar between the groups. Therefore, routine serologic testing for past chlamydia exposure, cervical cultures, and endometrial biopsy may be difficult to justify. However, further evaluation and treatment may be appropriate and prudent in infertile women with clinical cervicitis, chronic or recurrent bacterial vaginosis, or other symptoms that suggest pelvic infection.

# TUBAL FACTOR: TUBAL OCCLUSION AND ADNEXAL ADHESIONS

---

Tubal and peritoneal pathology is among the most common causes of infertility and tubal pathology accounts for 25–35% of female infertility.<sup>660</sup> **A history of pelvic inflammatory disease (PID), septic abortion, ruptured appendix, tubal surgery, or ectopic pregnancy strongly suggests the possibility of tubal damage.** Unquestionably, PID is the major cause of tubal factor infertility and ectopic pregnancies. Classic studies in women with PID diagnosed by laparoscopy revealed that the risk of subsequent tubal infertility increases with the number and severity of pelvic infections; overall, the incidence is approximately 10–12% after one episode, 23–35% after two, and 54–75% after three episodes of acute PID.<sup>661,662,663,664,665</sup> The risk of ectopic pregnancy is increased six- to sevenfold after pelvic infection. Although many women with tubal disease or pelvic adhesions have no known history of previous infection, evidence suggests strongly that “silent” ascending infection is the most likely cause.<sup>652,656</sup> Many such women will have detectable chlamydia antibodies suggesting prior infection (discussed below). Other causes of tubal factor infertility include inflammation related to endometriosis, inflammatory bowel disease, or surgical trauma. Endometriosis is considered at length in [Chapter 32](#); discussion here is focused on intrinsic tubal disease.

The mechanism responsible for tubal factor infertility obviously involves anatomic abnormalities that prevent the union of sperm and ovum. Proximal tubal obstructions prevent sperm from reaching the distal fallopian tube where fertilization normally occurs. Distal tubal occlusions prevent ovum capture from the adjacent ovary. Whereas proximal tubal obstruction is essentially an all-or-none phenomenon, distal tubal occlusive disease exhibits a spectrum ranging from mild (fimbrial agglutination) to moderate (varying degrees of fimbrial phimosis) to severe (complete obstruction). The likelihood or efficiency of ovum capture probably is inversely related to the severity of disease. Inflammatory damage to internal tubal mucosal architecture cannot be detected easily but may nonetheless impair sperm or embryo transport functions.

HSG and laparoscopy are the two classic methods for evaluation of tubal patency in infertile women and are complementary rather than mutually exclusive; each provides information the other does not and each has advantages and disadvantages. HSG images the uterine cavity and reveals the internal architecture of the tubal lumen, neither of which can be evaluated by laparoscopy. Laparoscopy provides detailed information about the pelvic anatomy that HSG cannot, including adhesions, endometriosis, and ovarian pathology. HSG is performed in an outpatient setting, is far less costly than laparoscopy, and may have some therapeutic value<sup>666</sup>; it also is often uncomfortable or

painful, involves some radiation exposure, and has risk of infectious complications that can further impair fertility.<sup>667</sup> Rare cases of shock and pulmonary and cerebral embolus and a case of hyperthyroidism due to iodine absorption have been reported following the use of oil-soluble media.<sup>668,669</sup> Laparoscopy is more invasive, usually requires general anesthesia, provides no information regarding the uterine cavity (unless hysteroscopy is also performed), and involves the usual risks of surgery. Sonohysterosalpingography (sonoHSG) is similar to HSG, using ultrasonography and sterile saline instead of fluoroscopy and contrast media, and is another, but less common, method for evaluating tubal factor. Hysterosalpingo-contrast sonography (HyCoSy) is similar to sonoHSG, but either contrast media or a more recently developed gel comprised of hydroxyethyl cellulose and glycerol is used for demonstrating fallopian tubes. Chlamydia antibody tests represent a fifth, albeit indirect, method for evaluating tubal factor that is relatively inexpensive and minimally invasive.<sup>670,671,672,673</sup> Chlamydia antibody tests have been used primarily for screening infertile women to identify those at high risk for having tubal disease who merit evaluation with laparoscopy.

# Hysterosalpingography

HSG is best scheduled during the 2–5-day interval immediately following the end of menses, to minimize the risk for infection, to avoid interference from intrauterine blood and clot, and to prevent any possibility that the procedure might be performed after conception. Even the most sensitive assays for hCG cannot exclude the possibility of pregnancy when HSG is performed during the early luteal phase of the cycle. HSG does not require any specific preparation, although pretreatment with a NSAID (30–60 minutes before) is helpful to decrease discomfort associated with the procedure; more potent analgesics and sedatives generally are not required. For those who are seeking alternative pain control measures, effectiveness of other oral analgesics is unclear, while improved pain relief with a single rectal dose of 50-mg indomethacin 30 minutes before HSG has been reported.<sup>674,675</sup> Infectious complications from HSG are relatively uncommon, even in high-risk women (1–3%).<sup>667,668,669,676</sup> Even though prophylactic antibiotic treatment is not absolutely necessary for everyone, it can be justified considering the potential consequences of a postprocedure infection. **Treatment with antibiotics (doxycycline 100 mg twice daily for 5 days, beginning 1–2 days before HSG) is prudent when tubal disease is highly suspected, and specifically indicated when HSG reveals distal tubal obstruction, because risk for acute salpingitis is increased (approximately 10%) and treatment can prevent clinical infection.**<sup>667,677</sup> To minimize the risk of infection, HSG is best avoided altogether for at least several weeks following any episode of acute PID.

The technique for performing an HSG is quite standard. The study should be performed using image intensification fluoroscopy with a limited number of radiographs. The average HSG requires only 20–30 seconds of fluoroscopic time with minimal radiation exposure and has very low risk. Usually, only three basic films are required (a scout, one film to document the uterine contours and tubal patency, and a postevaluation film to detect any areas of contrast loculation). Additional oblique films may be needed when the uterus obscures the tubes or the uterine cavity appears abnormal. Otherwise, they provide little or no more useful information and increase radiation exposure unnecessarily.<sup>678</sup> Contrast can be introduced using a common metal “acorn” cannula, a cervical vacuum cup device, or a balloon catheter. In general, the latter techniques require less fluoroscopic time and smaller volumes of contrast, produce less pain, and are easier to perform.<sup>679,680,681</sup> Slow injection of contrast (typically 3–10 mL) helps to minimize the discomfort associated with HSG.

