# Male Infertility

Our understanding of male reproductive function and the importance of male factors in infertility has advanced significantly over the last two decades. In the past, the female partner was the primary focus of attention and male factors were regarded as a relatively uncommon cause of infertility. We now recognize that abnormalities in the male are the sole cause of infertility in approximately 20% of infertile couples and are an important contributing factor in another 20–40% of couples with reproductive failure.<sup>1</sup>

Correct diagnosis and specific treatment can help many infertile men to achieve a natural conception with their partners. In others, mild but important semen abnormalities can be overcome by treatments such as intrauterine insemination (IUI). When all else is futile or fails, modern assisted reproductive technologies (ART) still may provide the means to achieve success. In vitro fertilization (IVF) by intracytoplasmic sperm injection (ICSI), involving the injection of a single sperm directly into a mature oocyte, offers men previously considered hopelessly infertile a realistic chance to father children. Artificial insemination using donor sperms, once the only option available for many couples with male factor infertility, remains an important and highly effective treatment strategy but now may be regarded as the treatment of last resort.

Physicians who care for infertile couples must know how to conduct a basic evaluation of male reproductive function and how to recognize men who require more extensive or sophisticated evaluation and treatment beyond the scope of their own expertise. This chapter will consider the regulation of testicular function, describe the causes of male infertility, discuss the analysis of semen and other methods for evaluation of infertile men, and review current concepts regarding the treatment of male factor infertility.

# REGULATION OF TESTICULAR FUNCTION

---

The testes have two distinct components, the seminiferous tubules (the site of spermatogenesis) and the Leydig cells (the source of testosterone). The seminiferous tubules are composed of germ cells, called spermatogonia, and Sertoli cells, which produce inhibin. Tight junctions between the Sertoli cells form a diffusion barrier known as the blood-testis barrier (similar to the blood-brain barrier), which protects the germ cells from antigens, antibodies, and environmental toxins.<sup>2</sup> The seminiferous tubules are therefore essentially avascular, so regulatory molecules must enter by diffusion. The Leydig cells are located in the connective tissue between the seminiferous tubules.

# Spermatogenesis

After migration of the germ cells to the genital ridge during embryogenesis, there are approximately 300,000 spermatogonia in each gonad. Each undergoes a series of mitotic divisions, and by puberty, there are about 600 million in each testis. Continued proliferation during adult life supports the production of approximately 100–200 million sperms each day and more than 1 trillion during a normal reproductive lifespan.<sup>3</sup> A spermatogonia-specific transcription factor identified in mice, Plzf, is required for maintenance of the spermatogonial stem cell pool.<sup>4,5</sup>

As spermatogenesis begins, the diploid (46 chromosomes) spermatogonia grow to become primary spermatocytes before entering meiosis. The first meiotic division yields 2 haploid (23 chromosomes, each made up of 2 chromatids joined at the centromere) secondary spermatocytes, each of which gives rise to 2 spermatids (23 chromosomes, each consisting of a single chromatid) during the second meiotic division. Thereafter, each spermatid gradually matures to become a mature spermatozoon. Approximately 3 million spermatogonia begin development each day, but about half of all potential sperm production is lost during meiosis (**Figure 26.1**).<sup>6</sup>

**FIGURE 26.1**

As spermatids develop into mature sperms, the nucleus moves to an eccentric position at the head of the spermatid and becomes covered by an acrosomal cap.<sup>7</sup> The core of the sperm tail consists of nine outer fibers around two inner fibers, surrounded in the middle section by mitochondria. The tail fibers are attached to each other by arms

containing the protein dynein, which is an ATPase. Hydrolysis of ATP (adenosine triphosphate) in the adjacent mitochondria provides the energy for sperm motility, which is accomplished by a sliding action between the fibers in the sperm tail.

**The spermatogenic process is directed by genes located on the Y chromosome<sup>8</sup> and takes approximately 70 days to complete from the spermatocyte stage.<sup>9</sup> Another 12–21 days are required for the transport of sperms from the testis through the epididymis to the ejaculatory duct.<sup>10</sup> During passage through the epididymis, sperms mature further to develop the capacity for sustained motility.<sup>11</sup> The long time required for sperm development and transit implies that the results of a semen analysis reflect conditions existing many weeks earlier.** Final maturation, or capacitation, of sperms may occur after ejaculation into the female genital tract. Normal spermatogenesis requires the lower temperature of the scrotum, but slight increases in scrotal temperature, such as those associated with the wearing of athletic supporters, do not appear to have any measureable adverse effect.<sup>12</sup> Semen includes secretions contributed by the prostate, the seminal vesicles, and the distal vasa deferentia.

# Hormone Regulation

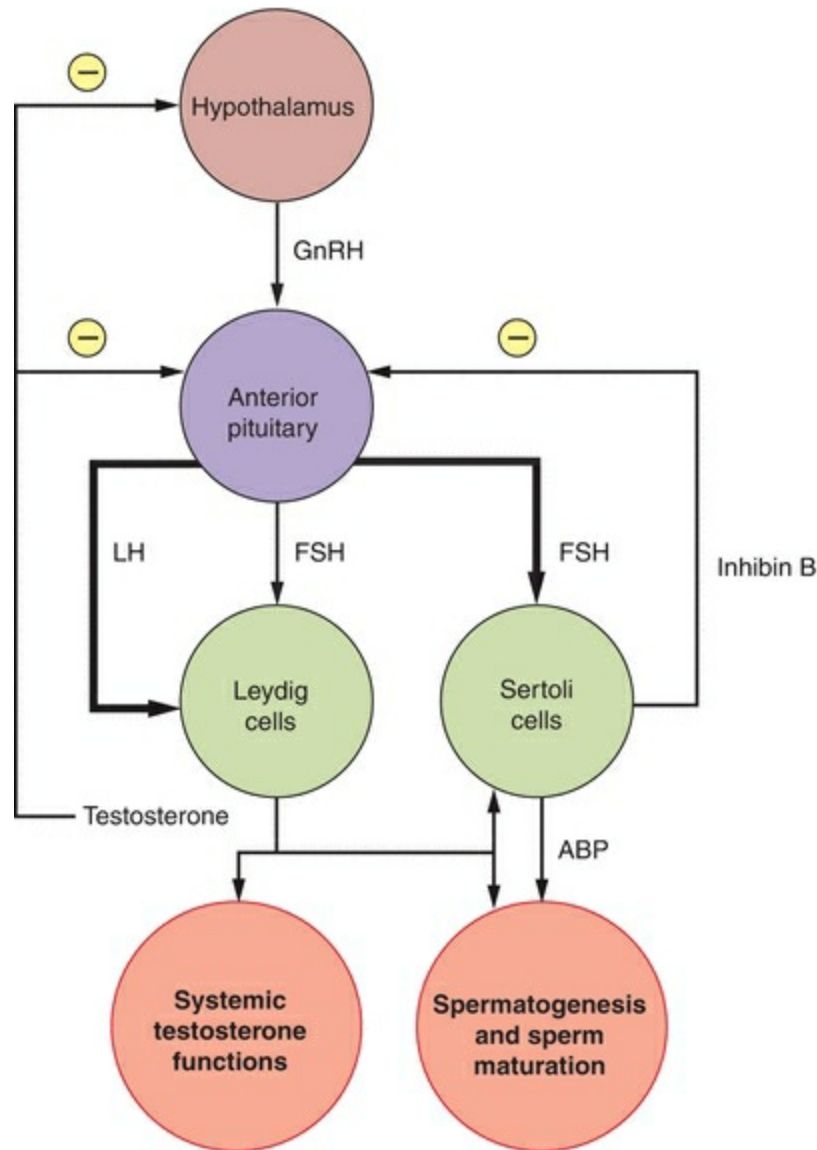

Normal testicular function requires the actions of both pituitary gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). LH stimulates the Leydig cells in the testicular interstitium to synthesize and secrete testosterone (approximately 5–10 mg/day). The actions of LH are supported indirectly by FSH, which induces the appearance of LH receptors on testicular Leydig cells<sup>13</sup> and stimulates synthesis of androgen-binding protein (ABP) in Sertoli cells.<sup>14</sup> Testosterone is secreted both into the circulation and into the lumen of the seminiferous tubules where it is highly concentrated to the levels needed to support spermatogenesis in the germinal epithelium and sperm maturation in the epididymis; concentrations within the testes are 50–100 times higher than in blood.<sup>15,16</sup> The actions of testosterone in support of spermatogenesis are mediated by the Sertoli cells, which line the seminiferous tubules and contain androgen receptors.<sup>16</sup>

Rising serum testosterone levels exert feedback inhibition on LH secretion, acting both at the hypothalamic level to slow the pulsatile release of hypothalamic gonadotropin-releasing hormone (GnRH),<sup>17,18</sup> probably via a mechanism involving endogenous opiates,<sup>19</sup> and at the pituitary level to decrease pituitary gonadotrope sensitivity to GnRH stimulation.<sup>20</sup> Numerous studies involving infusions of testosterone, estradiol, or dihydrotestosterone (which cannot be converted to estrogen) or the administration of estrogen antagonists in normal subjects,<sup>21,22</sup> in individuals with androgen insensitivity,<sup>23</sup> and in men with idiopathic hypogonadotropic hypogonadism<sup>24</sup> have established that testosterone exerts its negative feedback effects on LH secretion both directly and indirectly via conversion to estradiol in the brain. Evidence that estradiol is involved in LH feedback control derives from the observation that LH levels are elevated in men with aromatase deficiency<sup>25</sup> and after treatment with aromatase inhibitors.<sup>26</sup>

In contrast to its effects on LH secretion, physiologic levels of testosterone do not suppress FSH secretion. Rather, the regulation of pituitary FSH (but not LH) secretion is controlled by inhibin. FSH levels rise progressively after orchiectomy, the observation that led ultimately to the discovery of inhibin. Inhibin B is synthesized and secreted by Sertoli cells in response to FSH stimulation and specifically inhibits GnRH-stimulated pituitary FSH secretion.<sup>27,28,29</sup> In the castrated male monkey, treatment with recombinant human inhibin can restore normal FSH levels in the absence of testosterone.<sup>30</sup> Sertoli cell inhibin B secretion is modulated indirectly by LH via testosterone, which inhibits Sertoli cell inhibin B gene expression.<sup>31</sup> Inhibin A is not produced in any significant amount in men. Evidence from studies in vitro suggests that other autocrine/paracrine

regulatory mechanisms involving locally produced growth factors, neuropeptides, vasoactive peptides, and immune-derived cytokines also are involved, much like the complex interactions that operate in the ovarian follicle.<sup>32,33,34,35,36</sup> The Sertoli cells of the testis are analogous to the granulosa cells of the ovary, and the Leydig cells are comparable to the theca cells.

The extent to which FSH and LH are needed to initiate and maintain spermatogenesis has been difficult to define because observations in various natural and experimentally induced conditions have yielded conflicting evidence. The presence of sperms in the ejaculate of a man with an inactivating mutation in the LH  $\beta$ -subunit gene and in other men with isolated LH deficiency suggests that FSH alone can initiate spermatogenesis,<sup>37</sup> although the possibility of some residual LH activity or FSH-stimulated Leydig cell testosterone production via Sertoli cell factors cannot be excluded.<sup>38</sup> Conversely, low-level sperm production in men with inactivating mutations of the FSH receptor<sup>39</sup> and other forms of isolated FSH deficiency<sup>40,41</sup> suggest that LH-driven testosterone production alone can initiate spermatogenesis, although the possibility of residual FSH activity in the presence of high circulating FSH concentrations must be acknowledged. Evidence that high doses of exogenous testosterone can stimulate complete spermatogenesis in immature monkeys, albeit at low levels, further suggests that FSH is not an absolute requirement,<sup>42</sup> but descriptions of azoospermic men with mutations in the FSH  $\beta$ -subunit gene suggest the opposite.<sup>43,44</sup> In men with hypogonadotropic hypogonadism of prepubertal onset, normal spermatogenesis can be stimulated by combined treatment with human chorionic gonadotropins (hCG, having potent LH-like actions) and human menopausal gonadotropin (containing FSH), but not by treatment with hCG alone<sup>45</sup> (**Figure 26.2**).

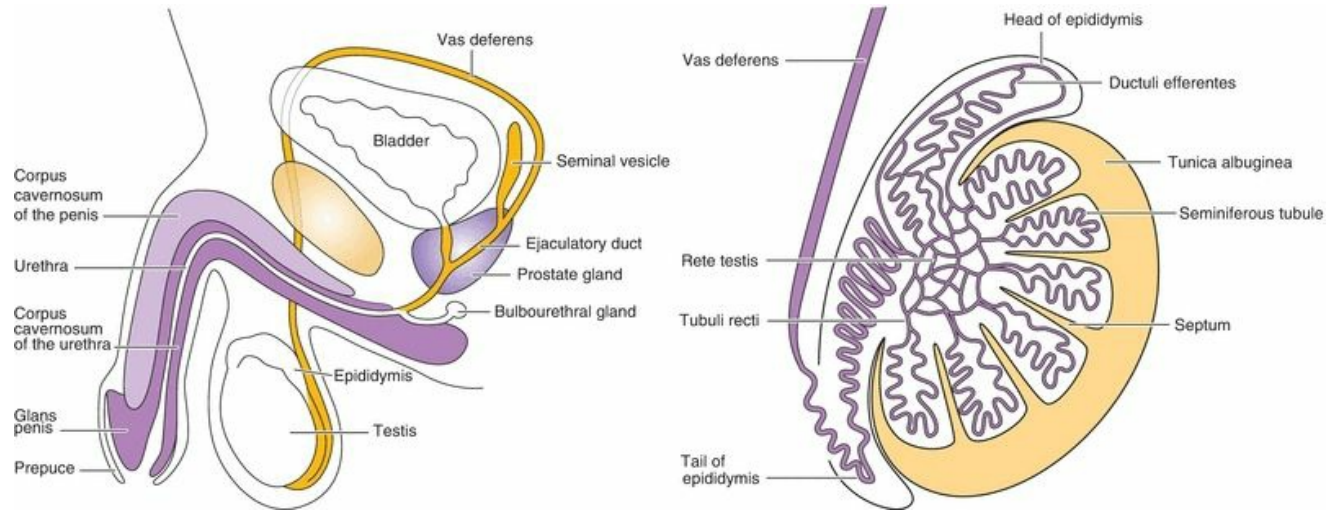

**FIGURE 26.2**

The requirements for the maintenance of spermatogenesis are similarly controversial. The observation in monkeys that exogenous FSH can maintain testicular volume and the numbers of spermatogonia after complete suppression of gonadotropin secretion by treatment with a GnRH antagonist suggests that FSH alone can maintain spermatogenesis in primates, at least to some degree.<sup>46,47</sup> The description of a unique individual with an activating mutation of the FSH receptor (function in the absence of FSH stimulation) and normal inhibin B levels (a marker for FSH-stimulated Sertoli cell function)<sup>48</sup> who had undergone hypophysectomy for removal of a benign pituitary tumor (eliminating all endogenous gonadotropin secretion) and remained fertile while receiving only physiologic exogenous testosterone replacement therapy (normally inadequate to support spermatogenesis in hypophysectomized men) serves to further illustrate the

importance of FSH in maintaining spermatogenesis.<sup>49</sup> In contrast, the restoration of fertility after treatment with only exogenous hCG in azoospermic men with isolated gonadotropin deficiency (low levels of both FSH and LH) suggests that although LH-stimulated testosterone production may be insufficient to initiate spermatogenesis, it is sufficient to maintain spermatogenesis.<sup>50</sup> In men who develop hypogonadotropic hypogonadism after puberty, during adulthood (e.g., due to a pituitary tumor), spermatogenesis stops but usually can be restored by treatment with hCG alone.<sup>45</sup>

**Regardless whether FSH- or LH-stimulated testosterone alone is sufficient to initiate or to maintain spermatogenesis, both clearly are required for qualitatively and quantitatively normal sperm production.** The importance of FSH has been demonstrated in a variety of experiments in nonhuman primates and men involving the selective suppression of FSH by immunization against FSH or by high-dose chronic exogenous hCG treatment. FSH suppression induces both qualitative and quantitative abnormalities of semen quality that can be reversed by simultaneous treatment with exogenous FSH but not with testosterone.<sup>51,52,53,54,55</sup> Moreover, in male contraceptive trials involving treatment with high doses of testosterone, alone or in combination with levonorgestrel to suppress spermatogenesis, azoospermia developed only in men whose serum FSH concentration was suppressed to undetectable levels.<sup>56,57</sup> The importance of testosterone in spermatogenesis is evident from observations that FSH alone can induce proliferation of the seminiferous epithelium in prepubertal monkeys, but only treatment with both FSH and hCG increases testicular volume and the numbers of Sertoli cells and spermatogonia.<sup>58,59</sup> Also, in men with idiopathic hypogonadotropic hypogonadism (due to absent GnRH stimulation), exogenous pulsatile GnRH stimulation or a combination of exogenous FSH and LH or hCG can induce spermatogenesis and achieve fertility,<sup>60,61,62</sup> but treatment with FSH, alone or in combination with low doses of testosterone (insufficient to achieve the high local concentrations of testosterone required to support spermatogenesis) (**Figure 26.3**).<sup>63</sup>

**FIGURE 26.3**

# AGING AND MALE REPRODUCTIVE FUNCTION

---

Although aging has adverse effects on male reproductive function, the impact of age is less obvious than it is in women. Semen quality and male fertility, as well as androgen production and serum testosterone levels, decrease very gradually as age increases.

# Aging and Male Fertility

The relationship between age and fertility in men is more difficult to define than in women, largely due to the fundamental difference in gametogenesis between the two sexes. In women, the number of oocytes present at birth inexorably declines as age advances until it is functionally exhausted at menopause, and fertility declines with the number of oocytes remaining (Chapter 25). In men, mitotic divisions in the spermatogonia throughout life replenish the supply of germ cells, and spermatogenesis continues well into advanced ages, allowing men to reproduce even during senescence. Although fertility in men does appear to decline as age increases, the effects of age are much less distinct. The issue may be growing in importance because an increasing number of men are choosing to father children at older ages. In the United States, birth rates for men between the ages of 35 and 54 increased by nearly 30% between 1980 (68.2 per 1,000 men) and 2000 (88.3 per 1,000 men).<sup>64,65</sup>

**Semen volume, sperm motility, and the proportion of morphologically normal sperm, but not sperm concentration, appear to decrease gradually as age increases.**<sup>66,67</sup> However, semen characteristics generally do not accurately predict fertilizing capacity<sup>68,69,70,71</sup>; neither do endocrine parameters.<sup>72,73</sup> A study in a convenience cohort of nearly 100 men aged 22–80 with no known fertility factors observed decreases in semen volume (−0.03 mL/year), total motility (−0.7% per year), progressive motility (−3.1% per year), and total (progressively) motile sperm count (−4.7% per year).<sup>67</sup> Another study that examined the relationship between age and semen quality among over 400 male partners of women pursuing pregnancy via IVF using donor oocytes found that total motile sperm count decreased by approximately 2.5 million sperms per year.<sup>74</sup>

**On balance, the available evidence indicates that pregnancy rates decrease and time to conception increases as male age increases.**<sup>66,75</sup> In studies of the effect of male partner age on pregnancy rates, female partner age and declining coital frequency with increasing age are obvious and important confounding factors.<sup>76</sup> A study of the risk of infertility associated with paternal age, involving over 6,000 randomly selected European women aged 25–44, observed that the risk of infertility was increased two- to threefold among women aged 35–39 when the male partner was 40 years or older.<sup>77</sup> Others have observed that pregnancy rates for men over 50 are 23–38% lower than for men under age 30<sup>66</sup> and that the probability of achieving pregnancy within a year is approximately 50% lower for men over age 35 than for those under age 25.<sup>78</sup> Results of a British study (adjusted for partner age and coital frequency) indicate that time to conception is fivefold longer for men over age 45 than for men under age 25, even when analysis is restricted to men with young partners.<sup>75</sup> Two other studies have suggested

that male fertility may start to decline before age 40.<sup>79,80</sup>

A study examining the effect of paternal age on pregnancy and live birth rates in couples undergoing ART found that pregnancy rates declined with each additional year of age of the male partner.<sup>81</sup> Another study of IVF outcomes involving almost 2,000 women with tubal factor infertility (absent or obstructed fallopian tubes) determined that advanced paternal age (40 years and greater) increased the risk for treatment failure approximately twofold for women aged 35–40 years and more than fivefold for women aged 41 and older.<sup>82</sup> Within the context of assisted reproduction, the effect of paternal age is perhaps best assessed in couples using oocyte donation, which makes male age the dependent variable (because almost all oocyte donors are aged 18–35). However, data from such studies are conflicting, with some indicating that male age has limited or no impact on pregnancy, implantation, and live birth rates<sup>74,83,84</sup> and others finding that paternal age is inversely related to reproductive outcomes,<sup>85,86</sup> including a decrease in live birth rates and an increase in miscarriage rates.

There are several possible biologic mechanisms that might contribute to an age-related decline in male fertility. One involves cellular or physiologic changes in the male reproductive tract. The testes and prostate exhibit morphologic changes with aging that might adversely affect both sperm production and the biochemical properties of semen.<sup>87</sup> Autopsy studies of men who died from accidental causes have observed narrowing and sclerosis of the seminiferous tubules, decreased spermatogenic activity, and reduced numbers of germ cells and Leydig cells as age increases.<sup>88,89</sup> Another possible mechanism is age-related changes in the hypothalamic-pituitary-testicular axis. Average FSH levels in men increase after age 30,<sup>90</sup> suggesting that the endocrine environment may begin to change during midlife.<sup>91</sup> Decreased semen volume may relate to reduced androgen-stimulated fluid production in the prostate and seminal vesicles because testosterone levels decrease with advancing age.<sup>92</sup> Whatever the mechanism(s), decreasing fertility with increasing male age in healthy couples suggests that normal sperm overproduction may not fully buffer the effects of increasing age. **However, because there is little or no overall measurable decline in male fertility before age 45–50, the available data suggest that male factors likely contribute relatively little to the overall age-related decline in fertility in women.**

## Paternal Age and Pregnancy Outcomes

Because male germ cells pass through more mitotic replications than those of females, there is greater opportunity for error. Older men also are more likely than younger men to have smoked (and for longer periods of time) and to have been exposed to gonadotoxins that may cause DNA damage.<sup>66,67</sup> **Increased paternal age has been**

associated with an increase in numerical and structural chromosomal abnormalities,<sup>93,94,95,96,97</sup> with increased DNA fragmentation,<sup>98</sup> and with a higher frequency of point mutations.<sup>99</sup> There also is evidence to suggest that increasing male age may raise the risk of spontaneous abortion in young women.<sup>85,86,100</sup>

A number of studies have observed that advanced paternal age is associated with an increase in the prevalence of **birth defects** (e.g., neural tube defects, cardiac defects, and limb defects) and **congenital diseases** (e.g., Wilms tumor).<sup>101,102,103,104,105</sup> In a large population-based retrospective cohort study that included over 5 million births, the observed overall prevalence of birth defects was 1.5%; compared with infants born to fathers aged 25–29 years, the adjusted odds ratios for birth defects were 1.04 for infants with fathers aged 30–35 years, 1.08 for those with fathers aged 40–45 years and 45–50 years, and 1.15 for those with fathers over 50 years old.<sup>106</sup> These data suggest that the risk for birth defects increases only slightly, if at all, with increasing paternal age.

Advanced paternal age has been associated with an increase in new **autosomal dominant mutations** (e.g., achondroplasia and Alpert, Waardenburg, Crouzon, Pfeiffer, and Marfan syndromes).<sup>107</sup> At least in theory, this observation might reflect a decrease in the activity of antioxidant enzymes in the semen and sperms of older men, increasing their susceptibility to mutation.<sup>108</sup> DNA repair mechanisms also may be impaired in older men. Although the relative risk of autosomal dominant disorders is increased markedly, the absolute risk is still very small (<1%) because autosomal dominant diseases are rare.<sup>109</sup>

Evidence indicates that advanced paternal age is associated with an increased risk for **schizophrenia** in offspring<sup>110,111,112</sup>; overall, the incidence is increased two- to threefold for children whose fathers are over age 45 years, possibly as a consequence of mutations emerging during spermatogenesis.<sup>113</sup> Similarly, increasing paternal age has been associated with an increased risk for **autism** in children, which may reflect de novo mutations or errors in genetic imprinting.<sup>114,115,116,117,118</sup>

In older fathers, mutations resulting in **X-linked disease** also may be more common; examples include hemophilia A and Duchenne muscular dystrophy.<sup>119</sup> The “grandfather effect” describes their transmission from carrier daughters to affected grandsons. Overall, **advanced paternal age does not appear to be associated with any significant increase in the risk of fetal autosomal or sex chromosome aneuploidy.**<sup>119,120,121,122,123,124</sup> However, available data are limited and confounded by female partner age. Moreover, results from one study examining the chromosomal complement of paternal gametes suggest that the incidence of sex chromosome aneuploidy may increase with age.<sup>124</sup> A population-based study involving more than 4

million children observed that paternal age was associated with a small but significant increase in risk of leukemia and central nervous system cancers.<sup>125</sup>

It still is not clear whether the risk for miscarriage increases with paternal age, because results of studies conducted thus far are conflicting, with some finding evidence for an association with both early and late fetal loss<sup>100,126,127</sup> and others not.<sup>128,129</sup> Whereas one retrospective study of 558 pregnancies conceived using donor oocytes observed no association between paternal age and live birth rate,<sup>74</sup> another found that risk for miscarriage increased with paternal age.<sup>83</sup> **On balance, the weight of available evidence suggests that advanced paternal age may be associated with a small increase in the risk of spontaneous abortion.** Limited data suggest that advanced paternal age does not significantly increase the risk for fetal growth restriction<sup>130,131</sup> or stillbirth.<sup>132</sup>

# Androgen Deficiency in the Aging Male

**Serum total and free testosterone levels decrease in men as age increases.**<sup>133</sup> However, unlike the profound estrogen deficiency and associated symptoms that occur after menopause in women, the age-related decline in androgen levels in men is more gradual and smaller,<sup>134</sup> and the clinical consequences of decreasing androgen levels are not yet clear.

Serum testosterone concentrations exhibit a distinct diurnal variation in young men (with highest levels in the morning) but vary relatively little in elderly men.<sup>135</sup> In the cross-sectional European Male Ageing Study, involving 3,220 men aged 40–79 years, serum total testosterone concentrations fell by an average of 0.4% per year and free testosterone levels by 1.3% per year.<sup>136</sup> Longitudinal studies have observed a somewhat greater age-related decline in testosterone concentrations and found that levels decrease at a fairly constant rate.<sup>133,137,138</sup> Because sex hormone-binding globulin (SHBG) concentrations increase gradually with age, free testosterone levels decrease more than do total testosterone concentrations.<sup>134</sup> In the Massachusetts Male Aging Study, free testosterone levels fell by an average of almost 3% per year.<sup>139</sup> SHBG levels also may rise in association with increased abdominal obesity, further contributing to the decrease in free testosterone.<sup>140</sup>

As testosterone levels fall steadily, an increasing percentage of aging men become hypogonadal, as defined by testosterone concentrations (total testosterone <300–325 ng/dL, free testosterone <5 ng/dL) and/or by signs and symptoms of hypogonadism. In one population-based observational survey, the prevalence of hypogonadism ranged from 3% to 7% among men aged 30–69 years and was 18% in men over age 70.<sup>141</sup> In a longitudinal study, serum total testosterone levels in the hypogonadal range were observed in 20% of men in their 60s, in 30% of those in their 70s, and in 50% of men in their 80s.<sup>133</sup>

In some men over age 50, decreasing serum androgen concentrations may be associated with clinical symptoms and signs of androgen deficiency suggesting “andropause.” Symptoms of androgen deficiency may include decreased libido,<sup>142,143</sup> with or without erectile dysfunction<sup>144</sup>; reduced strength, energy, or stamina<sup>145</sup>; irritability and perceptions of a lower quality of life<sup>146</sup>; sleep disturbance, depressed mood, and lethargy<sup>141</sup>; and changes in cognitive function.<sup>147,148</sup> Symptoms may be accompanied by physical changes, including osteopenia or osteoporosis,<sup>149</sup> decreased muscle mass,<sup>150</sup> increased visceral adipose tissue,<sup>151</sup> testicular atrophy, and gynecomastia. Epidemiologic studies have observed that low serum testosterone concentrations are associated with the development of central obesity, increased insulin

levels, the metabolic syndrome, diabetes, and increased mortality.<sup>152,153,154,155</sup> Validated questionnaires now are available for use in evaluating older men.<sup>156,157</sup> However, scores do not predict or correlate well with measured free and total testosterone levels<sup>158</sup> and therefore lack specificity for the diagnosis of androgen deficiency in the aging male (ADAM).<sup>159,160,161</sup>

**Men with symptoms or signs of androgen deficiency merit evaluation by measuring the serum total testosterone level, ideally during the morning hours to minimize the influence of pulsatile and circadian rhythms in testosterone secretion. Frankly low concentrations (<200 ng/dL) should be confirmed by repeated measurements.**<sup>162</sup> Serum total testosterone includes not only free testosterone but also testosterone bound to albumin and SHBG. “Bioavailable testosterone” is the sum of free and albumin-bound testosterone and the measurement that has correlated best with bone mineral density<sup>145</sup> and sexual<sup>163</sup> and cognitive function<sup>148</sup> in epidemiologic studies. Because the serum total testosterone level occasionally may be misleading, some prefer to measure free or bioavailable testosterone, but the accuracy of free testosterone assays has been challenged<sup>164</sup> and neither assay is widely available. A free testosterone index (FTI) calculated from measurements of total testosterone and SHBG (total testosterone/SHBG) provides an indirect measure of the amount of bioavailable testosterone. **It is important to emphasize that in men with documented androgen deficiency, a normal or low serum LH suggests a secondary hypogonadism that merits additional evaluation by measurement of serum prolactin and magnetic resonance imaging (MRI) to detect any hypothalamic or pituitary mass lesion.**

## Treatment

**A consensus of expert opinion published in 2002 suggested that a total testosterone level under 200 ng/dL (6.9 nmol/L) is evidence of hypogonadism that warrants treatment in symptomatic men, that those with concentrations between 200 and 400 ng/dL (6.9–13.9 nmol/L) may benefit from treatment, and that higher levels all but exclude androgen deficiency.**<sup>165</sup> A bioavailable testosterone level below the normal range for normal young adult men or an FTI less than 0.153 (nmol/nmol) also is consistent with the diagnosis of androgen deficiency.<sup>133</sup> **Evidence-based guidelines issued by the Endocrine Society in 2006 recommended that, in the absence of pituitary or testicular disease, testosterone therapy be reserved for men with clearly and consistently low serum total testosterone concentrations (<200 ng/dL) and clinically important symptoms of androgen deficiency.**<sup>162</sup>

The potential risks of testosterone treatment include fluid retention, gynecomastia, increased red blood cell mass, worsening of sleep apnea, promotion of benign or

subclinical malignant prostate disease, and possible added risk for cardiovascular disease.<sup>166</sup> **Accordingly, the Endocrine Society guidelines recommend against testosterone treatment in men with prostate or breast cancer, a palpable prostate nodule or induration, prostate-specific antigen (PSA) greater than 3 ng/mL without further urologic evaluation, erythrocytosis (hematocrit >50%), untreated obstructive sleep apnea, severe lower urinary tract symptoms (International Prostate Symptom Score >19), or class III or IV heart failure.**<sup>162</sup>

Any of the commercial formulations of testosterone may be used for treatment. Androgen therapy may involve parenteral testosterone esters (75 mg/week or 150 mg every 2 weeks), implanted pellets (225 mg every 4–6 months), scrotal (40 cm<sup>2</sup>, one patch daily) or peripheral skin patches (5 mg, one patch daily), or testosterone gel (5 g/day); treatment should be individualized. At present, there are no data to indicate that any one formulation is clearly superior. **The therapeutic goal is to raise serum testosterone concentrations over pretreatment values without exceeding the normal range for young adult men. The target serum testosterone concentration should be lower than that for younger men (e.g., 300–400 ng/dL) to decrease the potential risk of testosterone-dependent disease.**<sup>162</sup> Dehydroepiandrosterone may be converted to testosterone and is commercially available as an oral dietary health supplement; standard doses (50–100 mg daily) generally do not raise serum testosterone concentrations, although higher doses may.<sup>167</sup>

In randomized, placebo-controlled studies, the effects of testosterone therapy on bone density have been inconsistent. In one, no overall increase in hip or spine bone density was observed, but treatment had the greatest effect in men with the lowest pretreatment testosterone levels.<sup>168</sup> In another, testosterone treatment did not increase bone density but prevented the decrease observed in men receiving placebo.<sup>169</sup> In a third, testosterone treatment (with and without finasteride, which blocks conversion of testosterone to dihydrotestosterone) increased spine bone density by 9–10% and hip bone density by 2–3%.<sup>170</sup> All three studies<sup>168,169,171</sup> and a subsequent systematic review<sup>162</sup> found that testosterone treatment increased fat free mass and decreased fat mass. However, the increase in lean mass did not result in any consistent improvement in muscle strength or physical performance.<sup>168,169,171</sup> Testosterone treatment also was not accompanied by any demonstrable improvement in quality of life measures or sexual function, as judged by questionnaires.<sup>168,169</sup>

**Androgen therapy must be monitored because the long-term health risks and benefits of treatment have not been established.** A baseline physical examination (breasts, heart, lungs, prostate), serum PSA, and complete blood count should be obtained; prostate biopsy is recommended when the digital rectal examination or serum

PSA is abnormal. Within 3 months after therapy begins, men receiving androgen therapy should be evaluated for weight gain and any signs of emerging peripheral edema, gynecomastia or breast tenderness, sleep disorders, or prostate enlargement. Recommended monitoring also includes hemoglobin or hematocrit and a serum PSA. A rapid rise in PSA (>1 ng/mL) soon after treatment begins suggests the possibility of an undetected prostate cancer and is reason to discontinue treatment pending a thorough prostate evaluation.<sup>172</sup> Serum testosterone also should be measured to ensure that treatment is achieving the target concentration, but the subjective clinical response is the most important gauge of the effectiveness of androgen therapy. Men with a good clinical response, no apparent adverse effects, and normal testosterone levels may continue treatment but should return for similar monitoring after another 6 months and at least annually thereafter. If osteoporosis was one of the indications for treatment, bone mineral density also should be reevaluated approximately 1–2 years after treatment starts.

In clinical trials of testosterone treatment in elderly men, only a few cases of prostate cancer have been observed, but statistical power was insufficient to support a conclusion that testosterone treatment does not increase risk for prostate cancer. A meta-analysis including 19 trials found that testosterone treatment was associated with a higher prevalence of elevated PSA values and prostate cancer, although biopsy was more commonly performed in men receiving treatment.<sup>173</sup> There is little evidence that short-term treatment has adverse effects on the prostate,<sup>174</sup> but the effects of long-term treatment remain uncertain. Similarly, it is not clear whether physiologic testosterone therapy increases the risk of sleep apnea, because data are conflicting.<sup>173,175,176,177</sup> However, testosterone treatment in elderly men clearly can cause erythrocytosis. In individual studies, up to one-third of treated men have developed an abnormally elevated hematocrit,<sup>170,178</sup> and a meta-analysis concluded that testosterone treatment is associated with more than a fourfold increased risk for erythrocytosis.<sup>173</sup> Taken together, evidence indicates that testosterone treatment in hypogonadal men has little effect on serum concentrations of total and low-density lipoprotein cholesterol.<sup>179</sup>

# CAUSES OF MALE INFERTILITY

---

Male infertility may result from a variety of causes. Some, like ductal obstruction and hypogonadotropic hypogonadism, can be defined accurately and treated effectively. Others, like primary testicular failure, can be defined but are not amenable to treatment, and still others, like seminiferous tubule dysfunction, cannot be corrected but can be overcome by IUI or ART. Although rare, male infertility also may be the first indication of a serious underlying medical condition. **Unfortunately, much of male infertility is idiopathic, reflecting our still very poor understanding of the mechanisms that govern testicular function.**

The list of known causes of male infertility is long and varied but can be divided into four major categories: (1) hypothalamic-pituitary disorders (1–2%), which may be congenital, be acquired, or result from systemic illness; (2) primary gonadal disorders (30–40%), both congenital and acquired; (3) disorders of sperm transport (10–20%); and (4) idiopathic (40–50%). (See [Table 26.1](#) for additional details.)

## TABLE 26.1 Causes of Male Infertility

### Hypothalamic-pituitary disorders

- Idiopathic isolated gonadotropin deficiency
- Kallmann syndrome
- Single gene mutations (e.g., involving the GnRH receptor, FSH $\beta$ , LH $\beta$ , or transcription factors involved in pituitary development)
- Hypothalamic and pituitary tumors (e.g., craniopharyngioma, macroadenoma)
- Infiltrative diseases (sarcoidosis, histiocytosis, transfusion siderosis, hemochromatosis)
- Hyperprolactinemia
- Drugs (GnRH analogs, androgens, estrogens, glucocorticoids, opiates)
- Critical illness or injury
- Chronic systemic illness or malnutrition
- Infections (e.g., meningitis)
- Obesity

---

### Primary gonadal disorders

- Klinefelter syndrome
- Y chromosome deletions
- Single-gene mutations and polymorphisms (e.g., involving the androgen, estrogen, or FSH receptor)
- Cryptorchidism
- Varicoceles
- Infections (e.g., viral orchitis, leprosy, tuberculosis)
- Drugs (e.g., alkylating agents, alcohol, antiandrogens, cimetidine)
- Radiation
- Environmental gonadotoxins (e.g., heat, smoking, metals, organic solvents, pesticides)
- Chronic illness (renal insufficiency, cirrhosis, cancer, sickle cell disease, amyloidosis, vasculitis, celiac disease)

---

### Disorders of sperm transport

- Epididymal obstruction or dysfunction
  - Congenital bilateral absence of the vas deferens (relating to *CFTR* mutations)
  - Infections causing obstruction of the vas deferens (e.g., gonorrhea, *Chlamydia*, tuberculosis)
  - Vasectomy
  - Kartagener syndrome (primary ciliary dyskinesia)
  - Young syndrome
  - Ejaculatory dysfunction (e.g., spinal cord disease, autonomic dysfunction)
-

# Hypothalamic-Pituitary Disorders

**Any hypothalamic or pituitary disease or disorder causing a deficiency of GnRH or gonadotropins can cause male infertility.** The most common congenital cause is idiopathic isolated gonadotropin deficiency due to absent or defective GnRH secretion (resulting in sexual infantilism).<sup>180</sup> When accompanied by one or more extragonadal abnormalities, such as anosmia, red-green color blindness, midline facial defects (e.g., cleft palate), neurosensory hearing loss, synkinesis (mirror movements), or renal anomalies, the disorder is known as **Kallmann syndrome**.<sup>181,182,183</sup> A variety of mutations have been identified in affected men, involving genes encoding cell surface adhesion molecules or receptors, which are required for normal migration of GnRH neurons from the olfactory placode to the hypothalamus; examples include KAL1,<sup>184,185</sup> fibroblast growth factor 1 (also known as KAL2),<sup>186</sup> and prokineticin-2 (PROK2) and its receptor (PROKR-2).<sup>187</sup> Other genetic causes of hypogonadotropic hypogonadism include rare mutations affecting the GnRH receptor,<sup>188</sup> the  $\beta$ -subunit of FSH,<sup>43</sup> or LH<sup>37,189,190</sup> or transcription factors involved in pituitary development during embryogenesis, such as LHX3,<sup>191</sup> LHX4, HESX1,<sup>192</sup> and PROP-1.<sup>193</sup>

Hypogonadotropic hypogonadism also can result from hypothalamic disease or treatments that inhibit GnRH secretion, abnormalities of the pituitary stalk that interfere with GnRH delivery, and pituitary disease that prevents normal gonadotropin secretion. **Hypothalamic or pituitary tumors** can distort the pituitary stalk or compress and suppress pituitary gonadotropes.

**Infiltrative diseases** of the hypothalamus or pituitary (sarcoidosis, histiocytosis, transfusion siderosis, hemochromatosis) can inhibit GnRH or pituitary gonadotropin secretion.<sup>194,195</sup> **Hyperprolactinemia** from any cause<sup>196</sup> and **treatment with GnRH analogs** (e.g., for prostate cancer), **androgens** (e.g., anabolic steroids),<sup>197</sup> **glucocorticoids**,<sup>198</sup> or **opiates**<sup>199,200,201</sup> can suppress gonadotropin secretion. **Critical illness**<sup>202</sup> or **injury** (e.g., head trauma)<sup>203</sup> and **chronic systemic illness** (e.g., diabetes mellitus) or **malnutrition** also have been associated with hypogonadotropic hypogonadism. **Infections** (e.g., meningitis) are another rare but recognized cause of hypopituitarism.<sup>204</sup>

**Obesity** in men is associated with hypogonadotropic hypogonadism, involving several mechanisms.<sup>205</sup> Serum free testosterone concentrations are inversely related to body weight and body mass index, independent of changes in SHBG levels,<sup>206,207,208</sup> and estrogen concentrations are elevated due to increased aromatase activity in adipose tissue.<sup>209</sup> **Obstructive sleep apnea** is a separate but related additional factor, resulting

in hypoxia.

# Primary Gonadal Disorders

Primary gonadal failure (hypergonadotropic hypogonadism) is a major cause of azoospermia and oligospermia and can result from a variety of congenital or acquired disorders, including Klinefelter syndrome, Y chromosome deletions, single gene mutations, cryptorchidism, varicoceles, and other less common causes.

## Klinefelter Syndrome

Klinefelter syndrome is one of the most common causes of primary testicular failure, affecting approximately 1 in 1,000 males,<sup>210,211</sup> and is characterized by sex chromosome aneuploidy. Although an extra X chromosome (47,XXY) is the most common form, some men with Klinefelter syndrome have a greater or lesser number of X chromosomes (e.g., 48,XXXY, 46,XY/47,XXY)<sup>212</sup>; 46,XX males, resulting from translocation of the testis-determining gene (SRY) to an X chromosome, also have Klinefelter syndrome. The phenotype varies with the number of extra X chromosomes and possibly also with the number of trinucleotide CAG repeats on the androgen receptor gene (a polymorphism); as the length of the repeat sequence increases, receptor activity decreases. A longer CAG repeat sequence has been associated with taller stature, lower bone mineral density, gynecomastia, and decreased penile length.<sup>213,214</sup>

**Men with Klinefelter syndrome generally have small, firm testes, resulting from damage to both seminiferous tubules and Leydig cells. Serum concentrations of FSH and LH are elevated and testosterone levels are decreased to a varying extent. Affected men have severely reduced sperm counts and are undervirilized.**<sup>212,215</sup> Cryptorchidism is more common in men with Klinefelter syndrome and causes more severe testicular damage.<sup>216</sup>

The length of the arms and legs is increased in men with Klinefelter syndrome, due both to testosterone deficiency and to an independent abnormality of the long bones. Men with Klinefelter syndrome also exhibit a number of psychosocial abnormalities,<sup>217</sup> which have been described as a marked lack of insight, poor judgment, and an impaired ability to learn from adverse experience.<sup>218</sup> They also may have difficulty with complex speech and a decreased attention span.<sup>219</sup> Later in life, they have an increased risk for developing pulmonary diseases, breast cancer,<sup>220</sup> mediastinal germ cell tumors,<sup>221</sup> varicose veins and leg ulcers,<sup>222</sup> systemic lupus erythematosus,<sup>223</sup> and diabetes mellitus.<sup>224</sup>

Other chromosomal abnormalities associated with primary gonadal failure include the 46,XY/45,X karyotype, causing a syndrome characterized by short stature and other

features of Turner syndrome.<sup>225</sup> Because the testes may be streak, dysgenetic, or normal, the phenotype varies from female to normal male. In those with a streak and a dysgenetic testis (mixed gonadal dysgenesis), the risk of gonadoblastoma is increased (approximately 20%), and gonadectomy is therefore indicated.