Debate regarding the relative advantages and disadvantages of oil- and water-soluble contrast media has raged for years. Advocates of water-soluble contrast media emphasize that oil-soluble medium is too viscous to reveal internal tubal architecture

(having prognostic significance),<sup>682</sup> disperses poorly in the pelvis (and therefore cannot detect adnexal adhesions), and has significant risks (granulomatous reactions, intravasation, and embolism).<sup>683,684</sup> Those favoring oil-soluble contrast media argue that granulomatous reactions are rare and that intravasation and embolization are uncommon and almost uniformly benign<sup>685</sup> and cite evidence suggesting that oil-soluble media increase fertility in the months immediately following HSG in women with patent tubes.<sup>666</sup> A systematic review including five randomized controlled trials directly comparing pregnancy rates following HSG with oil contrast and those after HSG with water contrast reported similar pregnancy rates (odds ratio, 1.4; 95% CI = 0.8–2.5).<sup>666</sup> However, the original trials were methodologically limited. A more recent, methodologically sound trial randomized 1,119 women to HSG with oil or water contrast.<sup>686</sup> Despite identification of a similar number of women with tubal pathology, live birth rates with a combination of expectant management and IUI were significantly higher following the use of oil-based media (rate ratio, 1.38; 95% CI = 1.17–1.64;  $P < 0.001$ ).

HSG may reveal bilateral tubal patency (60–75%) or unilateral (15–25%) or bilateral (15–25%) tubal occlusion.<sup>687,688</sup> Both false-positive (obstructions that are not real) and false-negative results (patency that is not real) occur, the former being much more common than the latter. Injection of contrast may cause “cornual spasm” (uterine contractions that transiently close the interstitial segment and prevent distal perfusion) that can be misinterpreted as proximal tubal occlusion. HSG may reveal unilateral tubal patency and contralateral proximal occlusion. Although the observation may represent a true unilateral proximal obstruction, which is rare, catheter placement allowing contrast to take the path of least resistance is the more common cause; most often, the nonvisualizing tube is normal. A false-negative HSG may occur when the contrast entering a widely dilated hydrosalpinx is diluted to yield a blush that is misinterpreted as evidence of tubal patency. Peritubular adhesions surrounding an otherwise normal and patent tube can sequester contrast as it escapes from the tube, resulting in a focal loculation that can be misinterpreted as distal obstruction.

Compared to laparoscopy (the gold standard method) as a test of tubal patency, HSG has an overall sensitivity (ability to detect obstruction when the tubes appear obstructed at laparoscopy) of 94% (95% CI = 74–99%) and specificity (confirmation at laparoscopy when obstruction is detected by HSG) of 92% (95% CI = 87–95%).<sup>689</sup> Thus, if HSG shows patent tubes, tubal blockage is highly unlikely.<sup>690</sup> However, after a HSG that showed proximal tubal blockage, 60% of such women had tubal patency with a repeat HSG 1 month later.<sup>691</sup> Subsequent laparoscopy revealed a similar percentage of women having tubal patency following proximal tubal occlusion on HSG.<sup>690</sup> The PPV and NPV of HSG for tubal occlusion are 38% and 94%, respectively.<sup>690,692,693</sup> **The**

**clinical implications are that when HSG reveals obstruction, there is still a relatively high probability (approximately 60%) that the tube is open, but when HSG demonstrates patency, there is little chance the tube is actually occluded (approximately 5%).** However, interpretation of HSG results can vary significantly among different observers.<sup>694,695</sup> Consequently, when the treating clinician has not performed the HSG, a personal review of the films is prudent before making recommendations for additional evaluation or treatment. The probability of treatment-independent pregnancy is highest when HSG reveals bilateral tubal patency, substantially lower when neither tube is open, and reduced only slightly when one tube is patent.<sup>687,688</sup> These observations help in deciding whether laparoscopy is needed before starting treatment.

# Laparoscopy

Laparoscopy is regarded generally as the definitive test for the evaluation of tubal factors. Issues concerning the scheduling, the use of antibiotics, and the risks of infectious complications are the same as for HSG. Diagnostic laparoscopy is usually performed under general anesthesia, but may require only deep sedation and local anesthetic; operative laparoscopy for treatment of disease typically requires general anesthesia. With few exceptions, a systematic and thorough inspection of the pelvis will accurately define the location and extent of any disease. Examination should include the uterus, the anterior and posterior cul-de-sacs, the ovarian surfaces and fossae, and the fallopian tubes. Injection of a dilute blue dye through a cannula attached to the cervix or an intrauterine manipulator permits evaluation of tubal patency (“chromotubation”). Indigo carmine is preferred over methylene blue, which rarely may induce acute methemoglobinemia, particularly in individuals with glucose-6-phosphate dehydrogenase deficiency.<sup>696,697</sup> As with HSG, slow injection of fluid helps to reduce the incidence of false-positive results.

Laparoscopy provides both a panoramic view of the pelvic reproductive anatomy and a magnified view of the uterine, ovarian, tubal, and peritoneal surfaces. Consequently, it can identify milder degrees of distal tubal occlusive disease (fimbrial agglutination, phimosis), pelvic or adnexal adhesions, and endometriosis that adversely affect fertility but escape detection by HSG. Most importantly, laparoscopy offers the opportunity to treat disease at the time of diagnosis. Lysis of filmy or focal adhesions and excision or ablation of superficial endometriosis are relatively simple procedures well within the capabilities of most surgeons. Excision of ovarian endometriomas, lysis of dense or extensive adhesions involving the cul-de-sac or bowel, excision or ablation of widely disseminated or deeply invasive endometriosis, and fimbrioplasty or salpingoneostomy procedures require greater technical skill and experience.

Although laparoscopy is a better predictor of future fertility than HSG, it is not a perfect test for diagnosis of tubal pathology. Intraoperative chromotubation is subject to the same pitfalls causing false-positive results with HSG. False-negative results with laparoscopy are uncommon but do occur, particularly in cases where the fallopian tubes are obscured by adhesions. Whereas tubal obstructions detected by HSG are frequently not confirmed at laparoscopy, patency almost always is. Laparoscopy also is a better predictor of future treatment-independent pregnancy than HSG because the information gained is more accurate. Again, the prognosis is best when both fallopian tubes are patent, poor when both are blocked, and intermediate when only one tube is open.<sup>688,698</sup> Because many obstructions detected by HSG are not real and all but a few of those identified by laparoscopy are, the prognoses associated with unilateral and bilateral tubal occlusion diagnosed by laparoscopy are significantly worse than when the same

diagnosis is made by HSG.

# Sonohysterosalpingography and Hysterosalpingo-Contrast Sonography

Sonohysterography is recognized as having greater sensitivity than HSG for detection of intrauterine pathology. A natural extension of that technique, sonoHSG, has been viewed as a means to evaluate tubal patency at the same time, much like HSG. As originally described, sonohysterosalpingography (sonoHSG) relied on observations of fluid accumulation in the cul-de-sac as an indication of tubal patency. However, the technique provided no information regarding tubal anatomy and could not determine whether one or both tubes were patent. Introduction of a sonographic contrast medium consisting of a surfactant that produces microbubbles when stimulated by ultrasound improved sensitivity for detecting tubal patency, but the standard two-dimensional imaging in the sagittal and transverse planes was still inadequate to visualize the three-dimensional tubal anatomy.

Technologic advances in ultrasonography and introduction of new contrast media further expanded the capabilities of sonoHSG and hysterosalpingo-contrast sonography (HyCoSy). Three-dimensional TVUS provides the means to generate coronal images. Color-coded Doppler techniques have improved visualization of fluid movement through the fallopian tubes. A 2014 meta-analysis showed that pooled estimates of sensitivity and specificity of sonoHSG/HyCoSy in comparison to laparoscopy were 92% (95% CI = 82–96%) and 95% (95% CI = 90–97%), respectively. There was no significant difference between the diagnostic performance of sonoHSG compared to HyCoSy.<sup>689</sup> Additional advantages of sonoHSG/HyCoSy are avoiding the risk of ionizing radiation, higher sensitivity and specificity for the detection of intrauterine pathologies, concomitant visualization of the ovaries and myometrium, and completion of assessment at the office without referral to radiology. Even though more recent studies suggest higher diagnostic performance of HyCoSy using the gel foam as the sonographic contrast as compared with sonoHSG using saline, widespread use is possibly limited with availability of and experience with the required equipment.<sup>699,700,701,702</sup>

# Chlamydia Antibody Tests

A number of studies have suggested that chlamydia antibody tests can be as accurate as HSG or even laparoscopy for detection of tubal pathology, including tubal occlusion, hydrosalpinx, and pelvic adhesions.<sup>670,671,703</sup> The performance of the different tests varies widely with the assay method. Commercial assays differ in detection method (immunofluorescence, microimmunofluorescence, ELISA, immunoperoxidase) and in the source of antigen they use (general or genus-specific major outer membrane proteins, an inactivated organism, whole-cell inclusion). Some methods are highly specific for the chlamydia species of interest (*C. trachomatis*), and others do not distinguish antibodies to *C. trachomatis* from those directed against other chlamydia species (*C. pneumoniae*, *C. psittaci*). As expected, tests having the greatest specificity for *C. trachomatis* perform best for detection of tubal pathology.<sup>671,704,705</sup> Practical considerations suggest that a rapid, highly sensitive but less specific assay is the most suitable test for screening, using a more specific test to confirm the antibody specificity of sera selected by the screening assay.

The predictive value of any diagnostic test depends on the prevalence of the disease of interest in the population tested. If the prevalence of disease in the population is very low or very high, diagnostic testing has little or no value because the outcome rarely affects management, and false-positive (when the prevalence is very high) or false-negative test results (when the prevalence is very low) are common. Diagnostic tests tend to have greatest utility when the prevalence of disease is somewhere in between the extremes.<sup>690</sup> Some have suggested that chlamydia antibody tests might be used to select patients likely to benefit most from laparoscopy, but the predictive value of even some of the more specific chlamydia antibody tests may not be sufficient to justify that approach.<sup>706</sup>

The role for chlamydia antibody tests in the evaluation of infertile women has not been sufficiently defined. Chlamydia antibody tests could prove useful as a pretest to select women who warrant earlier or more detailed evaluation.<sup>707</sup> If applied as a screening tool early in evaluation, a positive test might alert one to the possibility of tubal factors relating to previous chlamydia infection not otherwise suspected. Although selective laparoscopy based on chlamydia antibody tests may be unjustified for all infertile women,<sup>706</sup> it might be effective if limited to women with unexplained infertility (including a normal HSG), identifying those most likely to have undetected tubal factors best addressed before starting aggressive and costly empirical treatments. The utility of chlamydia antibody tests in these or other clinical contexts is uncertain but warrants further investigation. **In summary, chlamydia antibody tests can provide useful information, but also have pitfalls that limit their clinical utility. Currently,**

**diagnostic performance of chlamydia antibody testing is limited, and HSG or other imaging modalities remain the standard for assessment of tubal patency.**<sup>708,709</sup>

# Tubal Surgery in the Era of ART

For women with tubal factor infertility, treatment options are reconstructive surgery and IVF. Over the last 2 decades, IVF success rates have increased steadily (from approximately 10% to over 40%) and now frequently exceed those achieved with surgery.<sup>190</sup> Consequently, IVF has become the treatment of choice for much or most tubal factor infertility, particularly for couples with other infertility factors or severe tubal disease. However, surgery remains an appropriate option in select circumstances and for couples with ethical or religious objections or financial restrictions that preclude IVF. **The decision between surgery and IVF should be based on the following<sup>708</sup>:**

- **The age of woman**
- **Ovarian reserve**
- **Prior fertility status**
- **Number of children desired**
- **Site and extent of tubal damage**
- **Presence or absence of other factors necessitating IVF**
- **Surgeon's experience**
- **Success rate of IVF program**
- **Patient preference, that is, religious belief, cost, and insurance coverage for each option**

Younger women, women with normal/high ovarian reserve, proven fertility, desiring multiple children will comprise more appropriate candidates for surgical repair. A semen analysis of the male partner should precede the decision. It is difficult to directly compare success rates of surgery and IVF, since the former is usually reported per patient, whereas the latter is per cycle. Advantages of surgery are relatively lower cost, especially if multiple children are desired or several IVF cycles are likely to be undertaken to achieve a live birth. In addition to the cost issues, risk of multiple pregnancy, possible complications, and adverse obstetric and perinatal outcomes as compared with spontaneous pregnancies are other disadvantages of IVF.<sup>710</sup> The indications, preliminary evaluation, techniques, risks, and outcomes for IVF and other forms of ART are the focus of a separate chapter ([Chapter 28](#)); discussion here is limited to surgical treatments for tubal factor infertility and the choice between surgery and IVF.