## Y Chromosome Deletions

**Microdeletions of the long arm of the Y chromosome are now recognized as a relatively common cause of severe oligospermia and azoospermia, affecting 2–5% of men with severe oligospermia and 8% of men with azoospermia.**<sup>226,227</sup> Most map to the Yq11 region (named azoospermia factor, or AZF), which contains three regions, AZFa, AZFb, and AZFc. Deletions of the AZFa or AZFb regions typically result in azoospermia. Mutations in the AZFc region cause infertility of varying severity, ranging from oligospermia to azoospermia, and are the largest known recurrent deletions in humans.<sup>228,229</sup> The DDX3Y and USP9Y genes, both located in the AZFa region, have been implicated as having an important role in spermatogenesis; azoospermia is consistently observed when both are deleted.<sup>230,231</sup> Y chromosome deletions also have been identified in men with cryptorchidism, varicocele, and obstructions of the vas deferens.<sup>232,233</sup>

**Because all Y chromosome abnormalities will be transmitted to sons of affected men conceived via ICSI, genetic testing and counseling should be offered to affected men before their sperms are used for that purpose.** Given the importance and potential consequences of Y chromosome deletions, there is a need to standardize the tests for their detection.<sup>234</sup>

## Single Gene Mutations and Polymorphisms

Normal male sexual differentiation and spermatogenesis require both normal androgen production and normal androgen receptors ([Chapter 9](#)). The androgen receptor plays an important role in the differentiation of spermatids and their release from the seminiferous epithelium. Consequently, it is not surprising that defects in androgen synthesis or androgen sensitivity are associated with infertility.<sup>235,236</sup>

As discussed above, the number of trinucleotide CAG repeats in exon 1 of the androgen receptor gene is inversely correlated with its transcriptional activity.<sup>213,214</sup> In one study in normal fertile men, those with short repeat sequences had the highest sperm concentrations.<sup>237</sup> However, studies in men with idiopathic infertility have yielded inconsistent results, with some finding an association between longer CAG repeat segments and male infertility<sup>238,239,240</sup> and others not.<sup>241</sup> **A meta-analysis including 33**

**studies concluded that men with idiopathic infertility had significantly longer CAG repeat lengths than did fertile men, suggesting that even subtle abnormalities in androgen action may adversely affect male fertility.**<sup>242</sup>

Evidence suggests that **disorders of estrogen synthesis or action** also may be associated with infertility in men. Impaired spermatogenesis has been observed in mice and in men lacking a functional estrogen receptor (alpha)<sup>243,244</sup> and in mice with an inactivating mutation in the aromatase enzyme.<sup>245</sup> Polymorphisms involving variations in the number of TA tandem repeats in the promoter region of the estrogen receptor gene also have been related to sperm production, with higher numbers of TA repeats being associated with lower sperm counts.<sup>246</sup> Inactivating mutations in the FSH receptor gene are a rare cause of male infertility.<sup>39,247</sup>

Several other autosomal and X-linked genes have been identified as important regulators of spermatogenesis. Men with myotonic dystrophy (an autosomal disorder associated with impaired motor function, cataracts, premature balding, mild mental retardation, and hypogonadism) also can exhibit abnormal spermatogenesis.<sup>248</sup> Mutations in the SYCP3 gene (involved in regulation of the synapse between homologous chromosomes during meiosis) have been implicated as a potential cause of male infertility.<sup>246</sup> Others include polymorphisms of DAZL (an autosomal homolog of the DAZ, deleted in azoospermia, gene),<sup>249,250,251,252,253</sup> PRM1 and PRM2 (protamines involved in chromatin compaction), TNP1 and TMP2 (transition nuclear proteins), and USP26 (deubiquitinating enzyme family).<sup>246</sup>

## **Cryptorchidism**

**Cryptorchidism results from a failure of testicular descent during fetal development, which is an androgen-dependent process.** Consequently, it is common in men with abnormalities of testosterone production, such as Kallmann syndrome, androgen resistance, and defects in testosterone synthesis. Cryptorchidism can be unilateral or bilateral and, in either case, is associated with impaired spermatogenesis and an increased risk for developing testicular tumors. Even in the absence of cryptorchidism, the incidence of testicular cancer is increased in infertile men.<sup>254,255</sup>

In men with cryptorchidism, serum FSH levels often are elevated, but LH concentrations generally are normal, reflecting normal Leydig cell function. **The severity of the semen abnormality relates to the duration of time the testes have been outside of the scrotum.** Because the testes are more easily retractable early in life, very young boys may appear transiently to have cryptorchidism, but in most, the testes descend and remain in the scrotum by age one.<sup>256</sup> Men having low serum inhibin

B levels, increased FSH concentrations, and decreased sperm density after repair of cryptorchidism are at increased risk for infertility.<sup>257</sup>

## Varicoceles

Varicoceles result from dilation of the pampiniform plexus of the spermatic veins in the scrotum. They are more prevalent in infertile men (up to 30%) than in fertile men (10–15%) and are 10 times more commonly found on the left than on the right, probably because the left spermatic vein is longer and joins the left renal vein at a right angle.<sup>258</sup>

**Although increased testicular temperature, delayed removal of local toxins, hypoxia, and stasis are viewed as the mechanisms likely responsible for the association between varicoceles and infertility, no causal relationship has been established.**<sup>259,260,261</sup>

## Other Causes of Primary Gonadal Failure

Certain **infections** are associated with male infertility. Mumps orchitis is widely recognized as a cause of male infertility. Although rare in prepubertal males, it occurs in up to 25% of adult men with mumps, some of whom become infertile. The mechanism may involve damage to the germinal epithelium, ischemia, or immune dysfunction.<sup>262,263</sup> Gonorrhea and chlamydial infections also can cause orchitis. Other infections associated with male infertility include tuberculosis, which may cause epididymal obstruction, leprosy,<sup>264</sup> and human immunodeficiency virus (HIV).<sup>265,266</sup>

**Drugs** that can adversely affect spermatogenesis or Leydig cell function include alkylating agents (e.g., cyclophosphamide, chlorambucil), antiandrogens (e.g., flutamide, cyproterone, spironolactone), ketoconazole, cimetidine, and anabolic steroids.<sup>267</sup> Doses of **radiation** as low as 0.015 Gy (15 rad) can suppress spermatogenesis, and doses above 6 Gy generally cause permanent azoospermia and infertility.<sup>268</sup>

Environmental exposures that may act as **gonadotoxins** include heat, smoking, metals, organic solvents, and pesticides. A modest increase in scrotal temperature can adversely affect spermatogenesis, and a febrile illness can result in dramatic, if also transient, decreases in sperm density and motility. Hyperthermia also may explain the infertility associated with spinal cord injuries and chronic sauna or spa exposure.<sup>269</sup> In theory, environmental sources of heat, including tight-fitting underclothing, hot baths and spas, and occupations that require long hours of sitting (long-distance driving) might decrease fertility, but none has ever been substantiated in clinical studies.<sup>12</sup> Smoking or heavy use of marijuana, alcohol, or cocaine can decrease semen quality and testosterone

levels.<sup>270,271,272</sup>

**Chronic illness,**<sup>273</sup> such as chronic renal insufficiency,<sup>274</sup> cirrhosis, or malnutrition,<sup>275</sup> can result in primary gonadal failure. Infertility also is common in men with sickle cell disease, probably due to testicular ischemia.

# Disorders of Sperm Transport

Even when sperm production is normal, epididymal obstruction or dysfunction can result in infertility. The cause of infertility is clear in men with obstruction, but relatively little is known about epididymal function. Isolated asthenospermia is presumed to result from epididymal dysfunction, and intrauterine exposure to diethylstilbestrol may be one cause.<sup>276</sup>

Congenital or acquired abnormalities of the vas deferens can cause obstruction and infertility. Approximately 1–2% of infertile men and up to 6% of men with obstructive azoospermia have **congenital bilateral absence of the vas deferens (CBAVD)**, almost always related to mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene.<sup>277</sup> These men most commonly present with one of two genetic scenarios: a severe mutation in one allele and a mild mutation, which leaves some residual CFTR activity, in the other allele; or two mutant alleles with mild effect on the protein. Most affected men do not exhibit any respiratory and pancreatic disease. **Infections** (gonorrhea, Chlamydia, tuberculosis) and **vasectomy** are other causes of vasal obstruction. **Primary ciliary dyskinesia (Kartagener syndrome)** is a genetic disease that adversely affects cilia structure and function and generally presents as recurrent sinus and pulmonary infections, bronchiectasis, situs inversus, and male infertility due to oligoasthenospermia.<sup>278,279</sup> **Young syndrome** is another genetic disease, in which inspissated secretions in the vas and epididymis result in obstructive azoospermia.<sup>280,281</sup>

Ejaculatory dysfunction resulting from spinal cord disease or injury, sympathectomy, or autonomic disease is another cause of infertility relating to disorders of sperm transport.

# THE MALE INFERTILITY EVALUATION

---

The evaluation of the infertile male should be directed toward achieving all of the following goals<sup>282</sup>:

- To identify and to correct specific causes of infertility, when possible
- To identify individuals whose infertility cannot be corrected but may be overcome by IUI or use of various forms of ART
- To identify individuals having a genetic abnormality that may affect the health of any offspring that may be conceived through the use of ART
- To identify individuals whose infertility can neither be corrected nor overcome with ART, for whom adoption and the use of donor sperms are options worthy of consideration
- To identify any important underlying medical condition that may require specific medical attention

**Evaluation of the male partner should begin at the same time as in the female partner, generally when pregnancy fails to occur after 1 year of reasonably regular unprotected intercourse.** Earlier evaluation is indicated for men with any obvious infertility risk factor, those whose partner is age 35 or older (where it is important to identify all potential infertility factors as quickly and efficiently as possible), and men who have reason to question their fertility.

In the male partner, the most relevant parts of the medical history and physical examination include the following<sup>282</sup>:

## **History**

- Duration of infertility and previous fertility
- Coital frequency and any sexual dysfunction
- Results of any previous evaluation or treatment for infertility
- Childhood illnesses and developmental history
- Previous surgery, its indications and outcome, and systemic medical illnesses
- Past episodes of or exposures to sexually transmitted infections
- Exposures to environmental toxins, including heat
- Current medications and allergies
- Occupations and use of tobacco, alcohol, and other drugs

## **Physical Examination**

- Examination of the penis, to include the location of the urethral meatus

- Palpation of the testes and measurement of their size
- The presence and consistency of both the vasa and epididymides
- Presence of any varicocele
- Secondary sex characteristics, including body habitus, hair distribution, and breast development
- Digital rectal examination

A history of cryptorchidism or mumps orchitis suggests the possibility of testicular atrophy.<sup>262,283</sup> The timing and extent of secondary sexual development may alert one to the possibility of an endocrinopathy. Ductal obstruction can result from sexually transmitted infections. Diabetes mellitus (bladder neck dysfunction resulting in retrograde ejaculation) and cystic fibrosis (highly associated with congenital absence of the vas deferens) are medical illnesses that may hinder fertility in men. Inguinal hernia repair, renal transplant, and scrotal surgery are associated with risks for unrecognized injury to the vas deferens.<sup>284</sup> Retroperitoneal surgery may disrupt neural pathways and cause ejaculatory dysfunction; treatment with alpha-blockers, phentolamine, methyl dopa, guanethidine, or reserpine may have similar effects.

When the infertility evaluation is directed by the gynecologist or primary clinician, physical examination of the male may be deferred pending the results of the first semen analysis when there is no history of any male genital abnormality, trauma, surgery, or sexual dysfunction. However, an abnormal reproductive history or semen analysis is indication for additional formal evaluation that may be conducted by the gynecologist having the necessary training and experience but is most often performed by the urologist or other specialist in male reproduction.

# Semen Analysis

If a male infertility factor exists, it almost always will be revealed by an abnormal semen analysis, although other male factors (sexual dysfunction) may be involved even when semen quality is normal. **The initial evaluation for male factor infertility should include at least one properly performed semen analysis. If abnormal, another semen analysis should be obtained after at least 4 weeks.**<sup>282</sup> Semen parameters can vary widely over time, even among fertile men,<sup>285,286,287,288</sup> and also exhibit seasonal variations.<sup>289,290,291</sup> Considering that the overall objective is to gain a sense of the usual semen quality, over time, more than one analysis is helpful, because a single semen sample yields only a point estimate that may or may not be representative. However, with relatively few exceptions, a normal initial semen analysis generally excludes an important male factor when there is no complaint or suspicion of sexual dysfunction. Conversely, abnormal semen parameters suggest the need for additional endocrine, urologic, or genetic evaluation.

Standard but detailed instructions for semen collection should be provided, to include a defined abstinence period of 2–3 days. Shorter intervals of abstinence decrease the semen volume and sperm density but generally have little or no impact on sperm motility or morphology.<sup>292</sup> **Longer abstinence intervals increase semen volume and sperm density but also increase the proportion of dead, immotile, or morphologically abnormal sperm.**<sup>293</sup> Ideally, the semen specimen should be collected by masturbation directly into a clean container. If necessary, semen may be collected via intercourse using a specially manufactured Silastic condom that does not contain spermicidal agents like those in condoms intended for contraceptive purposes. Collection after withdrawal during intercourse risks loss of the initial portion of the specimen, which generally contains the highest concentration of sperms. If possible, the semen specimen should be collected in a private room within or near the laboratory. When necessary, the specimen can be collected at home but should be kept at room or body temperature during transport. Regardless of the method of collection, the semen sample should be examined within an hour after collection.

## Normal Reference Values

The normal reference values in wide use are based on comparisons of the values observed in the male partners of fertile and infertile couples without specific exclusion of female infertility factors<sup>294,295,296</sup> and therefore do not necessarily represent the average ranges observed in fertile men. Unfortunately, there is considerable overlap between the semen parameters observed in fertile and infertile men.<sup>297</sup> The normal reference ranges certainly do not represent the absolute minimum values needed for

conception; many men with values outside the normal ranges are fertile and many with normal values are nonetheless infertile.<sup>297,298,299,300</sup> **Values outside of normal ranges suggest a male infertility factor that may require additional clinical or laboratory evaluation, but each parameter must be considered in the context of the whole.** A mildly low sperm density may have little significance when semen volume, sperm motility, and the proportion of abnormal sperms are normal. Conversely, a normal sperm density offers little reassurance when semen volume is frankly low or the proportion of motile or normal sperms is grossly abnormal. **Overall, the odds of male infertility increase with the number of major semen parameters (concentration, motility, morphology) in the subfertile range; the probability is 2 to 3 times higher when one is abnormal, 5 to 7 times higher when two are abnormal, and 16 times greater when all three are abnormal.**<sup>297</sup>

Although detailed procedures for semen analysis have been established by the World Health Organization (WHO), the methods and accuracy of semen analyses as they are performed in physician offices, hospitals, and specialty andrology laboratories may vary. Ideally, to ensure accurate and reliable results, semen analyses should be performed in a laboratory having an established quality control program that conforms to the standards outlined in the Clinical Laboratory Improvement Amendments (CLIA; [www.hcfa.gov/medicaid/clia/clihome.htm](http://www.hcfa.gov/medicaid/clia/clihome.htm)).<sup>301,302</sup> The traditional WHO normal reference values are shown in [Table 26.2](#).<sup>303,304,305</sup>

## **TABLE 26.2 Semen Analysis: Normal Reference Values**

<b>Volume</b>	1.5–5.0 mL
<b>pH</b>	>7.2
<b>Viscosity</b>	<3 (scale 0–4)
<b>Sperm concentration</b>	>20 million/mL
<b>Total sperm number</b>	>40 million/ejaculate
<b>Percent motility</b>	>50%
<b>Forward progression</b>	>2 (scale 0–4)
<b>Normal morphology</b>	>50% normal <sup>303</sup> >30% normal <sup>304</sup> >14% normal <sup>305</sup>
<b>Round cells</b>	<5 million/mL
<b>Sperm agglutination</b>	2 (scale 0–3)

Over time, the methods and normal reference values for determining sperm concentration and motility have changed little, but those for sperm morphology have changed rather substantially. Using the most recent and rigorous standard, even fertile men have relatively few normal sperms. The rationale for the change in the morphology standard and its clinical relevance are discussed below (see Sperm Morphology).

In 2010, the WHO published revised **lower reference limits** for semen analyses, which represent the fifth centile in a population of over 1,900 men from 8 countries on 3 continents whose partners conceived within 12 months ([Table 26.3](#)).<sup>306</sup>

**TABLE 26.3 Semen Analysis: Lower Reference Limits (95% CI) in Fertile Men**

<b>Volume</b>	1.5 (1.4–1.7) mL
<b>Sperm concentration</b>	15 (12–16) million/mL
<b>Total sperm number</b>	39 (33–46) million/ejaculate
<b>Total motility</b>	40 (38–42) %
<b>Progressive motility</b>	32 (31–34) %
<b>Normal morphology</b>	4 (3–4) %
<b>Vitality</b>	58 (55–63) %

These data provide clinically relevant reference values for use in the evaluation of infertile men and in assessing their prognosis for achieving pregnancies with their partners.

## Ejaculate Volume and pH

A low or absent ejaculate volume suggests the possibility of failed emission, incomplete collection, a short abstinence interval, CBAVD, ejaculatory duct obstruction, hypogonadism, or retrograde ejaculation. Other semen parameters can help to differentiate the cause.

**The majority of semen volume comes from the seminal vesicles, which share a common embryology with the vasa deferentia.** Seminal vesicle secretions are alkaline and contain fructose. Because the seminal vesicles are hypoplastic or absent in most men with CBAVD, they generally produce a low-volume acidic (pH < 7.2) ejaculate that contains little or no fructose and reflects the greater contribution of acidic prostatic secretions.<sup>307,308,309</sup> Men with ejaculatory duct obstruction produce an ejaculate having similar characteristics because the ejaculatory ducts are formed by the union of the vasa with the ducts exiting the seminal vesicles, proximal to the prostate; semen fructose concentrations decrease with increasing severity of ejaculatory duct obstruction.<sup>310,311,312</sup> **When both ejaculatory ducts are completely obstructed, the**

**semen is acidic (containing only prostatic secretions) and contains neither fructose nor sperms.** Hypogonadal men with either primary or secondary testicular failure also may exhibit low ejaculate volumes because the secretions of the seminal vesicles and prostate are stimulated by androgens; volume is therefore decreased when androgen levels are low.

**A postejaculatory urinalysis can detect retrograde ejaculation and should be considered whenever the ejaculate volume is less than 1 mL, except when hypogonadism, CBAVD, collection problems, or a short abstinence interval offers an obvious explanation.** When indicated, the postejaculatory urinalysis involves centrifugation for 10 minutes at no less than 300g, followed by microscopic examination of the pellet (400×). **In men with no or low semen volume and azoospermia (no sperms in the ejaculate), the observation of any sperm on postejaculatory urinalysis suggests retrograde ejaculation.** More substantial numbers of sperms must be observed in men with low-volume oligospermia before making the diagnosis of retrograde ejaculation because sperms found in the urine may simply have been washed from the urethra during urination.<sup>307</sup>

## **Sperm Concentration and Total Sperm Count**

Azoospermia describes the absence of sperms on standard microscopic examination. The prevalence of azoospermia is approximately 1% in all men<sup>313</sup> but up to 10–15% in infertile men.<sup>314</sup> To establish the diagnosis, the semen specimen should be centrifuged at high speed (3,000g for 15 minutes) and the pellet examined at high magnification (400×)<sup>305</sup>; **the absence of sperms should be documented on at least two separate occasions.** Azoospermia is generally classified as obstructive (normal sperm production) or nonobstructive (decreased or absent spermatogenesis).

Obstructive azoospermia may result from a blockage anywhere in the ductal system, from the efferent ductules to the ejaculatory ducts, as the consequence of severe infection, iatrogenic injury during scrotal or inguinal surgery, or congenital anomalies (CBAVD); approximately 40% of azoospermic men have an obstruction.<sup>307</sup> Nonobstructive azoospermia is caused by intrinsic testicular disease (primary testicular failure) or endocrinopathies and other conditions that suppress spermatogenesis (secondary testicular failure). Men with nonobstructive azoospermia may have low-level sperm production that is insufficient to drive epididymal transport and to permit sperms to enter the ejaculate.<sup>315</sup> Careful examination of a centrifuged semen sample will identify sperms in the ejaculates of up to one-third of men with a preliminary diagnosis of nonobstructive azoospermia.<sup>316</sup> The observation has practical significance because men in whom even a modest number of sperms can be recovered from the ejaculate may

not require surgical sperm retrieval for IVF (testicular sperm extraction, TESE).

Oligospermia is defined traditionally by a sperm density less than 20 million/mL and is considered severe when the sperm concentration is below 5 million/mL. **The probability of conception increases with increasing sperm concentrations up to approximately 40–50 million/ mL but does not rise further with higher sperm densities.**<sup>297,298</sup> The results of a large US study comparing semen parameters in fertile and infertile men with normal partners indicate that the likelihood of male infertility is increased approximately fivefold (5.3, 95% CI = 3.3–8.3) when sperm density is less than 13.5 million/mL.<sup>297</sup> In an earlier European study of similar design, the density representing the tenth percentile for fertile men was 14 million/mL.<sup>317</sup> These values are consistent with the most recent recommendations from WHO regarding the lower reference limit for fertile men (15 million/mL).<sup>306</sup> Oligospermia may be associated with a varicocele, hypogonadism, or specific microdeletions in the Y chromosome. **Endocrine and genetic evaluation is indicated for men with severe oligospermia** (discussed below).

Total sperm count is simply the product of multiplying the semen volume and sperm concentration. The total sperm count may be normal in oligospermic men when volume is high and also normal when volume is low but density is high. The two parameters fluctuate and must be considered together in making judgments regarding semen quality. Numerous studies have suggested that the average sperm count in men has been decreasing steadily over the past few decades,<sup>318,319</sup> raising concerns that environmental toxins and chemicals having estrogen-like activity (xenoestrogens) might be responsible. However, numerous others have observed no evidence of any significant change.<sup>320,321,322,323,324,325</sup> Most importantly, the prevalence of infertility has not increased significantly over the same intervals, indicating that any decrease in semen quality that may have occurred has had no global clinical impact.

## **Sperm Motility, Forward Progression, Total Motile Count, and Vitality**

Sperm motility is estimated as a percentage of the total sperm population exhibiting any motion. Forward progression generally is graded on an arbitrary scale (grade 0–4) and most often reported as the percentages exhibiting rapid (grade 3–4), slow (grade 2), and nonprogressive motility (grade 0–1). Total progressive motility generally represents an estimate of the percentage of sperms exhibiting purposeful forward motion (grade 2–4). **The probability of conception rises with increasing motility up to approximately 60%.**<sup>297</sup> According to one large US study, the likelihood of male infertility is increased approximately fivefold (OR = 5.6, 95% CI = 3.5–8.3) when progressive motility is less

than 32%.<sup>297</sup> In another study, the threshold separating fertile and infertile men was 45% and the tenth percentile motility for fertile men was 28%.<sup>317</sup> Again, these values compare well with the lower reference value for progressive motility now recommended by the WHO (32%).<sup>306</sup>

The total motile sperm count is calculated from the total sperm count and the percentage of progressively motile sperm and represents an estimate of the total number of active sperms in the ejaculate. Allowing for the inevitable procedural losses associated with processing a semen sample for IUI (up to approximately 50%), the total motile sperm count can be used to estimate the likely processed total motile sperm count, which correlates with the probability of pregnancy achieved with IUI in the treatment of male factor infertility (see Treatment, below).<sup>326,327,328,329,330</sup>

In general, poor sperm motility (asthenospermia) suggests testicular or epididymal dysfunction. Asthenospermia has been associated with sperm autoantibodies (predisposing to aggregation), genital tract infections (leukocytes in the semen), partial obstruction of the ejaculatory ducts or at the site of a vasectomy reversal (reanastomosis), varicoceles, and prolonged abstinence intervals.