## Sterilization Reversal

Approximately 1 million US women have an elective tubal sterilization procedure each year; up to 30% regret the decision and about 1% later request its reversal.<sup>23,711,712,713</sup>

The most commonly cited reasons for sterilization reversal requests include new relationships, changes in family planning goals, and death of a child. Regrets are more common in younger women, those who were unaware of the spectrum of contraceptive options, women whose decision for sterilization was influenced by a third party (partner, other family member, friend, or physician), and those sterilized postpartum or after an abortion.<sup>711,712,714,715</sup> Women 30 years old or younger are twice as likely as older women to express regret, 3.5–18 times more likely to request information about reversal of the procedure, and approximately 8 times more likely to actually have a sterilization reversal or IVF.<sup>711,712,716</sup> For women who want to conceive again, tubal anastomosis is a legitimate option. A preoperative HSG can be useful to assess the proximal segments and to confirm the type of sterilization performed. Laparoscopy may occasionally be necessary to assess the feasibility of surgical repair when the type of procedure is unknown and when destruction or removal of large segments of tube or other pelvic pathology is suspected; otherwise, fewer than 5% of women will have irreparable tubes.<sup>717</sup>

**The most important prognostic factor for achieving a live birth after microsurgical sterilization reversal is age. The type and location of procedure and the final length of the repaired fallopian tubes are also thought to play a role.** Younger women, those whose sterilization was performed using rings and clips, and women having no other infertility factors have the best prognosis; success rates are lower for older women, those who were sterilized by cautery (particularly multiple-burn techniques), and women with other infertility factors.<sup>718,719,720,721,722,723,724,725</sup> Cumulative pregnancy rates are similar when one or both tubes are repaired, although the time to conception is longer after unilateral anastomosis.<sup>724</sup> **In properly selected candidates, overall conception rates are generally quite good (45–82%) after microsurgical sterilization reversal.** Risk for ectopic pregnancy ranges between 2% and 10% and is higher after isthmic-ampullary than after isthmic-isthmic anastomoses.<sup>708,726,727</sup> Among all surgical treatments for tubal factor infertility, sterilization reversal has the highest postoperative fecundability. **The best candidates for the procedure are young women desiring more than one additional pregnancy and having no other infertility factors.** Laparoscopic tubal anastomosis abiding microsurgical principles by highly skilled surgeons experienced in the technique takes longer operation time but yields comparable pregnancy rates (25–53%).<sup>728,729,730</sup> While the use of robot can facilitate suturing for less experienced surgeons, early studies indicate that operating time is modestly greater, but hospital stay and recovery time are shorter, compared to open microsurgical procedures<sup>731,732</sup>; pregnancy rates are comparable, but risk for ectopic pregnancy may be increased.<sup>732</sup>

## Distal Tubal Obstruction

Distal tubal occlusive disease exhibits a wide spectrum of severity ranging from adherent fimbrial folds to varying degrees of phimosis, to complete obstruction with hydrosalpinges. HSG generally will reveal complete distal tubal obstructions but cannot reliably detect or accurately define lesser degrees of disease when the tubes are still patent. Laparoscopy is the definitive method for diagnosis of distal tubal occlusive disease and also provides the means for treatment. Fimbriolysis refers to the separation of adherent fimbria, fimbrioplasty describes the correction of phimotic but patent fimbria, and neosalpingostomy involves the reopening of a completely obstructed tube. Predictably, surgical success inversely relates to the severity of disease. The extent and character of associated tubo-ovarian adhesions, the tubal thickness, and the condition of the internal ampullary mucosal architecture are all variables that affect prognosis.<sup>733,734</sup> For the milder forms of distal tubal disease, postoperative live birth rates can exceed 50%.<sup>735,736,737</sup> Results achieved with surgery for more severe disease have varied widely, but success rates are lower (10–35%) and risk for ectopic pregnancy is higher (5–20%).<sup>734,738,739,740</sup> Postoperative tubal patency rates far exceed pregnancy rates; patency is more easily restored than function because mucosal regeneration is slow and often fails altogether.<sup>741,742</sup>

The majority of pregnancies occur within the first 2 years after surgical treatment of distal tubal obstruction. In general, the results achieved by experienced surgeons using traditional microsurgical techniques or laparoscopic methods have been similar. In a case series of 35 women with distal tubal occlusion treated by laparoscopic fimbrioplasty followed for at least 2 years after surgery, the global conception rate was 74%, the intrauterine pregnancy rate was 51%, the live birth rate was 37%, and the ectopic pregnancy rate was 23%.<sup>743</sup> **In younger women with mild distal tubal occlusive disease, laparoscopic surgery may be viewed as an alternative to IVF, but when disease is severe or pregnancy does not occur during the first postoperative year, IVF is the logical choice. For older women with any significant degree of distal tubal disease, IVF is generally the first and best option because cycle fecundability after distal tubal surgery is low (1–2%), time is limited, and IVF is both more efficient and more effective.**<sup>744</sup>

As success rates with IVF have improved steadily, the indications for reconstructive surgery in women with distal tubal occlusive disease have further declined. However, women with severe distal tubal disease still benefit from surgery because hydrosalpinges adversely affect IVF outcomes. Pregnancy, implantation, and delivery rates are decreased by approximately 50% and abortion rates are increased in the presence of hydrosalpinges.<sup>745,746</sup> Several mechanisms have been implicated to explain

the observation, including mechanical interference with implantation and toxic effects on the embryo or endometrium.<sup>747,748,749</sup> A 2010 systematic review including five randomized controlled trials involving 646 women observed that the odds of achieving an ongoing pregnancy were twice as great after laparoscopic salpingectomy for hydrosalpinges before IVF (OR = 2.14, CI = 1.23–3.73).<sup>750</sup> Laparoscopic occlusion of the fallopian tubes increased the odds of clinical pregnancy, compared to no intervention (OR = 4.66, CI = 2.47–10.01), and neither surgical procedure was superior.<sup>750</sup> **These data demonstrate clearly that laparoscopic salpingectomy or tubal occlusion improves IVF pregnancy rates in women with hydrosalpinges.** This holds true even when only one tube is affected. Moreover, removal or proximal occlusion of unilateral hydrosalpinx seems to improve chances of spontaneous pregnancy. A retrospective series including 25 women with unilateral hydrosalpinx reported 88% pregnancy rate without IVF with an average time to pregnancy of 5.6 months.<sup>751</sup> Similar observations are reported in other series.<sup>752,753</sup>

One concern with salpingectomy or even tubal occlusion or ligation is its impact on ovarian reserve. Despite contradictory results in early reports, salpingectomy does not impact ovarian reserve, perhaps except when it is done for ectopic pregnancy. Salpingectomy does not significantly decrease serum AMH concentration, ovarian response to stimulation, or clinical pregnancy rates with IVF.<sup>754,755</sup> Ovarian stimulation parameters and implantation and clinical pregnancy rates are similar in women who underwent salpingectomy or laparoscopic proximal tubal occlusion.<sup>756</sup>

Ultrasound-guided aspiration of hydrosalpingeal fluid at the time of oocyte retrieval has been suggested as an alternative treatment.<sup>757</sup> The procedure is effective in improving IVF outcome as compared to no intervention, simpler, and less costly than surgical options. However, salpingectomy and proximal tubal occlusion fare better than fluid aspiration with regard to ongoing pregnancy, clinical pregnancy, ectopic pregnancy, and miscarriage rates.<sup>758</sup> Moreover, the fluid reaccumulates rapidly.<sup>759</sup> Aspiration of hydrosalpingeal fluid can be an option reserved for women who are likely to have severe intra-abdominal adhesions prone to complications with pelvic surgery.

Essure is a 2-mm-thick and 4-cm-long microplug in its expanded form primarily used as a contraceptive device. Essure coil inserts have been used for occlusion of hydrosalpinges prior to IVF. Hysteroscopic placement of Essure coils are relatively easy; however, clinical pregnancy, implantation, and live birth rates following Essure are significantly lower than those achieved with laparoscopic management (salpingectomy or proximal occlusion) of hydrosalpinges.<sup>760</sup> Some evidence suggest that miscarriage rate is higher following Essure blockage of hydrosalpinges, as compared with other interventions.<sup>761</sup> Similar to hydrosalpinx aspiration, currently, Essure can be regarded as a second-line intervention for women under high risk of

intra-abdominal adhesions.

## Proximal Tubal Obstruction

Proximal tubal occlusions represent 10–25% of all tubal obstructions observed with HSG, many of which are not real (20–40%).<sup>660</sup> Mucus plugs, cellular debris, or uterotubal spasm can cause pseudo proximal obstruction. **Efforts to establish a certain diagnosis of true proximal tubal occlusion are justified; otherwise, many women may needlessly undergo major surgery or IVF.** Repeated HSG can decrease the number of false-positive tests of tubal patency; in a case series including 98 infertile women with a diagnosis of proximal tubal occlusion based on an HSG, repeating the procedure revealed bilateral tubal patency in 14 patients (14%), patency of 1 tube in 12 others (12%), and confirmed bilateral occlusion in 72 patients (74%).<sup>762</sup> Another series of 40 women, 18 with unilateral and 22 with bilateral proximal tubal occlusion, reported that 24 (60%) women achieved bilateral and 5 others achieved unilateral patency after a second HSG 1 month later.<sup>691</sup>

The pathogenesis of proximal tubal occlusive disease is not well understood; most is presumed to result from infection or chronic inflammation. Histologic studies suggest that obliterative luminal fibrosis is most common, followed by salpingitis isthmica nodosa (SIN), chronic inflammation, and intratubal endometriosis.<sup>660,763</sup> If proximal occlusion is not due to SIN, tubal cannulation using hysteroscopic or fluoroscopic methods is a proven alternative to traditional microsurgical repair. The specialized catheter systems involved require some training and experience but allow selective tubal perfusion for accurate diagnosis (true occlusion or not) and provide the means for treatment when needed.

A 2017 systematic review and meta-analysis pooled 27 studies involving women with proximal tubal occlusion.<sup>764</sup> Clinical pregnancy rate following tubal catheterization for unilateral or bilateral proximal tubal occlusion was 27% (95% CI = 25–30%). The pooled live birth and ectopic pregnancy rates were 22% (95% CI = 18–26%) and 4% (95% CI 3–5%), respectively. Pregnancy rates were not significantly different between tubal catheterization with hysteroscopic, laparoscopic, or fluoroscopic guidance (31% vs. 26%, respectively).<sup>764</sup> However, reocclusion rate of the opened tubes was approximately 30%,<sup>660</sup> and another study reported similar pregnancy rates following ovarian stimulation and IUI in women with untreated unilateral PTO and in those with unexplained infertility.<sup>765</sup> Yet, selective salpingography with catheterization immediately after HSG shows proximal occlusion can be an appropriate next step since it saves time for both physician and patient.

Microsurgical segmental tubal resection and anastomosis are a proven treatment for

true proximal tubal obstruction. Experienced surgeons can achieve pregnancy rates ranging between 50% and 60%,<sup>660,766,767,768</sup> but the number of surgeons having the necessary expertise is fast declining. Outcomes vary with the cause of the obstruction; reocclusion rates are relatively high with causes other than SIN.

Bipolar tubal disease involves both proximal and distal tubal obstructions. In general, success rates achieved with surgery have been extremely poor and IVF represents the best treatment option.<sup>767,769,770</sup> When cannulation fails, microsurgery may be considered if IVF is not an option.<sup>708</sup>

## **Summary: Tubal Surgery in the Era of ART**

Since only the best surgeons generally publish their results, the available estimates from surgical series also very likely represent the best possible outcomes. Even so, steady advances in ART have improved IVF outcomes to where they now exceed what can be achieved with tubal reconstructive surgery. Accordingly, surgical treatments for tubal factor infertility are generally in an era of decline; laparoscopic surgery has replaced simple open procedures, and ART has replaced more complicated ones. Tubal surgery remains a legitimate treatment option for women seeking pregnancy after a previous tubal sterilization, for those with mild distal tubal disease (particularly when they are young), and for some women with proximal tubal occlusion. Under virtually all other circumstances, IVF is the best choice. Laparoscopic salpingectomy or proximal tubal occlusion increases IVF success rates by twofold and should be recommended to all women with hydrosalpinges planning IVF.

# UNEXPLAINED INFERTILITY

---

Unexplained infertility is a diagnosis of exclusion, after systematic evaluation fails to identify a cause. The incidence of unexplained infertility ranges from 10% to as high as 30% among infertile populations, depending on diagnostic criteria.<sup>771,772,773</sup> **At a minimum, the diagnosis of unexplained infertility implies normal semen analysis, ovulatory function, a normal uterine cavity, and at least unilateral tubal patency.** Ruling out cervical factor by a postcoital test and LPD by endometrial biopsy and performing a diagnostic laparoscopy are no longer required for diagnosis of unexplained infertility.<sup>384</sup> Consequently, much of infertility previously attributed to cervical factors, LPD, and mild endometriosis or adhesions is now classified as “unexplained,” and couples with unexplained infertility comprise a very heterogenous group. As such, management is not aimed at correcting an underlying disorder; rather, the focus is on achieving pregnancy.

Excluding false-negative results of standard diagnostic tests, which do occur but are uncommon, there are two potential explanations for unexplained infertility: (1) there truly is no abnormality and the couple’s natural fertility is at the extreme lower end of the normal range, possibly due to female partner age or advanced reproductive aging, and (2) there is a specific cause, but not one that can be identified with existing diagnostic tests.