Large numbers of viable nonmotile sperms suggest the rare possibility of primary ciliary dyskinesia (Kartagener syndrome), in which sperm tails have a structural abnormality and cannot flagellate. The cilia of the respiratory tract usually also are involved; affected individuals are infertile and predisposed to chronic respiratory tract infections. Diagnosis is made by examination of sperms using electron microscopy.

**When no motile sperms are observed, a sperm vitality test can differentiate viable nonmotile sperms from dead sperms.** One method involves mixing fresh semen with a supravital dye (eosin Y or trypan blue); sperms with intact membrane function do not take up the stain. Another method, the hypo-osmotic sperm swelling test, involves incubation of sperms in a hypo-osmotic solution; the tails of sperms with normal membrane function swell and coil as fluid is transported across the membrane. In men with few or no motile sperms, the hypo-osmotic swelling test can be used to identify living nonmotile sperms for ICSI.<sup>331</sup>

## Sperm Morphology

Sperm morphology reflects the quality of spermatogenesis. Morphologic abnormalities (teratospermia) are categorized by location, involving the head, neck (midpiece), or tail. Cytoplasmic droplets in the midpiece that occupy more than approximately one-half of the area of a normal sperm head represent another specific defect. Sperms classified as normal must be normal in all respects. Teratospermia has been associated with varicocele and with both primary and secondary testicular failure. It may be observed in

association with abnormalities in sperm concentration and motility or occur as an isolated abnormality.

The most recent WHO reference values (since 1999) for the evaluation of sperm morphology are very similar to those known as the Kruger (Tygerberg) or “strict” criteria,<sup>332,333</sup> which arose from efforts to identify predictors of fertilization in IVF cycles. When sperm morphology was judged according to a strict normal standard, fertilization efficiency in vitro correlated with the percentage of morphologically normal sperms.<sup>332,334,335</sup> Conventional fertilization rates were highest when the percentage of normal sperms was 14% or higher, very poor (7–8%) when less than 4% of sperms had normal morphology, and intermediate when values fell between the two threshold values.<sup>332</sup> After several studies confirmed the predictive value of strict sperm morphology in IVF,<sup>336,337,338,339,340,341,342,343</sup> severe teratospermia (0–4% normal sperms by strict criteria) became widely accepted as an indication for ICSI in IVF cycles. However, others have observed no differences in the fertilization, pregnancy, and live birth rates achieved with ICSI and conventional fertilization and argue that isolated teratospermia is not a valid indication for performing ICSI.<sup>344,345,346,347</sup> **Controversy continues, but strict sperm morphology remains the best available predictor of sperm function (the capacity to fertilize a mature oocyte).**

It was logical to anticipate that if strict sperm morphology could predict fertilization efficiency under optimized conditions in vitro, it also might have value for predicting the likelihood of successful fertilization in vivo and help to discriminate fertile and infertile men. A number of studies have examined semen parameters in couples with no known infertility factors who were attempting pregnancy,<sup>298,348</sup> or compared the semen parameters of fertile and infertile men<sup>297,317,341,349</sup>; two have included only men whose partners had no apparent infertility factors.<sup>297,317</sup> **Whereas sperm concentration and progressive motility had value for distinguishing fertile from infertile men, strict sperm morphology (as determined by an individual having extensive training and experience) was the one most discriminating value.**<sup>297,317</sup> In the larger of the two studies, the likelihood of male infertility was increased approximately fourfold (OR = 3.8, 95% CI = 3.0–5.0) when strict sperm morphology was less than 9% normal.<sup>297</sup> The 9% threshold value had a sensitivity of 43% and a specificity of 81% for identifying infertile men; lowering the threshold value to 5% normal forms decreased sensitivity to only 19% but increased specificity to 94%.<sup>297</sup> In a smaller study of similar design, the threshold value that identified infertile men was 10% and the value corresponding to the tenth centile among fertile men was 5% normal forms.<sup>317</sup>

Strict sperm morphology is perhaps most relevant for couples with mild oligospermia or asthenospermia or with unexplained infertility (normal ovulatory

function, female reproductive anatomy, and semen parameters). In such couples, IUI (with or without ovarian stimulation) and IVF are the treatment options that offer the greatest likelihood for success (Chapter 27). Most,<sup>350,351,352,353</sup> but not all,<sup>354,355</sup> studies have observed that cycle fecundability in IUI cycles correlates with the proportion of morphologically normal sperms and is generally poor when strict morphology is less than 5% normal. **Although no threshold value excludes the possibility of pregnancy with expectant management or IUI, the relationship between strict sperm morphology and cycle fecundability with IUI merits careful consideration and discussion when planning treatment for couples with male factor and unexplained infertility.** Other important considerations include age of the female partner, the duration of infertility, and the comparative costs, logistics, risks, and prognosis associated with alternative treatment strategies, including IVF with and without ICSI.

It is important to emphasize that strict sperm morphology values, like other semen parameters, vary among specimens within individuals, among technologists within laboratories, and among laboratories.<sup>333,356</sup> A rigorous quality control program helps to ensure accuracy and consistency.<sup>357,358</sup> Unfortunately, relatively few of the laboratories that perform routine semen analyses have sufficient test volume and the highly trained and experienced personnel required to provide a valid assessment of strict sperm morphology. **Consequently, earlier WHO standards for sperm morphology (1987, 1992) that classify more sperms as normal are still widely used in most hospital laboratories.**<sup>303,304</sup> Although morphology assessments using the earlier standards have little value, results for semen volume, sperm concentration, and motility are still informative and can reveal an obvious male factor. However, a more sophisticated semen analysis, including strict sperm morphology, merits serious consideration before implementing treatment for couples with male factor or unexplained infertility.

## Round Cells and Leukocytospermia

Epithelial cells, prostate cells, immature sperm (round spermatids, spermatocytes), and leukocytes all appear as “round cells” and cannot be differentiated in a routine semen analysis. **When the round cell count exceeds 5 million/mL, additional studies should be performed to differentiate leukocytes from immature sperms and to identify those men having true leukocytospermia (>1 million leukocytes/mL) who may require additional evaluation for genital tract infection or inflammation.** Any of a variety of special stains, biochemical tests, and immunohistochemical techniques can be used to identify the proportion of round cells that is leukocytes.<sup>359,360</sup> Although leukocytospermia has been implicated as a cause of poor sperm motility and function,<sup>361</sup> more recent studies have failed to demonstrate any association between the leukocytospermia in men with chronic prostatitis and abnormal semen parameters.<sup>362</sup>

Nevertheless, documented leukocytospermia generally is regarded as an indication for semen culture (*Mycoplasma hominis*, *Ureaplasma urealyticum*, Chlamydia). When cultures are performed, the penis should be washed carefully with Betadine before sample collection to reduce the likelihood of contamination from skin flora. For reasons unknown, leukocytospermia unrelated to infection or inflammation also may be observed in the semen of men with spinal cord injuries.<sup>363</sup>

## **Semen Viscosity**

The viscosity of semen is evaluated routinely and graded on an arbitrary scale (grade 0–4). Seminal hyperviscosity is relatively uncommon and its causes have not been clearly defined. Not surprisingly, hyperviscosity has been associated with asthenospermia.<sup>364,365</sup> Although genital tract infections and sperm autoantibodies have been implicated as causes of seminal hyperviscosity, evidence for the association is lacking.<sup>366</sup> Like abnormalities of pH and fructose levels, increased semen viscosity suggests the possibility of dysfunction in the accessory glands (prostate, seminal vesicles),<sup>367</sup> but in practice, the parameter has relatively little importance.

## Specialized Tests

Although all of the major semen parameters (concentration, motility, morphology) have impact on fertility when clearly abnormal, they do not measure or answer what is arguably the most important question: can the sperm effectively attach to, penetrate, and fertilize the partner's ova? Strict sperm morphology is a useful indirect measure of sperm function by virtue of its correlation with fertilization rates in vitro, but the parameter leaves much to be desired and generally is available only in specialty andrology laboratories associated with IVF centers.

**Unfortunately, although a wide assortment of specialized tests and procedures has been developed to evaluate sperm attachment to the zona pellucida, penetration of the oocyte membrane, or the release of acrosomal enzymes, we still have no reliable validated test of sperm function.** Because we do not yet understand, cannot measure, and have no way to correct a suspected sperm function abnormality, attention has focused on ICSI as a way to negate or circumvent sperm function abnormalities. However, the need for a reliable sperm function test persists, because IVF and ICSI are not practical options for a great many infertile couples and all would like to use their available time and resources in the most efficient and effective way possible<sup>368</sup>; the time and expense associated with treatments involving IUI might be avoided if there was good evidence to indicate that only ICSI offered a realistic likelihood for success.

## Sperm Autoantibodies

The blood-testis barrier normally isolates sperms from immune recognition (sperms develop after immunocompetence is established), but if it is disrupted and sperms are exposed to blood, an antigenic response may result. Risk factors for antisperm antibodies include ductal obstruction, previous genital infection, testicular torsion or trauma, and sterilization reversal (vasovasostomy or vasoepididymostomy).<sup>369</sup> Sperm autoantibodies can be found in the serum, but evidence indicates they have no clinical significance.<sup>370,371</sup> In contrast, antibodies bound to sperm may be clinically relevant because they may interfere with sperm motility or prevent fertilization.<sup>372,373</sup>

Marked sperm clumping or agglutination, like isolated asthenospermia, may signal the presence of sperm autoantibodies, but neither is observed commonly. Some also regard unexplained infertility as an indication for antisperm antibody testing. The two most widely used tests for detection of sperm autoantibodies involve the use of beads or latex particles with attached antibodies (raised against human immunoglobulins) that bind to antibodies on the surface of sperms.<sup>305</sup> The threshold for a positive test is not well established, but antibodies generally are considered clinically important when

more than 50% of sperms are coated. However, the levels of antibody can fluctuate, even without treatment.<sup>374</sup> New research on sperm proteomics may help to link specific sperm proteins with their functions and to identify relevant sperm autoantibodies.<sup>375</sup>

Pregnancy rates are reportedly lower for men with demonstrable antisperm antibodies than for those without antibodies, and among those with antisperm antibodies, pregnancy rates are lower when more than 50% of sperms are antibody bound.<sup>376</sup> Antisperm antibodies have been associated with poor postcoital test results, but routine postcoital testing is no longer performed because results have no proven value (Chapter 27). Because IUI was among the most popular and effective treatments for antisperm antibodies<sup>377</sup> (as it was for presumed cervical factor infertility) and IUI has become a core element of most treatments for unexplained infertility other than IVF (Chapter 27), the results of antisperm antibody testing, like those from postcoital testing, rarely offer any information that affects treatment decisions or outcomes. **Sperm autoantibody testing is seldom any longer performed because when IUI fails or IVF is otherwise indicated, ICSI can effectively circumvent any adverse effects of antisperm antibodies.**<sup>378</sup>

## Sperm Penetration Assay

The zona pellucida surrounding the oocyte blocks entry of more than one sperm and fertilization by sperms of a different species, but if removed by gentle enzymatic digestion, sperms of another species can penetrate the egg. In the sperm penetration assay, zona-free eggs collected from superovulated golden hamsters are incubated with washed human sperms, and the proportion of eggs penetrated or the number of sperm penetrations per egg by the sperms of the test subject is compared to that observed in a parallel incubation using sperms from a known fertile individual.<sup>305,379,380</sup> In theory, the test evaluates four specific sperm functions: capacitation, the acrosome reaction, fusion with the oolemma, and decondensation within the egg cytoplasm.

Unfortunately, the results of the sperm penetration assay are quite sensitive to varying culture conditions and the test procedure has been difficult to standardize. The test relies on spontaneous in vitro or chemically induced acrosome reactions.<sup>381</sup> Test results also vary over time and even proven sperm donors may fail the sperm penetration assay on a given occasion.<sup>382</sup> The predictive value of the sperm penetration assay for IVF or natural conception among infertile couples has varied widely among studies and depends, in large part, on the experience of the individual laboratory.<sup>383,384,385,386</sup> Interestingly, test results also have not consistently correlated with strict sperm morphology, the most commonly accepted predictor of fertilization.<sup>387,388,389</sup> Perhaps most importantly, the test is cumbersome, costly, time-

consuming, and not widely available.

## **Human Zona Binding Assay**

Whereas sperm penetration of zona-free eggs may test the ability of sperms to penetrate the oocyte, it does not, by definition, test the ability of sperms to bind to and penetrate the zona pellucida. The hemizona assay uses bisected zonae derived from human oocytes not previously exposed to sperms and compares the binding of test subject and fertile control sperms.<sup>390,391</sup> Results have been used to predict fertilization in vitro,<sup>392,393</sup> but the limited availability of human zonae and the technical aspects of the test effectively preclude application beyond use as an investigative tool.

## **Computer-Assisted Sperm Analysis**

Computer-assisted sperm analysis (CASA) was developed in efforts to establish a precise, automated, and objective evaluation of sperm concentration and motion characteristics (velocity and head movement). The technology employs sophisticated instruments to generate digitized video images for analysis, but its accuracy is highly dependent on the methods of sample preparation, frame rate, and sperm concentration.<sup>394,395</sup> Although some have found that sperm motility characteristics have predictive value for fertilization in vivo and in vitro, others have not.<sup>396,397,398</sup>

## **Acrosome Reaction**

The acrosome is a membrane-bound structure located at the tip of the sperm head containing proteolytic enzymes necessary for penetration of the zona pellucida ([Chapter 7](#)), and acrosin is one of those enzymes.<sup>399</sup> The acrosome reaction involves the fusion of the acrosome and the plasma membrane, followed by release of the acrosomal enzymes and exposure of the sperm head, which must occur after sperm binding to the zona pellucida. The sperms of infertile men exhibit an increased prevalence of spontaneous acrosome loss and decreased acrosome reactivity in response to treatment with a calcium ionophore.<sup>400</sup> However, the clinical relevance of acrosin measurements and abnormal acrosome reactivity in vitro remains to be established.

## **Biochemical Tests**

Biochemical tests of sperm function include measurements of sperm creatine phosphokinase and reactive oxygen species. Creatine phosphokinase is an important enzyme involved in the generation, transport, and use of energy within the sperm. Studies of the levels or forms of the enzyme in the sperms of fertile and infertile men

have yielded conflicting results.<sup>401,402</sup>

Normal oxygen metabolism generates reactive oxygen species, which may be toxic in excess. In both fertile and infertile men, leukocytes are the principal source of reactive oxygen species, but sperms themselves also produce them. Increased levels have been observed in the semen of infertile men and implicated as a cause of otherwise unexplained male infertility.<sup>403,404,405</sup> Peroxidation of sperm lipid membranes and generation of toxic fatty acid peroxides may interfere with sperm functions.<sup>406</sup> Reactive oxygen species can be detected with chemiluminescent probes, but such tests remain investigational.

## **Sperm Chromatin Structure and DNA**

A significant proportion of infertile men have increased levels of DNA damage that may adversely affect fertility<sup>407,408,409,410,411,412,413</sup> even when all standard semen parameters are normal.<sup>414</sup> Men with abnormal semen parameters often exhibit high levels of DNA fragmentation, but the same can be observed in men with normal semen parameters.<sup>407,411,415,416,417</sup> Recently developed tests of sperm chromatin structure and DNA fragmentation provide a measure of sperm chromatin and nuclear integrity,<sup>418</sup> but their clinical utility has not been established. A meta-analysis including 13 relevant studies involving over 2,000 treatment cycles concluded that the small association between sperm DNA integrity test results and pregnancy in IVF and ICSI cycles is not sufficient to warrant their routine use in the evaluation of infertile men.<sup>419</sup>

# Endocrine Evaluation

Endocrine disorders involving the hypothalamic-pituitary-testicular axis are well recognized but uncommon causes of male infertility and are extremely uncommon in men having normal semen parameters. **Indications for endocrine evaluation in infertile men include an abnormal semen analysis (particularly a sperm concentration <10 million/mL), sexual dysfunction (decreased libido, impotence), and other clinical symptoms or findings that suggest a specific endocrinopathy.**<sup>307</sup> A basic endocrine evaluation of the infertile male involves measurements of serum FSH and total testosterone and will detect the vast majority of clinically significant endocrinopathies.<sup>420</sup>

When the total testosterone level is low (<300 ng/dL), the assay should be repeated to confirm the finding, and a serum free testosterone, LH, and prolactin should be obtained.<sup>307,421</sup> Together, the levels of FSH, LH, and testosterone help to differentiate the clinical condition. **In men with hypogonadotropic hypogonadism, generally all three hormone levels are distinctly low. In men with abnormal spermatogenesis, the FSH level may be normal or high and LH and testosterone levels are normal. Those with testicular failure exhibit high levels of FSH and LH and a low or normal testosterone concentration. Men with a prolactin-secreting pituitary tumor generally have normal or low gonadotropin concentrations, a low serum testosterone, and an elevated prolactin level. In those with hypogonadotropic hypogonadism, with or without hyperprolactinemia, MRI of the hypothalamic-pituitary region is indicated to exclude a mass lesion.**

In infertile men with severe oligospermia (<5 million/mL), low testosterone levels (<300 ng/dL), and normal gonadotropin concentrations, evaluation might be expanded to include a serum estradiol and calculation of the testosterone (ng/dL)/estradiol (pg/mL) ratio, because those with low values (<10) may benefit from treatment with an aromatase inhibitor.<sup>422,423</sup>

# Urologic Evaluation

**If not performed earlier, grossly abnormal semen parameters are indication for a thorough physical examination by a urologist or other specialist in male reproduction; some men also may require further urologic evaluation.**

In normal men, the testes are firm and measure 15–25 mL in volume.<sup>424</sup> Small soft testes suggest testicular failure. Epididymal fullness suggests obstruction in men with azoospermia.<sup>425</sup> The diagnosis of CBAVD is made by physical examination alone and does not require scrotal sonography or exploration.<sup>308,309</sup> Palpation of the spermatic cord (erect and supine, with and without Valsalva) may reveal a varicocele,<sup>426</sup> which can be graded (grade 1–3) according to severity.<sup>427</sup> Digital rectal examination defines the size and symmetry of the prostate and may reveal the presence of midline cysts or dilated seminal vesicles suggesting ejaculatory duct obstruction.

**Transrectal ultrasonography** is indicated for the diagnosis of ejaculatory duct obstruction in men with severe oligospermia or azoospermia, palpable vasa, low-volume ejaculates, and normal testis volume, particularly when the semen is acidic and contains little or no fructose.<sup>307,428</sup> Vasography offers an alternative method for diagnosis of ejaculatory duct obstruction, but transrectal ultrasonography is less invasive and avoids the risk of vasal injury.<sup>429</sup> Observations of midline cysts, dilated seminal vesicles, or ejaculatory ducts suggest, but do not establish, the diagnosis of ejaculatory duct obstruction. Conversely, the absence of any such findings does not exclude the possibility. Seminal vesicle aspiration and vesiculography under transrectal ultrasound guidance provides the means to make a definitive diagnosis; any sperms retrieved can be cryopreserved for use in IVF with ICSI.<sup>430</sup> Definitive treatment requires transurethral resection of the ejaculatory ducts.<sup>431</sup>

**Transscrotal ultrasonography** can help to clarify uncertain physical findings or to confirm the presence of a scrotal mass. It also may reveal nonpalpable varicoceles, but there is no evidence to indicate they have clinical importance.<sup>282</sup>

**Renal ultrasonography** is indicated for men with unilateral or bilateral vasal agenesis. Approximately 25% of men with unilateral vasal agenesis and 10% of men with CBAVD have unilateral renal agenesis.<sup>432</sup>

**Testis biopsy** may be performed for diagnostic purposes in azoospermic men. Those with elevated serum FSH levels do not require a diagnostic biopsy because a high FSH concentration is diagnostic for abnormal spermatogenesis. Although biopsy may be performed to determine the likelihood that sperms can be retrieved for IVF with ICSI, results may not be all that helpful because sperm production can be limited to

specific foci within the testes. In contrast, diagnostic biopsy is indicated for azoospermic men with normal testicular size, at least one palpable vas deferens and a normal serum FSH level, because the normal FSH does not guarantee that spermatogenesis is normal. When biopsy is performed, a portion of testicular tissue can be cryopreserved for use in a future IVF/ICSI treatment cycle to avoid the need for a second procedure. A biopsy that reveals normal spermatogenesis implies obstruction at some level, which then must be defined by surgical exploration with or without vasography (see Surgical Treatment, below).<sup>307</sup>

# Genetic Evaluation

Genetic abnormalities may cause infertility by interfering with sperm production or transport. Currently, those most relevant to male infertility and its treatment include (1) mutations within the CFTR gene, which are highly associated with CBAVD, (2) chromosomal anomalies resulting in testicular dysfunction (Klinefelter syndrome; 47,XXY), and (3) Y chromosome microdeletions associated with abnormalities of spermatogenesis. These conditions have implications that extend beyond their association with azoospermia and severe oligospermia because they can have consequences for the offspring of affected couples. Ideally, genetic counseling should be offered both before and after genetic testing.