Undoubtedly, much of unexplained infertility relates to the natural decline in fertility with increasing age. Unexplained infertility is more common in women over age 35; in a study involving over 7,000 infertile women, those over the age of 35 years were nearly twice as likely to have unexplained infertility (OR = 1.8, CI = 1.4–2.7).<sup>377</sup> Yet, it is important to differentiate age-related infertility and unexplained infertility. Despite the natural decline in fertility with age, diagnostic criteria for infertility do not include age. A mathematical model of human conception according to a woman’s age suggests that the rate of false-positive diagnosis of unexplained infertility, in women who are infertile due to natural age-related decline in fertility, rises from 10% for women trying for a pregnancy before the age of 35–80% for women who start trying to conceive at age 40.<sup>774,775</sup> Older reproductive-age women may benefit from different management strategies for unexplained infertility compared to younger women. For instance, while younger women with unexplained infertility could be more likely benefit from IVF (as they could be expected to have occult ovulation defects, occult endometriosis, subtle disorders of tubal function that cannot be noticed with tests of tubal patency, or a male factor, which wouldn’t show by a standard semen analysis), more often than older women with age-related infertility, who may be less likely to benefit from IVF, since IVF cannot improve oocyte quality, or even substantially increase the number of oocytes

available for fertilization if the ovarian reserve is also decreased with age.<sup>774,775</sup>

**Logically, the most likely occult causes of infertility relate to abnormalities in gametes or implantation, for which there is no valid diagnostic test.** Genetic or functional abnormalities in zona pellucida proteins could interfere with sperm penetration and cause fertilization failure.<sup>776</sup> Abnormalities in the centrosome could interfere with normal spindle formation and function, preventing fertilization or resulting in arrested early embryonic development.<sup>777</sup> Although failed fertilization occurs in less than 5% of IVF cycles and does not always reoccur in subsequent cycles,<sup>778,779</sup> a marked decrease in fertilization efficiency easily could result in unexplained infertility. A higher incidence of fertilization failure has been observed in several, but not all, studies of IVF outcomes in couples with unexplained infertility.<sup>780,781,782,783</sup> Evidence that up to 75% of human pregnancies fail soon after conception implicates early embryopathy and implantation failure as likely causes of unexplained infertility.<sup>38,784,785</sup> Although aneuploidy is common in early human embryos,<sup>786,787</sup> a recurring nonrandom genetic defect in the embryo or trophoctoderm could cause early loss. Intrinsic genetic abnormalities in endometrial function and receptivity could interfere with apposition, adhesion, attachment, or invasion of the embryo, causing implantation failure.<sup>788,789,790</sup> **It is important to emphasize that all of the potential causes of unexplained infertility could coexist with known causes for infertility, helping to explain why many couples with identified ovarian, male, uterine, or tubal infertility factors fail to achieve a successful pregnancy despite receiving proven effective treatments.**<sup>791</sup>

Unexplained infertility likely represents either the lower extreme of the normal distribution of reproductive efficiency or abnormalities of sperm or oocyte function, fertilization, implantation, or embryo development that cannot be detected reliably by standard methods of evaluation. Although many couples with unexplained infertility may be expected to conceive without treatment, their already low and steadily declining cycle fecundity provides ample justification for offering treatment to those concerned enough to seek evaluation. The goal of treatment is to increase monthly fecundability to a level more closely approximating that observed in normally fertile couples.

The prognosis for untreated couples with unexplained infertility is similar to that for couples with minor infertility factors, such as mild oligospermia or endometriosis; age of the female partner and duration of infertility are the primary variables that affect pregnancy rates.<sup>380,792,793</sup> **In studies evaluating treatments for unexplained infertility, untreated patients have a cycle fecundability ranging typically between 2% and 4%,<sup>794</sup> or about 80–90% lower than in normal fertile couples (20–25%). The likelihood of pregnancy without treatment decreases progressively with increasing**

**age of the female partner and increasing duration of infertility.**<sup>380,795</sup> After 3 years of infertility, the likelihood of pregnancy without treatment falls to approximately 40%, and after 5 years to about 20%, of what it was when efforts to conceive first began.<sup>369</sup> Only approximately 14% of couples with unexplained infertility managed expectantly for up to 7 years achieve a pregnancy resulting in a live birth within a year; the prognosis is better when the female partner is under age 30.<sup>380,793</sup> **The effect of duration of infertility is important to understand. Because spontaneous pregnancy rates are highest among couples with a relatively short duration of infertility and success rates achieved with all forms of treatment for unexplained infertility other than IVF are similar, treatments can appear more effective in couples with a longer duration of infertility having a lower probability for conceiving without treatment.**

By definition, the cause of unexplained infertility is unknown. Consequently, all treatments for unexplained infertility are empiric. Although methods differ, the basic strategy is the same for all—to bring together more than the usual numbers of oocytes and sperm in the right place at the right time. To this end, the most common treatments include IUI, ovarian stimulation with clomiphene or gonadotropins and IUI, and IVF.

# Intrauterine Insemination

Although several studies have examined the effectiveness of IUI as treatment for unexplained infertility in natural cycles,<sup>484,502,794,796,797</sup> a 2006 meta-analysis concluded that none provided reliable data because of problems with design, such as crossover trials that do not include data from the first phase of the study or populations not limited to couples with unexplained infertility.<sup>798</sup> The two most informative studies were published more recently and included only couples with unexplained infertility or an abnormal postcoital test, with expectant management as the control treatment.<sup>799,800</sup> In the first trial (average age 32 years, average duration of infertility 2.5 years), 43 live births were observed among 191 couples receiving IUI (23%) over 6 months, compared to 32 in 193 couples (17%) managed expectantly.<sup>799</sup> Although the effect difference (6% over 6 months) was not significant (OR = 1.46, CI = 0.88–2.43), more women randomized to IUI judged their treatment acceptable. In the second trial (average age 30 years, average duration of infertility 1.7 years), 11 ongoing pregnancies were observed among 51 couples receiving IUI (22%), compared to 9 in 48 couples (19%) managed expectantly.<sup>800</sup> **The best available evidence suggests that treatment with IUI in natural cycles has no clinically important effects.**

# Clomiphene Citrate and IUI

Numerous studies have examined the effectiveness of clomiphene therapy without IUI as treatment for unexplained infertility.<sup>801,802,803,804</sup> However, only two are truly informative trials, including only patients with unexplained infertility, using placebo or expectant management as the control treatment.<sup>799,805</sup> In one trial (average age 30 years, average duration of infertility 4.3 years), 10 pregnancies were observed among 76 couples (13%) receiving clomiphene treatment over 290 cycles (3%/cycle), compared to 4 in 72 couples (6%) receiving placebo over 274 cycles (1%/cycle).<sup>805</sup> In the other (average age 32 years, average duration of infertility 2.5 years), 26 pregnancies were observed among 192 couples receiving clomiphene (14%), compared to 32 in 193 couples (17%) managed expectantly.<sup>799</sup> The differences between treatment and control pregnancy rates (per couple or per cycle) were not significant in either trial. **Although clomiphene is commonly used as a treatment for unexplained infertility, the best available evidence indicates it has no significant benefit.**

Combined treatment with clomiphene and IUI is commonly recommended for couples with unexplained infertility, but evidence for its effectiveness has been limited. In a review of 8 studies involving 932 treatment cycles, the estimated cycle fecundity was 5.6% with clomiphene and 8.3% with clomiphene and IUI.<sup>794</sup> The one trial (average age 33 years, average duration of infertility 3.5 years), including an untreated control group (timed intercourse), included patients with unexplained infertility or treated endometriosis.<sup>806</sup> Limiting analysis to cycles observed before crossover, 8 pregnancies were observed in 23 couples (35%) receiving clomiphene and IUI over 73 treatment cycles (11%/cycle), compared to 4 in 28 couples (14%) over 103 cycles (4%/cycle). The 7.1% absolute difference (CI = -1.0-15.2) in cycle fecundability was not significant, and even if it were, the treatment effect was quite modest; the calculated number needed to treat was 15, implying that one additional pregnancy might be expected for every 15 treatment cycles. However, a more recent trial compared cumulative live birth rates between 201 couples with unexplained infertility who were randomized to expectant management or IUI with either clomiphene or letrozole (only 7 women) ovarian stimulation for 3 cycles.<sup>807</sup> Average female age was 34, and average duration of infertility was 4.5 years. Women in the clomiphene/letrozole IUI group had a significantly higher cumulative live birth rate than expectantly managed women (31 [31%] live births among 101 women vs. 9 [9%] live births among 100 women; risk ratio [RR] 3.41, 95% CI = 1.71-6.79). Per-protocol analyses yielded similar results. Based on these figures, the number needed to treat is five; one additional live birth can be expected for every five women undergoing up to three cycles of clomiphene IUI.

Results of three other crossover trials involving control groups receiving an active

treatment (instead of placebo or no treatment) are difficult to interpret confidently, because no data were provided for the first phase of the study.<sup>808,809,810</sup> A fourth management trial (the fast track and standard treatment [FASTT] trial) compared outcomes in two groups, one randomly assigned to receive three cycles of treatment with clomiphene and IUI followed by up to six cycles of IVF and the other assigned to receive three cycles of clomiphene and IUI, followed by three cycles of treatment with gonadotropins and IUI, followed by up to six cycles of IVF.<sup>811</sup> Notably, 55 pregnancies were observed among 233 couples over 646 treatment cycles (8.5%/cycle) in the first group and 68 in 242 couples over 648 treatment cycles (10.5%/cycle) in the second; overall, 123 pregnancies were observed in 475 couples (26%) over 1,294 cycles (9.5%/cycle). Per-cycle pregnancy rates for CC/IUI, FSH/IUI, and IVF were 7.6%, 9.8%, and 30.7%, respectively. The overall pregnancy rate achieved with CC/IUI in the FASTT trial compares favorably with the expected 2–4% cycle fecundability among couples with unexplained infertility, which supports the use of clomiphene and IUI in the treatment of unexplained infertility. In two large retrospective studies involving a total of more than 8,000 cycles of treatment with clomiphene and IUI, cycle fecundability ranged between 5% and 10% per cycle after four to six cycles for women aged 40 years and younger and was under 5% for those over age 40.<sup>812,813</sup>

**In sum, considering the relatively modest cost and complexity (compared to the alternatives, discussed below), treatment with clomiphene and IUI can be justified because the cycle fecundability observed in large prospective and retrospective studies is significantly higher than can be expected in couples with unexplained infertility receiving no treatment.**

# Gonadotropins and IUI

Gonadotropin therapy without IUI for treatment of unexplained infertility has been evaluated in only a few clinical trials. In the largest of these trials, pregnancy rates resulting from treatment with gonadotropins and intracervical insemination were higher than was achieved with insemination alone, but the difference was small (3.6%).<sup>814</sup>

**Although treatment with gonadotropins alone can increase cycle fecundability, compared with no treatment, the effect is quite modest and no better than can be achieved by treatment with clomiphene and IUI.**

More commonly, gonadotropin treatment is combined with IUI for the treatment of unexplained infertility. Among four trials comparing gonadotropins and IUI with no treatment, two were crossover trials providing no results for the first phase of treatment.<sup>815</sup> In a US trial (average age 32 years, average duration of infertility 3.6 years), 77 pregnancies were observed among 231 couples (33%) receiving treatment with gonadotropins and IUI over 618 cycles (12%/cycle), compared to 23 pregnancies in 233 couples (10%) receiving intracervical insemination over 706 cycles (3%/cycle); pregnancy rates per couple were 18% for treatment with insemination alone and 19% for gonadotropins and IUI.<sup>814</sup> A Dutch trial (average age 33 years, average duration of infertility 2 years) observed 29 pregnancies among 127 couples (23%) receiving gonadotropins and IUI over 676 cycles (4%/cycle), compared to 34 in 126 couples (27%) managed expectantly over 737 cycles (5%/cycle).<sup>816</sup>

The differing results of the two trials emphasize again the influence of the duration of infertility on outcomes achieved with treatment for unexplained infertility. In the US trial, involving couples infertile for an average of 3.6 years, fecundability in those receiving treatment with gonadotropins and IUI (12%/cycle) was 9% higher than in couples receiving intracervical insemination (3%/cycle), and only 10% of couples in the latter group conceived. In the Dutch trial, involving couples with an average of 2 years of infertility and a better prognosis for achieving pregnancy without treatment,<sup>793</sup> fecundability of those receiving gonadotropins and IUI (4%/cycle) was no better than in couples managed expectantly (5%/cycle), and 27% of couples receiving no treatment conceived. Together, the results of the two trials indicate that treatment with gonadotropins and IUI has little benefit when the prognosis is reasonably good and modest benefit when the prognosis is poor (1 additional pregnancy for every 11 treatment cycles).