**Mutations of the CFTR gene are highly associated with CBAVD; almost all men with cystic fibrosis have CBAVD and at least two-thirds of men with CBAVD have a demonstrable CFTR mutation.**<sup>433,434</sup> The gene encodes a protein involved in the formation of the seminal vesicles and the reproductive ductal system in men. Although approximately 4% of Caucasian men carry a known CFTR gene mutation, clinical CBAVD is much less common because penetrance is low in heterozygous individuals.<sup>435</sup> Common speculation, and the prudent clinical assumption, is that virtually all men with CBAVD may have such mutations, some of which have a low carrier frequency and have simply not yet been defined. It is important to note that the spectrum of vasal aplasia includes not only CBAVD but also unilateral absence of the vas deferens, bilateral partial absence of the vas or epididymides, and epididymal obstruction. **Men with CBAVD or less severe forms of vasal aplasia, and their female partners, should be screened for CFTR mutations before any attempts at pregnancy via ART to determine the risk for transmitting cystic fibrosis or CBAVD to offspring.**

The overall prevalence of **chromosomal anomalies** in infertile men is approximately 7% and inversely related to sperm concentration; the prevalence is highest in azoospermic men (10–15%), lower in oligospermic men (approximately 5%), and very low in men with normal semen quality (<1%).<sup>436,437</sup> By far, the most common chromosomal anomaly in infertile men is Klinefelter syndrome (47,XXY, 46,XY/47,XXY), which accounts for about two-thirds of chromosomal abnormalities in infertile men.<sup>438</sup> Structural chromosomal abnormalities (translocations, inversions) make up the majority of the remainder.<sup>439</sup> The partners of affected men are at increased risk for miscarriage and birth of children with aneuploidy and congenital anomalies. **Karyotyping should be offered to men with nonobstructive azoospermia or severe oligospermia (<5 million/mL) before their sperms are used for IVF with ICSI.**<sup>307</sup> Embryo biopsy and preimplantation genetic diagnosis using fluorescence in situ

hybridization or other techniques to evaluate chromosomal composition can be used to identify normal embryos suitable for transfer.<sup>440</sup>

Approximately 8% of azoospermic and 2–5% severely oligospermic infertile men harbor a **Y chromosome microdeletion** that cannot be detected with a standard karyotype but can be identified using more sophisticated genetic techniques.<sup>226,227,441</sup> Most such microdeletions occur in regions of the long arm of the Y chromosome (Yq11), designated as AZF (azoospermic factor) a (proximal), b (central), and c (distal), which appear to include genes necessary for normal spermatogenesis.<sup>442</sup> Many men with microdeletions in the AZFc region are only severely oligospermic,<sup>443,444</sup> and those who are azoospermic generally produce sufficient sperms to allow their recovery by testis biopsy. In contrast, the prognosis for sperm recovery in men with microdeletions in the AZFa or AZFb region is very poor.<sup>445,446,447</sup> Microdeletions in the AZFd region are associated with normal spermatogenesis, and their clinical significance is unknown.<sup>448</sup>

Sons of men with Y chromosome microdeletions can be expected to inherit the defect and its clinical consequences.<sup>449,450,451</sup> Until recently, infertility was the only known clinical consequence of Y microdeletions, but a 1.6-Mb deletion that removes part of the AZFc region (known as the gr/gr deletion) now has been associated with an increased risk for developing testicular germ cell tumors.<sup>452</sup> **Screening for Y chromosome microdeletions should be offered to all men with nonobstructive azoospermia or severe oligospermia (<5 million/mL) who are candidates for IVF with ICSI.**<sup>307</sup>

# **MEDICAL TREATMENT FOR MALE INFERTILITY**

---

With a few specific and important exceptions, male infertility generally is not amenable to medical treatment. Careful evaluation can identify those men with treatable conditions who may benefit from medical therapy.

# Hypogonadotropic Hypogonadism

**Men with hypogonadotropic hypogonadism represent one group in which medical treatment can be successful, after its cause has been defined.** Most affected men have a congenital isolated gonadotropin deficiency associated with abnormal puberty, due to absent or abnormal pulsatile hypothalamic GnRH secretion. The endocrinopathy may be genetic in origin, resulting from failure of GnRH neuronal migration during embryogenesis (Kallmann syndrome),<sup>453</sup> or idiopathic. When the disorder has onset after puberty, affected men are virilized but hypogonadal, impotent, and azoospermic.

Postpubertal hypogonadotropic hypogonadism is uncommon but may arise as the consequence of a hypothalamic or pituitary tumor or an inflammatory process (sarcoidosis, hemochromatosis, autoimmune hypophysitis).<sup>454</sup> Pituitary tumors, specifically prolactinomas, are the most common cause. Men with prolactinomas often present with impotence and androgen deficiency. In contrast to the microadenomas commonly identified in women, tumors in men are more often large (macroadenomas). The hypogonadism associated with hypothalamic or pituitary mass lesions may result from hyperprolactinemia and disruption of pulsatile GnRH secretion or from direct effects on the pituitary via compression of pituitary gonadotropes.

Hypogonadotropic hypogonadism due to hyperprolactinemia is generally uncommon in infertile men (approximately 1%)<sup>455</sup> but is amenable to treatment with dopamine agonists when it is identified. Treatment with bromocriptine or cabergoline can effectively restore normal prolactin and testosterone levels and, subsequently, improve libido, potency, semen quality, and fertility in hyperprolactinemic hypogonadal men.<sup>456,457,458,459</sup> Increased testosterone levels and potency are observed within approximately 3–6 months after normal prolactin levels are achieved; changes in semen quality generally take longer.<sup>458,459</sup> Improved semen quality may be expected, but not all men achieve normal semen parameters. In eugonadal infertile men with mild hyperprolactinemia, dopamine agonist treatment promptly restores normal prolactin levels but has little effect on semen quality.<sup>455,460</sup> Although prolactin levels are modestly higher in infertile than in fertile men, there is no evidence to indicate that dopamine agonist treatment in euprolactinemic men with idiopathic oligospermia or asthenospermia can improve semen quality or fertility.<sup>461</sup>

**Because concerns regarding delayed puberty generally arise well before any active interest in fertility, most men with congenital hypogonadotropic hypogonadism are treated first with hCG (to stimulate Leydig cell testosterone production) or exogenous testosterone; either can induce secondary sexual development, but neither can initiate and support normal spermatogenesis.**

**In contrast, hCG alone (2,000–5,000 IU three times weekly) often can restore meaningful spermatogenesis in men with adult onset of hypogonadotropic hypogonadism.**<sup>462,463</sup> Treatment always should begin with hCG alone (as a substitute for LH), without FSH, for several reasons: (1) hCG stimulates Leydig cells to produce testosterone, resulting in the high intratesticular testosterone concentrations required to stimulate and support spermatogenesis; (2) whereas hCG alone may be sufficient to stimulate spermatogenesis, FSH alone is not<sup>63</sup>; and (3) the annual costs of hCG treatment are substantially lower than the costs of treatment with human menopausal gonadotropins (hMG containing both FSH and LH) or recombinant FSH. During treatment, the serum testosterone concentration should be measured every 1–2 months for the first 3–4 months, aiming for a level between 400 and 900 ng/dL. If not achieved within that interval, dosage should be adjusted accordingly. Some require doses as low as 500 IU and others as much as 10,000 IU. The sperm count also should be monitored at regular intervals. In most, a normal sperm count can be restored within 6 months, but some require treatment for up to 24 months.<sup>464</sup> However, even low sperm concentrations do not preclude fertility.<sup>465</sup>

**In men with congenital hypogonadotropic hypogonadism and those with postpubertal onset who do not respond to treatment with hCG alone, normal spermatogenesis can be induced by combined treatment with hCG and hMG or pure FSH (75–150 IU three times weekly).**<sup>63,466</sup> Treatment with exogenous testosterone and FSH is ineffective because it cannot generate the highly concentrated intratesticular testosterone concentrations required for normal spermatogenesis.<sup>63</sup> The sperm count should be monitored at least monthly to detect a meaningful trend, because concentrations can fluctuate. As with hCG-only treatment, maximum sperm concentrations generally are achieved within 6–24 months. Once spermatogenesis is established by combined treatment with hCG and FSH/hMG, it can be maintained by hCG alone for extended intervals, although semen quality gradually declines again without further FSH treatment.<sup>467</sup>

**Men with hypogonadotropic hypogonadism unrelated to hyperprolactinemia or a hypothalamic or pituitary mass lesion also can be treated with exogenous pulsatile GnRH therapy,**<sup>468,469</sup> generally administered subcutaneously via a portable programmable pulsatile infusion pump in doses individually titrated to maintain normal adult male serum LH levels.<sup>470,471</sup> Treatment with pulsatile exogenous GnRH can successfully restore normal levels of gonadotropin secretion and thereby induce testosterone production and spermatogenesis. Although it is a very specific treatment for men with deficient endogenous GnRH secretion, exogenous pulsatile GnRH therapy is costly, is cumbersome, and may require extended periods of time to achieve the desired result. Normal serum gonadotropin levels can be achieved

within little more than a week of treatment and normal serum testosterone concentrations within just a few weeks, but stimulation of spermatogenesis takes considerably longer.<sup>472,473</sup> Evidence of spermatogenesis may be observed within a year after treatment with pulsatile exogenous GnRH begins, but up to 2 years of therapy may be required to achieve maximum testicular growth, spermatogenesis, and fertility. The best predictors of response are a postpubertal onset of hypogonadotropic hypogonadism, absence of cryptorchidism, and a serum inhibin B concentration greater than 60 pg/mL.<sup>469,474</sup> Pulsatile GnRH and gonadotropin treatment have comparable efficacy for stimulating spermatogenesis.<sup>475,476</sup>

# Eugonadotropic Hypogonadism

Men with severe oligospermia (<5 million sperms/mL), low serum testosterone levels (<300 ng/dL), and an abnormally low serum testosterone (ng/dL)/estradiol (pg/mL) ratio (<10) may benefit from medical treatment with an aromatase inhibitor. In such men, treatment (testolactone 50–100 mg twice daily, anastrozole 1 mg daily) can normalize ratios and improve semen quality.<sup>422,423</sup>

# Hypergonadotropic Hypogonadism

**There is no evidence that any form of medical treatment can improve semen quality and fertility in infertile men with hypergonadotropic hypogonadism.** For men with complete spermatogenic failure, the only treatment options are insemination with donor sperms and adoption. For those with severe oligospermia, IVF with ICSI still may offer a realistic chance for success, but preliminary genetic evaluation is strongly recommended, as described earlier.

# Retrograde Ejaculation

Men with documented retrograde ejaculation may benefit from medical treatment with sympathomimetics (imipramine 25 mg twice daily or 50 mg at bedtime, pseudoephedrine 60 mg or ephedrine 25–50 mg four times daily, phenylpropanolamine 50–75 mg twice daily), directed at control of the internal sphincter. Alternatively, sperms can be recovered directly from the bladder after masturbation; for best results, urine pH and osmolality (300–380 mOsm/L) must be carefully controlled by alkalinizing the urine (sodium bicarbonate 650 mg four times daily, beginning 1–2 days before collection) and managing fluid intake.<sup>477,478</sup> When such efforts prove cumbersome or ineffective, the bladder can be drained and filled with buffered medium (approximately 100 mL) immediately before ejaculation. In men with ejaculatory failure, electroejaculation may be required.<sup>479</sup> If sufficient numbers of motile sperms can be recovered, IUI may be performed, and if not, IVF and ICSI may be necessary.

# Leukocytospermia

Leukocytospermia has been associated with other abnormal semen parameters,<sup>480</sup> and antibiotic treatment (doxycycline, erythromycin, trimethoprim-sulfamethoxazole, or a quinolone) clearly is indicated for men with symptomatic genital tract infections. **However, antibiotic treatment does not improve semen parameters in men with asymptomatic leukocytospermia<sup>481</sup> and often fails even to decrease the numbers of leukocytes to normal levels (<1 million/mL).<sup>482,483</sup>** Leukocytospermia often is episodic and does not accurately predict genital tract infection.<sup>484</sup> Moreover, there is little evidence it has any adverse effects on fertility.<sup>485</sup> Treatment therefore probably is best limited to men with documented genital tract infections.

# Idiopathic Male Infertility

Most infertile men are eugonadotropic, normally virilized, and otherwise healthy but have low sperm density or other semen abnormalities for which the cause is unknown. Idiopathic male subfertility is common, and a wide assortment of empiric medical treatments has been described; androgens, gonadotropins, and antiestrogens have received the most attention. **Unfortunately, no medical treatment has proven reliably effective for improving semen parameters or fertility in men with idiopathic subfertility.**

**Androgen therapy** has been advocated as a means to stimulate spermatogenesis, directly by increasing intratesticular androgen concentrations and indirectly via a “rebound” increase in pituitary gonadotropin secretion after an interval of androgen-induced suppression. However, the results of a meta-analysis of 11 randomized clinical trials involving almost 1,000 men indicate that neither treatment strategy reliably improves semen parameters or fertility.<sup>486</sup> There is no substantial evidence that androgen therapy is an effective treatment for idiopathic male infertility.<sup>487</sup>

Results of studies involving the use of **exogenous FSH** to stimulate spermatogenesis directly have been conflicting. Whereas two randomized trials in subfertile men found no evidence that such treatment improves semen quality or fertility,<sup>488,489</sup> others suggest that exogenous FSH may improve semen quality in a subset of men with idiopathic oligospermia in whom testicular biopsy reveals maturation arrest and serum FSH and inhibin B levels are normal.<sup>490,491,492</sup>

Empiric treatment (3–6 months) with either **clomiphene citrate** (25 mg daily) or **tamoxifen** (20 mg daily) commonly is offered to stimulate increased pituitary gonadotropin secretion and spermatogenesis in men with idiopathic subfertility. The results of numerous studies are inconsistent. Whereas treatment appears to benefit some men, there is no reliable method for identifying those who might respond. **Overall, antiestrogen treatment is not effective.** A randomized clinical trial conducted by the WHO involving nearly 200 men and over 1,300 couple-months of observation found no differences among men treated with clomiphene or placebo.<sup>493</sup> Moreover, a meta-analysis including 10 randomized trials involving over 700 men concluded that evidence is insufficient to indicate that antiestrogen treatment improves semen quality or male fertility.<sup>494</sup>

# INTRAUTERINE INSEMINATION

---

Artificial insemination has been used to treat infertile couples for almost 200 years and is an accepted form of treatment for men with severe hypospadias, retrograde ejaculation, neurologic impotence, and sexual dysfunction. Artificial insemination also has been used as a means to overcome oligospermia, asthenospermia, low ejaculate volumes, sperm autoantibodies, and cervical factors. Therapeutic insemination using donor sperms is an established and highly effective treatment for severe and uncorrectable male factor infertility, inherited genetic disorders in the male partner, and single or lesbian women who desire pregnancy. Before the advent of IVF and ICSI, therapeutic donor insemination was the only viable treatment option for couples with severe male factor infertility, and it remains highly effective when ART is rejected or fails.<sup>495</sup>

Artificial insemination may be performed by depositing sperms into the cervical os or directly into the uterus, but IUI is now almost universally performed, for several reasons. First, when trying to overcome the limitations of decreased sperm density or motility in the treatment of male factor infertility, cervical insemination offers no significant advantage over what can be achieved by intercourse. Second, whereas the potential for reactions to the proteins, prostaglandins, and bacteria in semen severely limits the volume of untreated semen (and thus the numbers of sperms) that can be delivered to the upper female genital tract, IUI with a “washed” sperm concentrate (devoid of seminal plasma) delivers most of the sperms in an ejaculate. **Most importantly, IUI yields substantially better overall results than does cervical insemination.** In one meta-analysis including 12 separate studies involving nearly 700 women and over 2,000 insemination cycles, the overall pregnancy rate per cycle was 18% for women receiving IUI, compared to 5% for women who received cervical insemination; considering only the 10 studies in which frozen donor sperms were used, the pregnancy rate per cycle with IUI was more than twice that of cervical insemination (OR = 2.63, 95% CI = 1.85–3.73).<sup>496</sup> An earlier analysis including seven studies yielded similar results (OR = 2.4, 95% CI = 1.5–3.8).<sup>497</sup>

It is difficult to gauge the effectiveness of IUI using the sperms of infertile men because almost all of the many published series examining IUI cycle outcomes have included couples with a variety of infertility factors and have employed combined treatment with IUI and empiric ovarian stimulation. There are ample data from retrospective studies of outcomes in therapeutic donor insemination cycles (IUI with or without ovarian stimulation), but the results achieved using infertile partner sperms cannot be expected to equal those using normal donor sperms. **Considering all of the relevant variables, the available data suggest that cycle fecundity ranges between**

**3% and 10% when IUI is performed using infertile partner sperms<sup>326,498,499,500,501</sup> and is approximately 3 times higher (9–30%) when donor sperms are used.<sup>501,502,503,504,505,506,507</sup>**

Regardless whether infertile partner sperms or frozen donor sperms are used, the methods for sperm preparation, the timing and technique of IUI, and the influence of other infertility factors on prognosis are largely the same. The number, motility, and morphology of frozen donor sperms generally are not limiting because sperm donors are highly selected for their semen quality, but semen parameters definitely do affect the prognosis for success with IUI using infertile partner sperms.

# Semen Parameters and Prognosis

Not surprisingly, the likelihood for success with IUI using infertile partner sperms depends, to some extent, on the severity of the semen abnormality. Sperm density, motility, and morphology all have influence on success rates.

The probability of successful IUI increases with the number of total motile sperms inseminated. **Best results are achieved when the number of total motile sperms exceeds a threshold of approximately 10 million.**<sup>326,328,498</sup> Higher counts do not further increase the likelihood for success<sup>498,508</sup> and IUI is very seldom successful when fewer than 1 million total motile sperms are inseminated.<sup>499,509</sup> Combining the yield from two ejaculates obtained approximately 4 hours apart may increase the numbers of sperms available from oligospermic men.<sup>510</sup>

As might be expected, considering that strict sperm morphology has some predictive value for successful conventional fertilization in vitro,<sup>332,333</sup> the percentage of morphologically normal sperms (strict criteria)<sup>305</sup> appears to have similar predictive value for IUI. Numerous studies have examined the correlation between strict sperm morphology and IUI cycle outcomes. Most,<sup>350,351,352,353,511</sup> but not all,<sup>354,355</sup> have found a strong relationship between the two. Like the results observed in IVF cycles, the probability for success with IUI rises with the percentage of morphologically normal sperms. **Success rates with IUI are highest when 14% or more of the sperms have normal morphology, intermediate with values between 4% and 14%, and generally quite poor when fewer than 4% of sperms are normal.**<sup>350</sup> In general, therefore, couples with male factor infertility involving severe teratospermia (<4% normal sperms) may be best advised to apply their available resources to IVF and ICSI when that is possible.

## Other Prognostic Factors

Needless to say, the prognosis for success with IUI in the treatment of male factor infertility is best when there are no other coexistent infertility factors. Most specifically, the prognosis is greatly influenced by the age of the female partner, the consistency and quality of her ovulatory function, and the condition of her reproductive anatomy. The extent to which these additional factors should be evaluated before treatment with IUI begins must be individualized.

### Maternal Age

Maternal age is a key variable in all infertile couples. Even when donor sperms are used, the probability for success declines progressively with increasing maternal age.<sup>503,506,512,513,514</sup> Cycle fecundability and cumulative pregnancy rates in women under age 35 inseminated with donor sperms (20% per cycle, 88% after up to 7 cycles) equal those observed in normal fertile couples but are lower for women between ages 35 and 40 (12% per cycle, 65%) and those over age 40 (6% per month, 42%).<sup>515</sup> Ovarian reserve testing ([Chapter 27](#)) merits consideration when the female partner is over age 35; has a family history of early menopause, previous ovarian surgery, chemotherapy, or radiation; and is a smoker or previously has responded poorly to exogenous gonadotropin stimulation. Women with a poor ovarian reserve have a significantly reduced probability for success with IVF and, by inference, likely have a relatively poor chance for success with IUI.

### Ovulatory Function

**At a minimum, it is certainly prudent to assess ovulatory function by some objective means when the treatment plan does not include empiric ovarian stimulation (discussed below).** Ovulatory disorders are common, even in women seeking therapeutic donor insemination.<sup>513,515,516,517</sup> Ovulation induction increases success rates with therapeutic donor insemination for women with ovulatory dysfunction,<sup>516</sup> although cycle fecundability remains lower than in women with spontaneous ovulatory cycles.<sup>512,518</sup>

### Uterine and Tubal Factors

**Hysterosalpingography (HSG) is recommended for women over age 35 and when the medical history or physical examination raises suspicion of endometriosis or uterine or tubal infertility factors because IUI is less likely to succeed in couples with combined male factor and tubal factor infertility; IVF, with or without ICSI,**

**usually is a better treatment option.** In the absence of such suspicions, the likelihood of abnormal HSG results is quite low.<sup>519</sup> If not performed before treatment begins, HSG is recommended for women who fail to conceive after 4–6 therapeutic donor insemination cycles. Laparoscopy and hysteroscopy are unnecessary for most women but appropriate for those with an abnormal HSG or signs or symptoms of advanced pelvic disease.

# Empiric Ovarian Stimulation

Empiric ovarian stimulation with clomiphene citrate or exogenous gonadotropins is commonly combined with IUI in the treatment of couples with male factor infertility, based on observations that cycle fecundability (probability of pregnancy per cycle) is higher after combined treatment than after IUI or ovarian stimulation alone in couples with unexplained infertility.<sup>500,520,521</sup> Although the value added by ovarian stimulation when IUI is performed using infertile partner sperms is unproven, data derived from large case series of therapeutic donor insemination cycles provide some useful insight.

The cycle fecundability observed in spontaneous and clomiphene-stimulated therapeutic donor insemination cycles is similar (6–13%),<sup>503,522,523</sup> suggesting that clomiphene stimulation has little or no added value. It is possible, but unproven, that clomiphene treatment might have benefits limited to cycles in which it achieves multifollicular development and ovulation. In contrast, exogenous gonadotropin stimulation appears to increase cycle fecundability in therapeutic donor insemination cycles approximately twofold (14–24%).<sup>503,522,523,524</sup> However, the risks (multiple ovulation, ovarian hyperstimulation), costs, and logistical demands associated with gonadotropin treatment are also substantially higher.

The outcomes observed in large case series strongly suggest that exogenous gonadotropin stimulation increases cycle fecundability in therapeutic donor insemination cycles, particularly because combined treatment generally has been added only after inseminations in spontaneous cycles proved unsuccessful. Equivalent or better outcomes have been observed after gonadotropin stimulation even though comparisons were biased against combined treatment because the selected population already had demonstrated intrinsically lower fertility.<sup>503,522,523</sup> In one randomized trial, cycle fecundability in gonadotropin-stimulated cycles (14%) was more than twice that observed in clomiphene-stimulated cycles (6%).<sup>524</sup> By inference, gonadotropin stimulation also might be expected to improve cycle fecundability when IUI is performed using infertile partner sperms. However, because the poorer quality of infertile partner sperms may be the limiting factor, gonadotropin stimulation may have less value than in therapeutic donor insemination cycles.

**When male factor infertility is the diagnosis, and ovulatory function is normal, treatment with IUI alone is reasonable and appropriate. When IUI in spontaneous cycles or indicated clomiphene-induced cycles fails (approximately 3–4 cycles) or when the female partner is over age 35, exogenous gonadotropin stimulation may be expected to improve the likelihood for success.**

# Sperm Preparation

There are a variety of methods for extracting sperms from the seminal plasma for IUI. The most common methods include conventional washing, the “swim-up” procedure, and density gradient centrifugation. The best choice among them may vary with the quality of the semen sample.<sup>525,526</sup> The results of a randomized study comparing the pregnancy rates achieved with IUI after a variety of sperm preparation methods suggest that swim-up and density gradient centrifugation may offer a greater chance for success than conventional sperm washing.<sup>525</sup> Another study found that density gradient centrifugation yielded better results than does conventional washing when the insemination specimen contains less than approximately 20 million sperms.<sup>526</sup> However, a meta-analysis including 5 trials involving over 250 couples and comparing 3 techniques concluded that evidence is insufficient to recommend any specific preparation technique.<sup>527</sup> Results achieved with IUI using cryopreserved donor sperms are comparable, regardless whether the sperms are prepared before freezing or after thawing.<sup>504</sup>

Both the conventional washing and swim-up methods allow sperms to remain in contact with dead or defective sperms and leukocytes, which produce high levels of reactive oxygen species that may cause oxidative damage to sperms membranes and motility.<sup>528,529</sup> **Whereas methods more sophisticated than conventional washing or swim-up may be used to prepare sperms (density gradient centrifugation, glass wool filtration, others), and often are used when preparing sperms for IVF,<sup>530</sup> they generally are not required for IUI.**

## Washing

The simplest method of washing sperms involves diluting the liquefied semen sample in buffered medium (available from a number of commercial suppliers) in a sterile tube (1:1–1:3, depending on volume), followed by low-speed centrifugation (200–300g for approximately 10 minutes) and removal of the supernatant. After two or more cycles, the final pellet is resuspended in a small volume (approximately 0.5 mL) of medium for insemination. Sperm washing yields the greatest numbers of sperms, but the final specimen also contains dead and abnormal sperms and other cellular debris. When sperm viability or motility is abnormally low or the round cell concentration in the semen is abnormally high, methods to exclude them from the insemination specimen deserve consideration.

## Swim-Up

The swim-up method for preparing sperms adds another step to the washing process. The final pellet is gently overlaid with 0.5–1.0 mL of fresh medium and incubated at 37°C for 30–60 minutes, allowing the most motile sperms to swim up into the supernatant.<sup>531</sup> The method generates a cleaner specimen, devoid of dead sperms and other cellular debris, but also yields significantly lower numbers of sperms (albeit with high motility) and therefore may be inadvisable when the sperm concentration is already very low.

## **Density Gradient Centrifugation**

The typical methodology for density gradient centrifugation involves overlaying the liquefied ejaculate on a column of higher-density media that are layered to create a gradient of increasing density from the top to the bottom of the column, followed by low-speed centrifugation for 15–30 minutes.<sup>532</sup> The most highly motile sperms traverse the gradient more rapidly and can be recovered from the soft pellet at the bottom. The method also appears to select a population of sperms with normal morphology.<sup>533,534</sup> As with the swim-up procedure, the sperm yield is substantially lower than with conventional washing.

## Timing and Technique

For obvious reasons and for best results, IUI should be timed to coincide with the time of spontaneous or induced ovulation. Normal sperms can survive in the female reproductive tract and retain the ability to fertilize an egg for at least 3 days, but an oocyte can be successfully fertilized for only approximately 12–24 hours after it is released.<sup>535</sup> In normal fertile couples, the probability of conception rises progressively over an interval of 5–6 days and peaks when intercourse occurs on the day before or day of ovulation.<sup>80,536,537</sup> The longevity of normal sperms in the female genital tract relates, in part, to their retention within the cervical mucus, which, of course, is bypassed by IUI. Although unproven, there is reason to believe that sperms may have a significantly shorter functional lifespan after IUI. Logically, the lower numbers and motility of infertile partner sperms may be even more limiting. Cryopreservation damages sperms,<sup>538</sup> and even frozen-thawed donor sperms lose viability and motility more rapidly than do fresh normal sperms. **The timing of IUI in the treatment of male factor infertility is therefore far more critical for success than the timing of natural intercourse in infertile couples, regardless whether infertile partner sperms or frozen donor sperms are used.**

The various methods that may be used to detect ovulation and to ensure that IUI is optimally timed are described at length elsewhere in this text ([Chapter 27](#)); only the most commonly used methods and their relationship to the time of ovulation are again briefly summarized here. Ovulation generally may be expected to occur on the day before the midcycle rise in basal body temperature (BBT)<sup>80,537</sup> or 14–26 hours after the urinary LH surge is first detected.<sup>539,540</sup> **In natural and clomiphene-stimulated cycles, the most practical and reliable method for timing IUI involves urinary LH monitoring beginning approximately 3 days before expected ovulation and insemination on the day following detection of the LH surge. When ovulation is triggered by injection of exogenous hCG in natural or stimulated cycles, IUI generally is best performed approximately 34–40 hours later.**

Immediately before performing IUI, removal of any excess mucus that might clog the catheter tip is recommended. The tip of the insemination catheter is then simply inserted into the cervical os and advanced slowly into the uterine cavity. A large variety of specialized catheters having varying rigidity is readily available from commercial sources and any may be used. Designs involving a stiffer moldable outer sheath over a more atraumatic and flexible inner catheter are the most versatile. The insemination specimen (approximately 0.5 mL) should be introduced slowly over 10–30 seconds. Although there are no data to indicate that it matters, it is customary to have the patient remain supine for approximately 10–15 minutes after insemination.

Although some have suggested that two inseminations (12 and 34 hours after hCG-induced ovulation) yield a higher cycle fecundability than a single IUI,<sup>541</sup> other similarly designed studies have found no such advantage.<sup>542,543,544</sup> A meta-analysis including 3 randomized controlled parallel trials involving nearly 400 couples concluded that available data do not allow a confident conclusion.<sup>545</sup> Two studies of cycle fecundability after therapeutic donor inseminations have observed that two inseminations are no more effective than one.<sup>546,547</sup>

Most women who pursue therapeutic donor insemination are otherwise fertile and conceive within 4–6 insemination cycles; cycle fecundability declines by half to two-thirds thereafter.<sup>515,548,549,550</sup> Cumulative conception rates after up to 12 insemination cycles reach 75–80%<sup>503,505,515</sup> but are approximately 50% lower for those having other infertility factors.<sup>513</sup> Combined with gonadotropin stimulation, donor insemination succeeds in more than half of treated couples achieving superovulation after up to three cycles.<sup>550</sup> As expected, success rates for insemination with infertile partner sperms are significantly lower but may still approach 30% after up to six treatment cycles.<sup>499</sup> The number of treatment cycles offered must consider the influence of female partner age, coexisting infertility factors, the duration of infertility, the quality of the insemination specimen, and the number of mature preovulatory follicles when ovarian stimulation also is used.

# Donor Sperms

In general, commercial and university-based sperm banks recruit healthy young donors having desirable general physical characteristics and consistently outstanding semen quality. However, it is important to understand that whereas sperm banks generally adhere to the guidelines established by the American Society for Reproductive Medicine,<sup>551</sup> they remain, at present, self-regulated. The choice of a sperm bank should therefore consider whether it has formally adopted the established guidelines.

Current guidelines require extensive screening of prospective sperm donors before acceptance. Semen quality, to include an evaluation of sperm viability and motility after a trial freeze and thaw,<sup>538,552</sup> excludes approximately 75% of all candidates. Personal health history and physical examination, family medical history, genetic screening for cystic fibrosis and other carrier states (depending on ethnicity), and screening for sexually transmitted infections (syphilis, gonorrhea, Chlamydia, cytomegalovirus, hepatitis B and C, HIV types I and II, and human T-lymphocytic virus [HTLV] types I and II), which is regulated by the Food and Drug Administration (FDA) in the United States, exclude another 5–10% of candidates. Sperm donors must be screened repeatedly for sexually transmitted infections at intervals, generally every 6 months. Sperm banking practices changed forever in 1985 after documentation of HIV seroconversion in four of eight women inseminated with cryopreserved sperms from an asymptomatic HIV (then called HTLV-III) carrier.<sup>553</sup> **Now, sperm specimens must be quarantined and cannot be released for use unless they have remained sequestered for at least the 180 days preceding the most recent negative test for HIV.** Even with rigorous adherence to current guidelines, human semen can never be regarded as completely safe. Although perhaps remote, the possibility remains that frozen donor sperm specimens may contain other microorganisms not generally considered as sexually transmitted infections or as yet unknown viruses.

Ideally, donor-specific cycle fecundability rates, which may vary significantly, also would be defined after a reasonable number of inseminations.<sup>552,554</sup> However, such information generally is not available, primarily because outcomes of donor inseminations are difficult to track accurately and vary substantially among recipients, depending on age and the presence or absence of other infertility factors. In the absence of such information, it is reasonable to select an alternative donor after four to six unsuccessful insemination cycles when there are no other coexisting infertility factors.

**Although the quality of frozen donor sperm specimens generally is reliable, it should not be assumed.** Frozen donor sperm specimens typically do not include all of the sperms in an ejaculate; a number of aliquots are prepared from each sample, depending on its quality. One study found a tenfold variation in the number of motile

sperms in random specimens obtained from seven different commercial sperm banks (4.3–39 million).<sup>555</sup> As when using infertile partner sperms, the likelihood of success with therapeutic donor insemination increases with the number of motile sperms in the specimen and is greatest when the count exceeds 20 million.<sup>515</sup> Most sperm banks guarantee a minimum number of motile sperms in each specimen, but that guarantee is not always met and only implies a refund of the purchase price when it is not. Consequently, it is prudent to determine the motile sperm count after thaw of donor sperm samples and to seek an alternative source when quality consistently falls below a reasonable minimum standard (10 million total motile sperms).

# SURGICAL TREATMENT FOR MALE INFERTILITY

---

Although IVF with ICSI now provides the means to treat even the most severe forms of male factor infertility, including irreparable reproductive tract obstruction and nonobstructive azoospermia, the associated costs and risks are substantial. For men with obstructive azoospermia or a varicocele, specific surgical treatment offers a viable alternative, but proper patient selection is key.<sup>556,557,558,559</sup>

# Vasovasostomy and Vasoepididymostomy

**About one-half million American men undergo vasectomy every year and approximately 2–6% of vasectomized men later seek reversal of their sterilization procedure.** Obstructive azoospermia also may result from iatrogenic injuries to the vas deferens, usually during hernia repair.<sup>284</sup>

In most vasectomized men, microsurgical vasovasostomy or vasoepididymostomy can restore patency of the ductal system and return sperms to the ejaculate. When microscopic examination of the fluid in the testicular end of the vas reveals no sperms even after lavage, vasoepididymostomy can be performed.<sup>560</sup> When sperms are found in the vasal fluid on at least one side, microsurgical vasovasostomy returns sperms to the ejaculate in nearly all vasectomized men<sup>561</sup>; late obstruction after initial patency may be observed in up to 12% of men.<sup>562</sup> **Over 2 years or more after vasovasostomy, pregnancy rates in the range of 50–60% may be expected, depending on whether other infertility factors also must be overcome.**<sup>563</sup> The likelihood of pregnancy decreases modestly with time since vasectomy, but not dramatically; for most, surgery offers comparable or better results than can be achieved with IVF and ICSI.<sup>564,565</sup> The results of reoperation may approach the same outcomes when the first attempt is technically unsuccessful.<sup>566</sup> Compared to vasovasostomy, vasoepididymostomy is less often successful, with patency rates between 50% and 85%, pregnancy rates between 40% and 50%, and a greater likelihood of reocclusion, depending on the site of anastomosis.<sup>556,567</sup> Newly described tubal intussusception techniques have simplified the procedure and yielded excellent patency rates.<sup>568,569</sup> Cryopreservation of sperms collected at the time of vasectomy reversal offers those with failed procedures the opportunity to pursue pregnancy by IVF and ICSI without further intervention.<sup>567,570</sup>

# Transurethral Resection of the Ejaculatory Ducts

Ejaculatory duct obstruction is a cause of infertility in 1–5% of infertile men<sup>571</sup> and should be suspected in men with normal, palpable vasa deferentia and semen analyses revealing low ejaculate volumes combined with low or normal sperm concentration and low or absent motility.<sup>572</sup> The condition also may present as hemospermia and painful ejaculation. Ejaculatory duct obstruction usually is congenital but also can result from chronic prostatitis or compression by prostate or seminal vesicle duct cysts and from duct calcification or blockage due to postinfectious or postoperative scar and may be amenable to correction by transurethral resection.<sup>573,574</sup>

Methods for evaluating suspected ejaculatory duct obstruction include transscrotal vasography (antegrade or retrograde injection of contrast medium into the vas deferens or seminal vesicle), transrectal ultrasonography (to detect an enlarged seminal vesicle), and seminal vesicle sperm aspiration and ejaculatory duct chromotubation. A study comparing the accuracy of the methods found that diagnosis by transrectal ultrasonography was confirmed at surgery in fewer than half of cases and concluded that dynamic tests (vasography, chromotubation) can decrease unnecessary duct resection procedures and improve the outcomes of those that are indicated.<sup>575</sup>

Transrectal ultrasound-guided aspiration of cystic or dilated ejaculatory ducts or seminal vesicles and microscopic examination of the aspirate may yield sperms that can be cryopreserved.<sup>430</sup> Subsequent introduction of indigo carmine dye diluted in radiographic contrast and x-ray provides the means to define the lesion and to confirm successful surgical resection. When no sperms are found, vasography may be performed, and if ejaculatory duct obstruction is confirmed, a coincident epididymal obstruction is likely. Under such circumstances, microsurgical epididymal sperm aspiration or testis biopsy and cryopreservation of sperm for IVF and ICSI generally is a better option than simultaneous epididymovasostomy and transurethral resection of the ejaculatory ducts.

**Transurethral resection of an ejaculatory duct obstruction results in increased semen volume in approximately two-thirds of affected men and returns sperms to the ejaculate in about half of azoospermic men.** Results are better in men with midline cysts and men with partial obstruction than in those with complete obstructions. Whereas IVF and ICSI are obvious alternatives to transurethral resection, successful surgery can allow many men to conceive naturally or by IUI without need for ART.<sup>576</sup>

# Varicocele Repair

The prevalence of varicoceles is approximately 10–15% in the normal male population and about 25–40% in infertile men.<sup>307,427</sup> The weight of available evidence indicates that varicoceles have an adverse effect on spermatogenesis. The pathophysiology involved is unclear but widely believed to involve venous reflux and increased testicular temperatures because spermatogenesis is exquisitely temperature sensitive. **Since only palpable varicoceles have any documented association with infertility, other means of diagnosis (scrotal ultrasonography, thermography, Doppler ultrasonography, radionuclide scanning, and spermatic venography) generally are not indicated for infertile men with no palpable varicocele.** Scrotal ultrasonography may be useful when physical examination is inconclusive and spermatic venography can help to better define the location of refluxing spermatic veins that recur or persist after repair.<sup>307</sup>

**Varicocele repair is considered primarily for men with palpable varicoceles and abnormal semen parameters having either a partner with normal fertility or treatable infertility or an interest in future fertility.** Adolescent males with unilateral or bilateral varicoceles associated with decreased testicular size also may be candidates for varicocelectomy; those with normal testicular size should be followed carefully to detect any decrease in testicular size or semen quality.<sup>577,578</sup> Similarly, young adult men with palpable varicoceles and normal semen may be at risk for progressive testicular dysfunction and should be monitored to detect any evidence of decreasing semen quality.<sup>426,579,580</sup>

**Treatment options for men with abnormal semen quality associated with a palpable varicocele include surgical repair, IUI, and IVF with or without ICSI. The best choice among these options depends on the age of the female partner and presence of other infertility factors.** Varicocelectomy offers the potential advantages of a permanent cure and natural conception.<sup>558</sup> Even when there are other clear female partner indications for IVF, varicocele repair may deserve consideration because surgery can restore sperms to the ejaculate in some men with nonobstructive azoospermia.<sup>581,582</sup>

Varicoceles can be repaired with a variety of surgical approaches (retroperitoneal, inguinal, subinguinal, laparoscopic) or by percutaneous embolization. No one method has proven clearly superior. Most male reproductive specialists prefer microsurgical inguinal or subinguinal repair.<sup>583</sup> Percutaneous embolization of varicoceles requires expertise in interventional radiologic techniques and is not universally applicable. Surgical treatment corrects over 90% of varicoceles; results achieved with

embolization are more variable.

Semen quality often improves after varicocele repair<sup>584</sup> and men with large varicoceles generally realize the greatest improvement.<sup>585</sup> **However, the results achieved with varicocele repair have varied widely and convincing evidence for improved fertility is still lacking.**<sup>558,586,587,588</sup> The results of two randomized trials in men with palpable varicoceles, abnormal semen parameters, and normal female partners are perhaps the most informative. In one, 60% of men who underwent surgical repair achieved pregnancy with their partner during the first postoperative year, compared to only 10% of untreated controls; after surgical repair of varicoceles in the still infertile men not initially treated, more than 40% achieved pregnancy during the following year.<sup>589</sup> In the second trial, men who underwent varicocele repair had improved semen parameters compared to untreated controls but were no more likely to achieve pregnancy.<sup>590</sup> **In general, the best candidates for varicocele repair are young men with large varicoceles and infertility of relatively short duration. Atrophic testes, elevated FSH levels, and severe oligospermia or azoospermia indicate severe epithelial damage and are associated with a poor prognosis after varicocele repair.**

One other potential benefit of varicocelectomy deserves mention. Even when varicocele repair is not followed by natural conception, improvement in semen parameters may be sufficient to allow IUI when IVF would otherwise be necessary, or IVF with conventional fertilization rather than with ICSI.<sup>591</sup>

# Orchiopexy

Cryptorchidism is associated with a high incidence of infertility even when it is unilateral; when both testes are undescended, azoospermia is all but certain. Occasionally, an undescended testis will escape detection until adulthood; if the contralateral testis is normal, fertility may be preserved. Even in adult men with bilateral cryptorchidism, orchiopexy can result in spermatogenesis and fertility; at the least, it preserves testicular hormone production.<sup>592</sup>

# **Vibratory Stimulation and Electroejaculation**

Men with neurologic conditions affecting the sympathetic system frequently have dysfunctional or absent emission. Examples include men with spinal cord injuries, demyelinating neuropathies, and diabetes and those who have had retroperitoneal lymph node dissections. In most, ejaculation can be achieved with vibratory stimulation, and in those who don't respond, electroejaculation can be used to obtain motile sperms for IUI or IVF and ICSI.<sup>479,593</sup> Because ejaculation may be retrograde, additional techniques for recovery of sperms from the bladder may be required (described above).

# ASSISTED TECHNOLOGIES

# REPRODUCTIVE

---

IVF and ICSI have revolutionized the treatment of male infertility. As it was originally performed, IVF involved insemination of each oocyte with 2–6 million sperms; consequently, the method had only limited application when the male was severely oligospermic. With refinements in technique over time, the number of motile sperms used for insemination decreased to 50–100 thousand per oocyte, opening the door to wider application of ART in couples with male factor infertility. The advent of ICSI further expanded capabilities to overcome even the most severe forms of male infertility.<sup>594,595</sup> Now, a male factor is the single one most common diagnosis among couples who undergo IVF. In the US national summary of ART success rates for the year 2015, 35% of all cycles were performed for male factor indications, and a male factor was one of multiple infertility factors in another 18% of cycles.<sup>596</sup> In 2015, ICSI was performed for over 90% of cycles involving fresh nondonor oocytes with an indication of male infertility.<sup>596</sup> In the same year, ICSI was used for over 70% of all cycles using fresh nondonor oocytes without a male factor.<sup>596</sup> **Overall, the results achieved with IVF in couples with male factor infertility, with and without ICSI, are comparable to those observed in couples with other indications for IVF.**<sup>596</sup>

# Sperm Retrieval

Although ICSI is now applied rather liberally in IVF cycles, even in couples without male factor infertility, it is most specifically indicated in couples with severe male factor infertility where poor or failed fertilization is more likely. When few or no viable sperms can be recovered from the ejaculate, a variety of sperm retrieval techniques may be used to obtain sperms for IVF and ICSI. Even when substantial numbers of sperms are retrieved, ICSI is prudent because sperms obtained from chronically obstructed reproductive systems usually exhibit poor motility and decreased fertilizing capacity.

# Epididymal Sperm Aspiration

Sperms may be obtained by microsurgical epididymal sperm aspiration at the time of vasopididymostomy or as an isolated procedure in men with CBAVD or uncorrectable obstructions. The technique involves incision of an isolated dilated tubule, gradually moving more proximally, if necessary, until sperms are obtained.<sup>597,598</sup> Sperms are collected into a micropipette by capillary action with gentle compression of the testis and epididymis and flushed into a container with a small volume of IVF culture medium. Recovered sperms are cryopreserved in multiple aliquots for use in IVF cycles, if required.<sup>599</sup>

Percutaneous epididymal sperm aspiration (PESA) using a fine needle has also been used successfully to obtain sperms and achieve pregnancy,<sup>600,601</sup> but the technique is less reliable, the small quantities of sperms obtained are sometimes inadequate to allow cryopreservation, and pregnancy rates achieved have generally been lower than with the open technique.