In a recent multicenter US trial, 900 women with unexplained infertility (average age 32.2 years, average duration of infertility 35 months) were randomized to ovarian stimulation and IUI up to 4 cycles with gonadotropin, clomiphene, or letrozole.<sup>817</sup> Clinical pregnancies occurred in 35.5%, 28.3%, and 22.4% of women and live birth in

32.2%, 23.3%, and 18.7%, respectively; pregnancy rates with gonadotropin were significantly higher than the rates with letrozole (absolute difference = -13.1, 95% CI = -20.3 to -6.0,  $p = 0.001$ ), but not with clomiphene alone (-7.2, 95% CI = -14.7-0.2). Per-cycle pregnancy rates were 12.3%, 7.9%, and 6.2% with gonadotropin, clomiphene, and letrozole, respectively. Despite the favorable trend in favor of gonadotropin over clomiphene, the former was associated with significantly higher multiple pregnancy rate, 31.8% versus 9.4% (22.4%, 95% CI = 11.6%-33.2%). Of note, while there were only twin pregnancies in the clomiphene and letrozole groups, 10 out of 34 multiple pregnancies were triplets in the gonadotropin group. This trial clearly shows that letrozole is not the agent of choice for ovarian stimulation IUI cycles for unexplained infertility. Regarding the comparison between gonadotropin and clomiphene, a Belgian trial randomized 330 couples (average female age 32 years, average duration of fertility 25.5 months) with unexplained infertility to ovarian stimulation IUI with low-dose gonadotropin or clomiphene at cycle level.<sup>818</sup> Gonadotropin starting dosage was 37.5-75 IU/day. Both clinical pregnancy (14.4% vs. 9%) and live birth rates (13.8% vs. 8.7%) were significantly higher in gonadotropin-stimulated cycles. Multiple live birth rates were similar between the groups (6.5% vs. 3.6%), while cycle cancellation rate was higher in the clomiphene group.<sup>818</sup>

The results of treatment with gonadotropins and IUI for unexplained infertility raise two clinically relevant questions. The first concerns what benefits treatment with gonadotropins and IUI might have in couples first treated with clomiphene and IUI and failing to conceive. The only data addressing the question directly come from the "FASTT" trial described above, in which 50 pregnancies were observed among 169 couples (30%) receiving treatment with gonadotropins and IUI over 439 cycles (11%/cycle) after failing to conceive over 3 cycles of treatment with clomiphene and IUI.<sup>811</sup> Although cycle fecundability (11%/cycle) was slightly higher than was achieved with clomiphene and IUI in the same population (9.5%/cycle), the difference is not clinically important, especially when considering the greater costs, complexity, and risks associated with the use of gonadotropins.

The second question relates to whether success with clomiphene and IUI depends on multifollicular development, and there are no reliable data that address the question directly.

A number of studies have examined the efficacy of various adjuvant treatments in couples receiving treatment with gonadotropin and IUI for unexplained infertility. The available evidence indicates that whereas pretreatment with a GnRH agonist does not improve outcomes,<sup>819</sup> based on a systematic review and meta-analysis, adding a GnRH antagonist to the treatment regimen might (OR = 1.4, CI = 1.1-1.8).<sup>820</sup> However, the original trials included heterogeneous populations with varying methodologic quality.

The results were heterogenous as well. Thus, routine use of GnRH antagonists in gonadotropin IUI cycles is not justified.

**In summary, treatment with gonadotropins and IUI is modestly effective treatment for couples with longer durations of unexplained infertility (>3 years) and should be considered for couples who fail to conceive during treatment with clomiphene and IUI and when clomiphene treatment fails to stimulate multiple follicular development, especially when IVF is not a viable option. Based on the results of the two large randomized trials mentioned above, gonadotropins and IUI could also be utilized as the first alternative; however, the concerns regarding multiple pregnancy often preclude this approach.**

# Assisted Reproductive Technology

Observations in ART cycles frequently provide insight into the possible causes of a couple's unexplained infertility because the procedures involved address or eliminate many of the unknown variables. Sperm and oocytes will be combined effectively. Fertilization and early embryonic development can be observed directly, and embryo transfer ensures that embryos will reach the endometrial cavity. Although the chromosomal composition of embryos and endometrial receptivity may seem like the only factors remaining, the list of unknowns is, in truth, much longer.

Few trials have compared ART with no treatment or a different treatment such as gonadotropins and IUI,<sup>821,822,823,824,825</sup> and only some has been limited to couples with unexplained infertility. In the 2015 US national summary of ART outcomes, the overall live birth rate per-cycle start for couples with unexplained infertility (all ages) was 29%.<sup>33</sup> When compared on a per-cycle basis, IVF is clearly superior to ovarian stimulation with IUI. However, other factors in addition to effectiveness are considered in decision-making. Given the more invasive nature, higher cost, and per-cycle success rate of IVF, trials have compared IVF with three to six cycles of ovarian stimulation cycles.<sup>823,824,825</sup> Three randomized controlled trials, all including women with an average age of 32–34 years and average duration of infertility about 2.5 years, compared IVF with ovarian stimulation IUI. The first multicenter Dutch trial randomized 116 couples to 1 cycle of IVF elective single embryo transfer or 3 cycles of ovarian stimulation IUI and reported similar ongoing pregnancy rates (24% vs. 21%).<sup>823</sup> Another multicenter Dutch trial randomized 602 women to 3 cycles of IVF with elective single embryo transfer, 6 cycles of natural cycle IVF, or 6 cycles of ovarian stimulation IUI and reported similar cumulative live birth rates of 52%, 43%, and 47%.<sup>824</sup> The most recent British trial randomized 207 women to 1 cycle of IVF or 3 cycles of ovarian stimulation IUI and reported similar cumulative live birth rates of 33.9% and 28.7%, respectively.<sup>825</sup> It is unclear which couples can benefit from IVF rather than ovarian stimulation IUI.<sup>826</sup>

**In summary, IVF is clearly the most effective treatment for couples with unexplained infertility, regardless whether it is the first or the last treatment.**

## **Summary: Treatment of unexplained infertility**

Overall, the effects of treatments for unexplained infertility other than IVF are relatively small. In many cases, treatment may only hasten pregnancy for couples who would ultimately conceive on their own, given time. IVF is the most effective treatment for unexplained infertility. Careful counseling is essential and must take into account the couple's age, the duration of infertility, and the outcome of any previous pregnancies; before treatment is recommended, an ovarian reserve test also is prudent.<sup>138</sup> Couples who choose treatment should be informed thoroughly about the relative costs, risks, prognoses, and logistical challenges associated with different treatments so that they may select the one that best meets their needs and preferences. Partners can have differing levels of concern about their infertility and tolerance for risk and uncertainty.<sup>827</sup> Together, the medical evidence and shared decision-making determine the choice of management.<sup>828</sup>

# ADOPTION

---

With proper evaluation and treatment, the majority of couples evaluated for infertility will achieve pregnancy. For those who fail treatments, ART with donor eggs and/or a gestational surrogate and adoption are realistic options. Couples considering adoption have a wide range of choices including social agency adoptions, private adoptions, and international adoptions. In some states, private adoption is not legal, but where it is, private adoption can be an effective, more rapid alternative to adoption through a social agency. In most cases, the biologic mother has the opportunity to know the adopting parents and may reconsider her decision and reclaim her child for a time before the adoption is finalized. Those who prefer anonymity or who wish to avoid such potentially devastating disappointments likely will make a different choice. Couples interested in adoption should be referred to those knowledgeable about adoption laws in individual states and all of the available options.