# Testicular Sperm Extraction and Aspiration (TESE and TESA)

In men with nonobstructive azoospermia and those in whom epididymal sperm aspiration techniques fail or are inapplicable, sperms may be retrieved directly from the testis.<sup>602,603</sup> Open microsurgical testicular sperm extraction yields the greatest number of sperms with potential for cryopreservation. Percutaneous core biopsy and aspiration of the testis have also been described and are most applicable in men with normal spermatogenesis and obstructive azoospermia.<sup>604</sup>

Using the preferred open microsurgical technique, sperms can be retrieved from the majority of men. Magnification minimizes the risk of injury to the testicular blood supply, increases the probability of retrieving a blood-free biopsy specimen, and allows identification of larger caliber tubules that are more likely to yield sperms.<sup>605,606</sup> Normal pregnancies have been achieved even in those with congenital or acquired testicular failure,<sup>607,608,609</sup> postchemotherapy azoospermia,<sup>610,611,612</sup> and Klinefelter syndrome.<sup>440,613</sup>

# GENETIC RISKS ASSOCIATED WITH ICSI

---

Because ICSI may override natural safeguards that serve to prevent fertilization by sperms with abnormal or damaged DNA, there is reason for concern that children born after ICSI might be at increased risk for chromosomal and other major congenital anomalies,<sup>94,614,615</sup> cancers,<sup>616,617,618</sup> or infertility.<sup>449,450,451,616</sup> Most studies,<sup>619,620,621,622</sup> but not all,<sup>614</sup> have failed to identify any increased incidence of major congenital malformation among children born after ICSI (beyond that associated with conventional IVF),<sup>622,623</sup> perhaps, at least in part, because embryos derived from damaged paternal DNA are less likely to implant and naturally select out.<sup>410,418</sup> One specific malformation that may be more prevalent in children born after ICSI is hypospadias, possibly due to paternal infertility.<sup>624</sup> **Regardless, karyotyping and Y chromosome deletion analysis should be offered to all men with severe male factor infertility who are candidates for IVF with ICSI, and additional studies are clearly needed to determine what if any increased risks might be imposed on children born after ICSI.**<sup>625</sup>

# Induction of Ovulation

Although it seems commonplace today, indeed even routine, the ability to induce ovulation and attain pregnancy in anovulatory infertile women remains one of the greatest achievements of reproductive endocrinology. Once limited to clomiphene citrate, the therapeutic armamentarium for ovulation induction now includes a wide variety of agents.

Ovulatory disorders can be identified in 18–25% of infertile women.<sup>1</sup> When anovulation is the only infertility factor, the prognosis for pregnancy generally is quite good because modern ovulation induction strategies are highly effective. When a specific cause for anovulation can be identified, treatment often restores normal cycle fecundity. Even when no specific cause can be found, as in most anovulatory women, empiric treatments with low costs and risks usually succeed. When those fail, other more complex forms of treatment are effective. One way or another, almost all anovulatory infertile women can be induced to ovulate. Unfortunately, many still do not conceive, often because there are other coexisting infertility factors.

Clinicians caring for infertile couples must have a thorough understanding of the methods for treatment of anovulatory infertility. This chapter reviews the principles that guide the choice of treatment, the results achieved with different therapies, and their associated risks.

# DIAGNOSIS OF ANOVULATION

---

The diagnosis of anovulation generally is not difficult to establish. **Women with irregular, unpredictable, or infrequent menses do not require specific diagnostic tests to prove what is already obvious.** When anovulation is suspected but uncertain, a variety of methods can be used to evaluate ovulatory function, as discussed in [Chapter 25](#) and summarized briefly here.

Ovulatory cycles typically are associated with a classic “biphasic” basal body temperature (BBT) pattern that is not difficult to recognize, when present.<sup>2</sup> **BBT recordings having no sustained interval of temperature elevation preceding the onset of menses strongly suggest anovulation.** Biphasic recordings exhibiting a short luteal phase (onset of menses <12 days after the midcycle rise in BBT) suggest a subtle, but still important, form of ovulatory dysfunction. Although uncommon, BBT recordings are not clearly biphasic in some ovulatory women. Since BBT cannot reliably define the time of ovulation and can become tedious, it is not the method of choice for evaluating ovulatory function for most infertile women.<sup>3</sup>

**A serum progesterone measurement is the simplest, most common, objective, and reliable test of ovulatory function, as long as it is appropriately timed. A progesterone concentration less than 3 ng/mL implies anovulation, except when drawn immediately after ovulation or just before the onset of menses, when lower levels naturally might be expected.**<sup>4,5</sup> A normal ovulatory cycle is 25–35 days in duration and exhibits a luteal phase lasting approximately 14 days. **Ideally, the serum progesterone level should be drawn approximately 1 week before the expected onset of menses, when the concentration is at or near its peak. Contrary to popular belief and practice, cycle day 21 is not always the best time to measure the serum progesterone concentration and the threshold level indicating ovulation is not 10 ng/mL.** Cycle day 21 is a good choice for women with cycles lasting approximately 28 days but a poor choice for women with 35-day cycles. A serum progesterone concentration greater than 10 ng/mL suggests normal luteal function but not when the luteal phase is grossly short, and a level less than 10 ng/mL can be quite normal, because progesterone is secreted by the corpus luteum in distinct pulses, temporally linked to pulsatile luteinizing hormone (LH) secretion<sup>6</sup>; random sampling can coincide with a transient nadir in serum levels. **If the menses does not commence 7 days after a serum progesterone reading of less than 3 ng/mL, it may be reasonable to repeat the test.**

Other simple tests of ovulation include monitoring urinary LH excretion. This has been simplified by the wide availability of home urine LH kits that are designed to

detect a high LH value at the time of the LH surge. More sophisticated test available for home use also includes a measure of rising estrogen production preceding the LH surge. Serial transvaginal ultrasonography can be useful once ovulation has been achieved but is unnecessary and not always accurate for the diagnosis of anovulation. Ruptured follicles can refill with fluid, and a nondominant follicle that has progressed in size can be mistaken for the missing follicle.

# CLASSIFICATION OF OVULATORY DISORDERS

---

After evaluation for the causes of anovulation is completed, virtually all women can be classified according to the criteria adopted by the World Health Organization (WHO).<sup>7</sup> Hyperprolactinemic anovulation is considered as a fourth and specific category.

# **WHO Group I: Hypogonadotropic Hypogonadal Anovulation**

The group accounts for approximately 5–10% of anovulatory women and includes those with low or low-normal serum follicle-stimulating hormone (FSH) concentrations and low serum estradiol levels, due to absent or abnormal hypothalamic gonadotropin-releasing hormone (GnRH) secretion or pituitary insensitivity to GnRH. Examples include women with hypothalamic amenorrhea relating to physical, nutritional, or emotional stress; weight loss; excessive exercise; anorexia nervosa and its variants; Kallmann syndrome; and isolated gonadotropin deficiency. Women in the group may require hypothalamic-pituitary imaging to exclude a mass lesion.

# **WHO Group II: Normogonadotropic Normoestrogenic Anovulation**

This group is the largest, including 75–85% of anovulatory women, and is characterized by normal serum FSH and estradiol levels and normal or elevated LH concentrations.<sup>8</sup> The most common examples are women with polycystic ovary syndrome (PCOS), some of whom ovulate at least occasionally. Women with PCOS should be assessed for cardiovascular disease risk factors and glycaemic status.<sup>9</sup>

# **WHO Group III: Hypergonadotropic Anovulation**

The group accounts for approximately 10–20% of anovulatory women and includes those with elevated serum FSH and low AMH concentrations; most, but not all, have amenorrhea. The classic example is premature ovarian insufficiency, due to follicular depletion, and few respond to treatment aimed at ovulation induction.

# Hyperprolactinemic Anovulation

Approximately 5–10% of anovulatory women have hyperprolactinemia, which inhibits gonadotropin secretion. Consequently, serum FSH concentrations generally are low or low-normal, and serum estradiol levels also tend to be relatively low. Most hyperprolactinemic women have oligomenorrhea or amenorrhea. When hyperprolactinemia cannot be attributed confidently to coexisting hypothyroidism or to medications, hypothalamic-pituitary imaging is indicated to exclude a mass lesion.

# PRETREATMENT EVALUATION AND TREATMENT

---

The causes of anovulation are many and varied. Thyroid disease, hyperprolactinemia, adrenal disease, pituitary or ovarian tumors, eating disorders, extremes of weight loss or exercise, PCOS, and obesity all are commonly associated with ovulatory dysfunction. Treatment should be directed at the underlying cause, when that can be determined, because specific treatment is more likely to succeed and some conditions can have longer-term health consequences if not recognized and treated.

**All anovulatory women deserve at least some preliminary evaluation, both to exclude important pathology that may require medical attention before ovulation induction begins and to identify the most likely successful form of treatment.** Chapter 10 considers the causes and management of amenorrhea and galactorrhea. Chapters 11 and 12 discuss the pathophysiology and treatment of PCOS and hirsutism. Chapter 15 describes the evaluation of abnormal uterine bleeding. At a minimum, anovulatory women should be screened for thyroid disorders (serum TSH) and hyperprolactinemia (serum prolactin) because both require further evaluation and specific treatment.<sup>10,11,12</sup> Depending on the menstrual history, endometrial sampling also merits consideration, because chronic anovulation is associated with increased risk for endometrial hyperplasia. Persistently thick endometrium, prolonged amenorrhea, abnormal vaginal bleeding, or excess weight should require investigation for endometrial cancer in women with PCOS.<sup>9</sup>

**Glycemic status should be assessed at baseline in all women with PCOS. In high-risk patients, that is, with a BMI greater than 25 kg/m<sup>2</sup>, history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of diabetes mellitus type 2, hypertension, or high-risk ethnicity, oral glucose tolerance test is recommended.<sup>9</sup> Even though OGTT is the preferred method of testing for impaired glucose tolerance and early type 2 diabetes, fasting plasma glucose or HbA1C levels can suffice for others.<sup>9</sup> When OGTT is done, 2 hours after a 75 g oral glucose load, glucose concentrations between 140 and 199 mg/dL indicate impaired glucose tolerance and levels of 200 mg/dL or greater indicate non-insulin-dependent diabetes.**

Anovulation offers an obvious potential explanation for infertility but often is not the only infertility factor. **Before ovulation induction begins, a screening semen analysis is prudent because male factors are an important contributing cause in 20–40% of infertile couples.<sup>13</sup> Early recognition of a significant coexisting male factor helps to avoid wasted time, effort, expense, and associated frustrations.**

Additional preliminary evaluation with hysterosalpingography (HSG) or transvaginal ultrasonography merits serious consideration, particularly in women with a history of previous pelvic infection or surgery, ectopic pregnancy, inflammatory bowel disease, pelvic pain or other symptoms of endometriosis, or an abnormal physical examination. In the absence of such risk factors, the likelihood of tubal disease is low and HSG can be deferred safely in young women and those who do not require complicated and costly forms of ovulation induction. In older women with a narrowing window of opportunity, it is generally wise to evaluate objectively all relevant infertility factors before treatment begins to ensure that time is used to the best possible advantage. In women who require ovulation induction with exogenous gonadotropins, the associated costs, logistics, and risks also justify a thorough preliminary evaluation. **Preliminary HSG and transvaginal ultrasonography are recommended when the medical history or physical examination raises suspicion for coexisting uterine or tubal infertility factors, for women over age 35, and when ovulation induction requires treatment with exogenous gonadotropins.** Laparoscopy and hysteroscopy are unnecessary for most women but certainly appropriate for those with an abnormal HSG or signs or symptoms of pelvic disease.

Lifestyle management for weight loss is recommended for PCOS patients with a BMI greater than 25 kg/m<sup>2</sup>. **Even modest weight loss (5–10% of body weight) often restores ovulatory cycles in obese anovulatory women with PCOS.**<sup>14,15,16,17,18,19,20</sup> In overweight and obese women with PCOS, unless age-related infertility is a concern, intensive lifestyle modification, including hypocaloric diet and exercise, with or without behavioral interventions, may be the first-line treatment for 3–6 months, to determine whether ovulation is resumed.<sup>9</sup> At a minimum, weight loss can increase sensitivity to ovulation-inducing drugs and decrease the complexity of treatment required. In one study, 60 of 67 obese anovulatory women (90%) who lost an average of 10 kg/m<sup>2</sup> in a diet and exercise program resumed spontaneous ovulation and 52 (78%) ultimately achieved pregnancy, 18 (27%) without other interventions.<sup>20</sup> In another study, 149 infertile women with PCOS were randomly allocated to (1) continuous oral contraceptive pills (OCP); (2) lifestyle modification consisting of caloric restriction with meal replacements, weight loss medication (either sibutramine or orlistat), and increased physical activity to promote a 7% weight loss; or (3) combined treatment with both OCP and lifestyle modification, for 16 weeks prior to four cycles of ovulation induction with clomiphene and timed intercourse.<sup>21</sup> Women receiving lifestyle modification or combined lifestyle modification with OCP achieved significant weight reduction (–6.2% and –6.4%, respectively) and had significantly higher cumulative ovulation rates than women receiving OCP (60%, 67%, and 46%, respectively).<sup>21</sup> Compared to similar women who received clomiphene right away in

another randomized trial,<sup>22</sup> women receiving lifestyle modification in the aforementioned trial achieved significantly higher cumulative ovulation (lifestyle, RR = 1.4; 95% CI = 1.1–1.7; combined, RR = 1.4; 95% CI = 1.2–1.8) and significantly better live birth rates (lifestyle, RR = 2.5; 95% CI = 1.3–4.7 and combined, RR = 2.5; 95% CI = 1.3–4.8).<sup>22,23</sup>

Bariatric surgery can be considered as a second-line treatment option when significant obesity (BMI > 35 kg/m<sup>2</sup>) and anovulation are resistant to lifestyle intervention and/or pharmacotherapy, especially in the presence of obesity-related comorbidities.<sup>9,24</sup> Even though bariatric surgery improves anovulation, hirsutism, insulin resistance, sexual activity, and libido, whether maternal and fetal outcomes are improved is uncertain.<sup>25,26</sup> A 2016 meta-analysis, including 13 case series with 2,130 PCOS patients who underwent bariatric surgery, reported that 12 months after surgery, the incidence of PCOS decreased to 6.8% from 45.6%, menstrual irregularity to 7.7% from 56.2%, and hirsutism to 38.6% from 67.0%.<sup>25</sup> The incidence of preoperative infertility was 18.2%, which significantly decreased to 4.3% at study end.<sup>25</sup> A 2017 meta-analysis corroborated these findings and furthermore reported 96% (CI = 88–100%) resolution rate for PCOS among 82 severely obese patients.<sup>27</sup> Bariatric surgery can cause malabsorption and eating disorders, which may adversely affect maternal and neonatal health. Risks of small-for-gestational-age babies, preterm delivery, and, possibly, neonatal mortality seem to increase after bariatric surgery. Therefore, it is recommended to avoid pregnancy during rapid weight loss and for at least 12 months after bariatric surgery. In sum, bariatric surgery is considered an experimental therapy for infertility associated with PCOS.<sup>9</sup>

# CLOMIPHENE CITRATE

---

Clomiphene citrate was first synthesized in 1956, introduced for clinical trials in 1960, and approved for clinical use in the United States in 1967.<sup>28,29</sup> In early clinical trials, 60–80% of anovulatory women treated with clomiphene achieved ovulation and half of those who ovulated also conceived.<sup>28,29,30</sup> The collected clinical experience gained in the years since remains consistent with those early observations.

# Pharmacology and Mechanism of Action

Clomiphene is a nonsteroidal triphenylethylene derivative that acts as a selective estrogen receptor modulator (SERM), having both estrogen agonist and antagonist properties.<sup>31</sup> However, in almost all clinical circumstances, clomiphene acts purely as an antagonist or antiestrogen; its weak estrogenic actions are clinically apparent only when endogenous estrogen levels are very low. Clomiphene is cleared through the liver and excreted in the stool; approximately 85% is eliminated within a week, but traces can remain in the circulation for a longer time.<sup>32</sup> Clomiphene is a racemic mixture of two different stereoisomers, enclomiphene (62%, originally known as cis-clomiphene) and zuclomiphene (38%, originally known as trans-clomiphene).<sup>31,33</sup> Enclomiphene is the more potent isomer and the one responsible for its ovulation-inducing actions.<sup>31,34</sup> The half-life of enclomiphene is relatively short, so serum concentrations rise and fall quickly during and after treatment.<sup>32,35</sup> Zuclomiphene is cleared much more slowly; serum levels remain detectable for weeks after a single dose<sup>32</sup> and may even accumulate gradually over a series of cycles, but there is no evidence that residual zuclomiphene has any important clinical effects or consequences.<sup>35</sup>

Structural similarity to estrogen allows clomiphene to compete with endogenous estrogen for nuclear estrogen receptors at sites throughout the reproductive system. However, unlike estrogen, clomiphene binds to nuclear estrogen receptors for an extended interval of time and thereby depletes receptor concentrations by interfering with receptor recycling.<sup>31</sup> At the hypothalamic level, estrogen receptor depletion prevents accurate interpretation of circulating estrogen levels; circulating estrogen levels are perceived as lower than they truly are. **Reduced negative estrogen feedback triggers normal compensatory mechanisms that alter the pattern of GnRH secretion and stimulate increased pituitary gonadotropin release, which, in turn, drives ovarian follicular development.** In the pituitary, clomiphene also may increase the sensitivity of gonadotrophs to GnRH stimulation (**Figure 27.1**).<sup>36</sup>

**FIGURE 27.1**

When administered to already ovulatory women, clomiphene increases GnRH pulse frequency.<sup>37</sup> In anovulatory women with PCOS who already exhibit an increased GnRH pulse frequency, clomiphene increases only pulse amplitude.<sup>38</sup> Serum levels of both FSH and LH rise during clomiphene treatment and fall again soon after the typical 5-day course of therapy is completed.<sup>39</sup> In successful treatment cycles, one or more follicles emerge and grow to maturity. In parallel, serum estrogen levels rise progressively, ultimately triggering an LH surge and ovulation. In sum, clomiphene works primarily by stimulating the normal endocrine mechanisms that define the hypothalamic-pituitary-ovarian feedback axis. The importance of other effects it may have on insulin-like growth factors (decrease in IGF-I concentrations) and sex hormone-binding globulin (increase in serum levels) is uncertain.<sup>40,41</sup>

## Peripheral Actions

In addition to its desirable central actions, clomiphene can exert less desirable antiestrogenic effects at peripheral sites in the reproductive system, which some have suggested might explain the difference between ovulation and pregnancy rates achieved with clomiphene treatment. **Adverse effects of clomiphene on the endocervix, the endometrium, the ovary, the ovum, and the embryo have been described, but there is no compelling evidence to indicate that such effects have important clinical consequences in most women.**

On balance, the weight of evidence from controlled trials suggests that the quality and quantity of **cervical mucus production** can be decreased in clomiphene treatment cycles. Whereas some have observed no significant changes in mucus characteristics during treatment,<sup>42</sup> others have found clomiphene has dose-dependent adverse effects.<sup>43,44</sup> The conflicting results have several possible explanations. The effect may be more apparent when the interval between the end of treatment and ovulation is short.<sup>43</sup> The effect might often be negated by higher serum estradiol levels resulting from clomiphene-induced multifollicular development.<sup>45</sup> It also is possible that some individuals may be more sensitive to the effect.<sup>46</sup> Regardless, any adverse effect that clomiphene may have on cervical mucus does not prevent pregnancy ([Chapter 25](#)). In recent years, even the evaluation of cervical mucus has all but disappeared from clinical practice because controlled trials have demonstrated that postcoital testing (the traditional test of cervical factors) has little or no predictive value<sup>47,48</sup> and because modern advanced treatment regimens for persistent infertility now routinely incorporate intrauterine insemination (IUI), which bypasses the cervix altogether.<sup>49,50</sup>

Impaired **endometrial growth** also has been reported in clomiphene-treated women. However, preovulatory endometrial thickness in clomiphene-induced cycles remains well within the range normally observed in spontaneous ovulatory cycles in the large majority of women.<sup>49,51,52,53,54,55,56</sup> Other subtle differences in endometrial morphology have been attributed to the effects of clomiphene, but their clinical relevance, if any, is uncertain.<sup>57,58</sup> It is likely that clomiphene inhibits endometrial growth, at least in some women, for the same reasons that it may inhibit cervical mucus production, but the same caveats apply; the effect is inconsistent, may be offset by the higher estrogen levels in clomiphene-induced cycles, and probably has little clinical importance, except perhaps in those individuals exhibiting grossly poor endometrial growth (peak preovulatory thickness <5–6 mm).

Clomiphene does not appear to have any clinically relevant direct effects on the **ovary** or **embryo**. Although clomiphene can inhibit steroid hormone production by

cultured avian,<sup>59</sup> ovine,<sup>60</sup> and human granulosa/luteal cells in vitro,<sup>61</sup> serum estrogen and progesterone concentrations in clomiphene-induced cycles are typically higher, not lower, than in spontaneous ovulatory cycles. Adverse effects on mouse ovum fertilization and embryo development have been observed in vitro,<sup>62</sup> but studies in women indicate that serum concentrations of enclomiphene and zuclomiphene never approach the levels required to induce such effects, even after several consecutive treatment cycles.<sup>35</sup>

# Clinical Indications

Before the introduction of aromatase inhibitors, and large randomized controlled trials demonstrating higher live birth rates with letrozole, clomiphene citrate was the traditional drug of choice for ovulation induction in anovulatory infertile women with normal thyroid function, normal serum prolactin levels, and normal endogenous estrogen production, as determined by clinical observations (oligomenorrhea, estrogenic cervical mucus), a serum estradiol determination ( $>$  approximately 40 pg/mL), or a normal menstrual response to a progestin challenge (WHO Group II).<sup>63,64</sup> Although the drug also frequently is used empirically to stimulate multifollicular development in ovulatory women with unexplained infertility (in combination with IUI),<sup>50,65,66,67,68</sup> the focus here is on ovulation induction in anovulatory women; empiric clomiphene and other treatments for unexplained infertility are discussed in detail in [Chapter 25](#).

**Given its mechanism of action, it is not surprising that clomiphene typically is ineffective in women with hypogonadotropic hypogonadism (WHO Group I).** Together, low or low-normal FSH levels and low serum estrogen concentrations indicate that the hypothalamic-pituitary-ovarian axis is not functioning normally in women with hypothalamic amenorrhea; if it were, FSH levels would be high because estrogen concentrations are low. If low endogenous estrogen concentrations cannot stimulate increased FSH secretion, there is little reason to think that a clomiphene-induced decrease in the level of negative estrogen feedback will succeed, and it rarely does. Alternative treatments that directly stimulate the pituitary (pulsatile exogenous GnRH) or the ovary (exogenous gonadotropins) usually are required.

Because the corpus luteum derives from the ovulatory follicle, its functional capacity depends, in part, on the quality of preovulatory follicular development. Logically, inadequate follicular development can be expected to cause or predispose to poor luteal function, if ovulation still occurs. Indeed, the most obvious example of poor luteal function, a short luteal phase, is associated with abnormally low follicular phase FSH levels.<sup>69,70</sup> Consequently, clomiphene could be both a logical and effective choice for treatment.<sup>71,72,73,74</sup> Progesterone levels typically are higher in clomiphene-induced ovulatory cycles than in normal spontaneous cycles, likely because preovulatory follicular development is optimized and because treatment often results in more than one corpus luteum.<sup>74,75</sup>

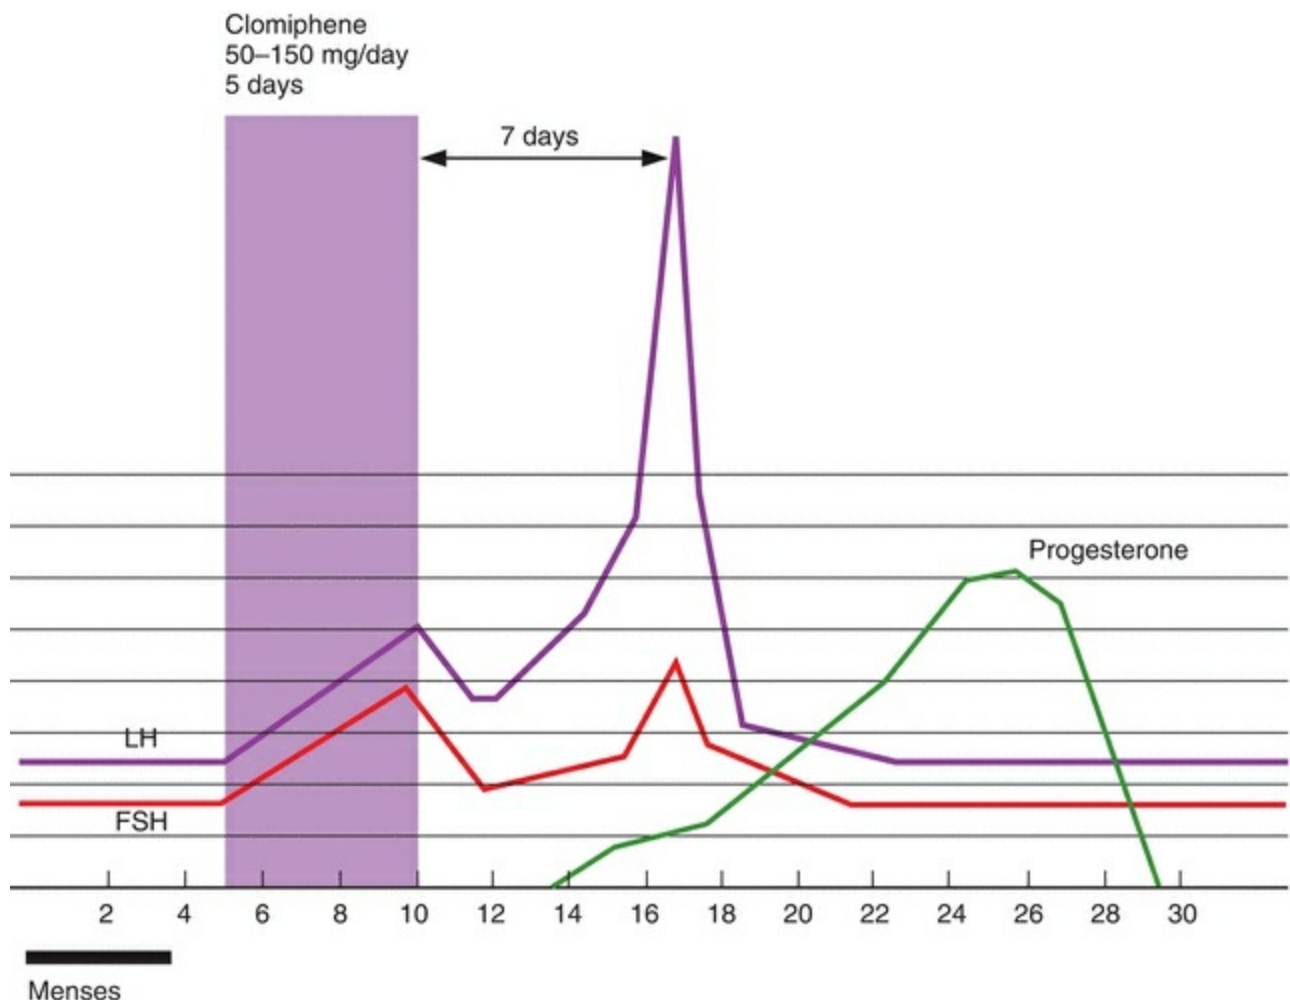

Clomiphene citrate treatment is generally limited to women with demonstrated ovulatory dysfunction but has also been offered to normally ovulating women whose infertility remains unexplained, particularly when they are young and infertility is of short duration, and those unwilling or unable to pursue more aggressive treatments. The putative efficacy of clomiphene treatment in women with unexplained infertility has

been attributed to optimizing follicular development or to the “superovulation” of more than a single ovum. However, clomiphene alone does not seem to significantly improve live birth rates or time to pregnancy compared to expectant management in unexplained infertility.<sup>65</sup> **Empiric clomiphene treatment for unexplained infertility is most effective when combined with IUI, in an effort to increase the numbers of both ova and sperm (Chapter 25).**<sup>50,65,76</sup> **On the contrary, in anovulatory women with PCOS treated with clomiphene, IUI is not superior to timed intercourse, when the semen analysis is within the normal range.**<sup>77</sup>

# Clomiphene Treatment Regimens

Clomiphene is administered orally, typically beginning on the third to fifth day after the onset of a spontaneous or progestin-induced menses. Ovulation and conception rates and pregnancy outcomes are similar when treatment starts anywhere between cycle days 2 and 5.<sup>78</sup> In women with amenorrhea, treatment can begin immediately, without inducing endometrial shedding, if pregnancy has been excluded. Indeed, available evidence suggests that progestin-induced endometrial shedding is associated with a longer treatment cycle, lower conception and live birth rates, and longer time to pregnancy.<sup>79,80</sup> The dose of clomiphene required to induce ovulation correlates with body weight but cannot be predicted confidently for an individual woman.<sup>81,82</sup> Although obese women often require higher doses of clomiphene treatment, the results achieved ultimately are similar to those observed in lean women.<sup>83,84</sup> No clinical or laboratory parameter has proven utility for predicting the dose of clomiphene needed to induce ovulation (**Figure 27.2**).<sup>81,84</sup>

## FIGURE 27.2

Treatment usually starts with a single 50-mg tablet daily for a 5-day interval and, if necessary, increases by 50 mg increments in subsequent cycles until ovulation is achieved. **Most women who respond to clomiphene will respond to either 50 mg (52%) or 100 mg (22%).**<sup>85,86</sup> Lower doses (12.5–25 mg daily) deserve consideration for women who prove highly sensitive to the drug or develop large ovarian cysts that prevent continued treatment.<sup>87</sup> Although not approved by the U.S. Food and Drug Administration, higher doses of clomiphene (150–250 mg daily) sometimes can succeed when lower doses fail (150 mg, 12%; 200 mg 7%; 250 mg 5%).<sup>85,86</sup> We believe that treatment with doses up to 150 mg is reasonable before considering alternatives and recommend against the use of higher doses.<sup>85</sup> Longer durations of clomiphene treatment (7–10 days) can succeed in some women when standard treatment does not and occasionally may be useful when there are no practical alternatives.<sup>82,88,89</sup>

The same methods used for diagnosis of anovulation can be used to evaluate the response to treatment. BBT recordings are simple and inexpensive but can become tedious over time. **A serum progesterone level greater than 3 ng/mL provides reliable evidence that ovulation has occurred**<sup>4,5</sup> **but must be timed appropriately for confident and correct interpretation.** Measuring the serum progesterone concentration between cycle days 22 and 25 will minimize the risk of sampling immediately after ovulation (occurring as late as cycle day 19–20 in cycles lasting up to 35 days) or before menses, when levels less than 3 ng/mL might be observed and misinterpreted. More sophisticated tests of ovulation involving greater costs and logistical demands are unnecessary to determine only if ovulation occurred but may be justified once successful ovulation induction has been achieved.

Commercial test kits can detect the midcycle urinary LH surge and help to determine not only whether ovulation occurred, but when, and to accurately define the length of the luteal phase.<sup>90</sup> **In clomiphene-induced ovulatory cycles in anovulatory women, the LH surge typically occurs 5–12 days after treatment ends, most often on cycle day 16 or 17 when clomiphene is administered on days 5–9.**<sup>91</sup> Ovulation generally occurs 14–26 hours after surge detection and almost always within 48 hours.<sup>90</sup> However, in clinical practice, both false-negative and false-positive results are relatively common.<sup>92,93</sup> An endometrial biopsy yielding secretory endometrium also implies recent ovulation,<sup>94</sup> but the associated costs and discomfort cannot be justified for that purpose alone. Serial transvaginal ultrasonography can demonstrate the size and number of developing follicles, track endometrial growth, and provide presumptive evidence of ovulation<sup>95,96</sup> but is difficult to justify when less complicated and costly methods can

provide the necessary information. Some advocate monitoring at least the first cycle of treatment to identify those who respond excessively.<sup>97</sup> A study comparing fecundity in clomiphene-induced cycles monitored with BBT, urinary LH excretion, or serial transvaginal ultrasonography found no clear advantage for any one of the three methods.<sup>98</sup>

Traditionally, when the serum progesterone concentration reveals persistent anovulation after clomiphene treatment, a progestin is prescribed (e.g., medroxyprogesterone acetate, 5–10 mg daily for 5–7 days) to induce menses before the next cycle begins at a higher dosage. Although effective, the sequence takes time and several months may pass before a patient is proven unresponsive to clomiphene. A “stair-step” treatment protocol is an alternative that can shorten the time required to achieve ovulation and to identify those who require different treatment. The regimen involves treatment with clomiphene (50 mg) on cycle days 5–9 after a spontaneous or induced menses, ultrasonography on days 11–14, immediate treatment at the next higher-dose level (100 mg) if no dominant follicle ( $\geq 15$  mm) has emerged, repeated ultrasonography 1 week later, and, if still no dominant follicle is observed, immediate treatment at the highest dose level (150 mg) and ultrasonography again 1 week later.<sup>99</sup> Stair-step protocol is associated with shorter time to ovulation, higher rate of ovulation, and similar pregnancy rates, albeit with higher incidence of mild side effects.<sup>80,100,101</sup>

In the past, monthly pelvic examinations to exclude residual ovarian enlargement were recommended before each new clomiphene treatment cycle began. It is still prudent to postpone further treatment when symptoms lead to discovery of a large cyst or grossly enlarged ovaries, but clinical studies and experience indicate that routine baseline physical examination or ultrasonography is unnecessary.<sup>91</sup> Nevertheless, regular contact should be maintained to review the progress of treatment and to ensure that any additional evaluation needed is accomplished efficiently.

# Results of Clomiphene Treatment

**Clomiphene will induce ovulation successfully in 70–80% of properly selected women.**<sup>102,103</sup> The likelihood of response decreases with increasing age and body mass index and with the extent of any associated hyperandrogenemia in anovulatory women. Interestingly, women with amenorrhea are more likely to conceive than those with oligomenorrhea,<sup>102</sup> possibly because infertile women who menstruate also likely ovulate, albeit infrequently, and are more likely to have other coexisting infertility factors.

**Among anovulatory infertile women who respond to clomiphene treatment, the overall cycle fecundability is approximately 15%.** In women with no other infertility factors, cycle fecundability may reach as high as 22%, comparable to that observed in normal fertile couples after discontinuation of barrier contraception and those with male factor infertility receiving therapeutic donor inseminations.<sup>102</sup> **Cumulative pregnancy rates of 70–75% can be expected over six to nine cycles of treatment.**<sup>100,104</sup> Thereafter, cycle fecundability falls substantially. **When pregnancy is not achieved within 3–6 clomiphene-induced ovulatory cycles, the infertility investigation should be expanded to exclude other infertility factors not yet evaluated, or the overall treatment strategy should be modified if evaluation is already complete. Prolonged treatment with clomiphene is inappropriate, particularly for women over age 35.**

## Side Effects

Clomiphene treatment generally is very well tolerated. Minor side effects are relatively common but rarely are persistent or severe enough to require that treatment be discontinued.

Transient hot flashes, usually limited to the short interval of treatment, occur in 10–20% of women.<sup>105</sup> Considering that clomiphene causes a central misperception that endogenous estrogen levels are low, vasomotor symptoms are not difficult to understand. Other mild and less common side effects include headache, breast tenderness, pelvic pressure or pain, and nausea (2–5%). Visual disturbances (blurred or double vision, scotomata, light sensitivity) are uncommon (1–2%) and reversible, but reports of persistent “afterimages” (palinopsia) and light sensitivity (photophobia) make them nonetheless unnerving<sup>106</sup>; when such symptoms appear, prudence dictates that treatment be abandoned in favor of alternative methods for ovulation induction.

# Risks

Clomiphene treatment has risks, but serious complications are rare. Inevitably, questions arise concerning the risks for multiple pregnancy, congenital anomalies, and other potential adverse outcomes associated with clomiphene treatment.

The principal risk associated with clomiphene treatment is an increased risk for conceiving a **multiple pregnancy**. The clomiphene-induced increase in FSH secretion is only transient, so normal selection mechanisms still operate to yield only a single mature follicle in most treatment cycles in anovulatory women. **Nevertheless, multifollicular development is relatively common and the overall risk of multiple pregnancy is increased to approximately 7–10%.**<sup>107,108,109</sup> The large majority of multiple pregnancies conceived in clomiphene-induced cycles are twins; the risk for triplets is 0.3–0.5%, for quadruplets 0.3%, and for quintuplets 0.1%.<sup>29,110</sup> **The higher risk of multifetal gestation is another reason to treat with the lowest effective dose of clomiphene; higher doses do not improve results and only increase the risk of superovulation and multiple pregnancy, with all of the attendant antenatal and neonatal complications.**

**There is no evidence that clomiphene treatment increases the overall risk of birth defects or of any one anomaly in particular.**<sup>111</sup> Several large series have examined the question and have drawn the same conclusion.<sup>107,108,109,111,112</sup> In a series of 1,034 pregnancies resulting from clomiphene treatment, 14.2% ended in miscarriage, 0.5% in ectopic pregnancy, 0.1% in molar pregnancy, and 1.6% in stillbirth, and among 935 live born infants, malformations were detected in 21 (2.3%).<sup>111</sup> Earlier suggestions that the risk of neural tube defects might be higher in pregnancies conceived after clomiphene treatment were not confirmed in later investigations.<sup>113,114</sup> A small study of pregnancy outcomes in women exposed inadvertently to clomiphene during the first trimester of pregnancy found no evidence of teratogenicity.<sup>115</sup> There also is no evidence that clomiphene treatment increases the risk of **developmental delay or learning disability** in children conceived during clomiphene treatment.<sup>116</sup>

Early studies suggested that the incidence of spontaneous **miscarriage** in pregnancies resulting from clomiphene treatment might be increased, but a number of others have observed miscarriage rates no different from those in pregnancies conceived without treatment.<sup>85,100,104,117,118</sup>

The incidence of **ovarian hyperstimulation syndrome** (OHSS) in clomiphene-induced cycles is difficult to determine confidently because definitions of the syndrome vary widely among studies. In general, mild symptoms of ovarian hyperstimulation (transient abdominal discomfort, mild nausea, vomiting, diarrhea, and abdominal

distention) are not altogether uncommon but require only expectant management. When induction of ovulation proceeds in the recommended incremental fashion to establish the minimum effective dose, the risk of clinically significant OHSS (massive ovarian enlargement, progressive weight gain, severe abdominal pain, intractable nausea and vomiting, gross ascites, oliguria) is remote.

The incidence of **ovarian cancer** is decreased among parous women and those using hormonal contraception for prolonged intervals, suggesting that “incessant ovulation” (repeated epithelial disruption and repair) predisposes to the development of ovarian cancer and that treatment with ovulation-inducing drugs might increase the risk.<sup>119</sup> The results of case-control studies conducted in the 1990s lent credence to the notion and raised considerable concern,<sup>120,121</sup> although their conclusions were challenged because of important methodologic flaws. One study compared infertile treated women to fertile women rather than to infertile untreated women, even though infertility and nulliparity were known risk factors for ovarian cancer.<sup>120</sup> Another included cancers of all types and tumors of low malignant potential despite their differing pathophysiology.<sup>121</sup> Since then, numerous studies have confirmed that the incidence of ovarian cancer is increased in infertile women but have failed to find any substantive evidence that ovulation-inducing drugs increase the risk,<sup>122,123,124,125,126,127,128,129,130,131,132</sup> and a pooled analysis of results from eight case-control studies found that fertility drug use among nulliparous subfertile women was associated with an increased incidence of borderline serous ovarian tumors (OR = 2.43, CI = 1.01–5.88) but not with any invasive cancers (OR = 1.60, CI = 0.90–2.87).<sup>133</sup> In 2013, a large U.S. study including 9,825 women, with an average follow-up time of 17.6 years for ovarian cancer cases and 26.2 years for noncases, found that while ever use of clomiphene was not associated with ovarian cancer, women who remained nulligravid were found to have an increased risk of breast cancer with ever use of clomiphene (RR = 3.63, 95% CI = 1.36–9.72).<sup>134</sup>

The results of studies of the risk for **breast cancer** have been conflicting, with some showing no association with ovulation-inducing drugs and others suggesting possible increases in risk in certain subgroups.<sup>128</sup> A 2014 study including 9,892 women who were evaluated for infertility with a median follow-up time of 30 years reported unchanged risk of breast cancer with ever use of clomiphene (HR = 1.05; 95% CI = 0.90–1.22). However, receiving multiple cycles of clomiphene was associated with an increased risk of invasive cancers (HR = 1.69; 95% CI = 1.17–2.46).<sup>135</sup>

A 2017 meta-analysis reported a positive association between clomiphene exposure and **endometrial cancer** among subfertile women (RR = 1.32; 95% CI = 1.01–1.71; very low-quality evidence), although only at high dosage (RR = 1.69, 95% CI = 1.07–2.68) and at a high number of cycles (RR = 1.69, 95% CI = 1.16–2.47). However,

whether the association is due to the underlying conditions requiring clomiphene or the drug itself is uncertain.<sup>136</sup>

Overall, the available data are quite reassuring. **No causal relationship between ovulation-inducing drugs and ovarian, breast, or endometrial cancer has been established, but prolonged treatment with clomiphene nonetheless should be avoided, primarily because it has little hope of success.**

# Adjuvant and Combination Treatments

Clomiphene resistance describes women who do not ovulate in response to clomiphene treatment, not those who fail to conceive despite successful clomiphene-induced ovulation. In the latter group, additional evaluation is indicated to identify other potential coexisting infertility factors not already excluded. If or when that has been accomplished, persistent infertility is best regarded and treated as unexplained infertility ([Chapter 25](#)).

Although most properly selected women will ovulate in response to clomiphene treatment, many do not. Direct ovarian stimulation with exogenous gonadotropins, discussed later in detail, is an obvious alternative, but it is by no means the only option that merits consideration. Many clomiphene-resistant anovulatory infertile women will respond to supplemental or combination treatment regimens. Options include adjuvant treatment with glucocorticoids, exogenous human chorionic gonadotropin (hCG), or metformin and preliminary suppressive therapy (hormonal contraceptives). **It is helpful to be familiar with these less common ovulation induction strategies because many couples are understandably reluctant or unable to pursue the obvious alternative of gonadotropin treatment once fully advised of the associated costs, logistical demands, and risks.**

Failure to respond to one or more of these less commonly employed treatment regimens is not a prerequisite for exogenous gonadotropin therapy. They are simply useful alternatives for those unwilling or unable to pursue gonadotropin therapy and, for some, may be the only option when clomiphene treatment has failed. A choice among them is not entirely arbitrary but should consider specific elements of the patient's history, the results of laboratory evaluation, and observations in previous unsuccessful clomiphene treatment cycles.

## Clomiphene and Glucocorticoids

Numerous studies have examined the efficacy of adjuvant treatment with glucocorticoids in clomiphene-resistant anovulatory women, and all have found that combined treatment with clomiphene and a glucocorticoid can successfully induce ovulation in many who fail to respond to clomiphene alone.<sup>89,137,138,139,140,141</sup> Both continuous and more limited follicular phase treatment regimens (cycle days 5–14) have been described, using either prednisone (5 mg daily) or dexamethasone (0.5–2.0 mg daily). Whereas some studies have suggested that combined treatment with clomiphene and glucocorticoids is most effective in women having elevated serum dehydroepiandrosterone sulfate (DHEA-S) concentrations,<sup>137,138</sup> others have found that treatment also can be effective in those with normal DHEA-S levels<sup>139,141</sup> and in unselected populations of clomiphene-resistant

women.<sup>89,140,142</sup>

In the largest randomized trial involving more than 200 clomiphene-resistant anovulatory infertile women, over 80% of those receiving combined treatment with clomiphene (200 mg daily, cycle days 5–9) and dexamethasone (2 mg daily, cycle days 5–14) ovulated, compared to 20% of controls treated with clomiphene and placebo; the cumulative pregnancy rate in women receiving dexamethasone (40%) was 10-fold higher than in those who received placebo (4%).<sup>141</sup> The mechanism of glucocorticoid action remains unclear but appears to involve more than simple androgen suppression. Other possibilities include direct effects on the developing oocyte and indirect effects on intrafollicular growth factors and cytokines, which may act synergistically with FSH.<sup>143</sup> Regardless, adjuvant treatment with glucocorticoids may be justified for three to six cycles when it is successful but should be promptly discontinued when it is not. There is no evidence that glucocorticoid treatment has any important side effects or risks when used in the doses and durations described.

## Clomiphene and HCG

Although there are few if any data to demonstrate its value, exogenous hCG has been used commonly as a surrogate LH surge to trigger ovulation in clomiphene-induced cycles, particularly when IUI is performed, as in couples with unexplained infertility and those with a coexisting male factor. Adjuvant hCG treatment can be useful but has limited indications, distinct disadvantages, and potential consequences.

In anovulatory women who fail to ovulate in response to clomiphene alone, adjuvant hCG treatment is based on the premise that clomiphene may be successful in stimulating the emergence of a preovulatory follicle but ultimately fail to trigger an endogenous LH surge and to induce ovulation. Physiologically, and in practice, the scenario is unlikely. Moreover, serial transvaginal ultrasonography is required to demonstrate the phenomenon and to ensure that the ovulatory stimulus is delivered at the appropriate time. If administered blindly and prematurely, before the dominant follicle is mature enough to respond, hCG is more likely to induce atresia than ovulation.

The question of when to administer hCG presents a dilemma. Although hCG commonly is administered when the lead follicle reaches 18–20 mm,<sup>144</sup> clinical studies indicate that the peak preovulatory follicular diameter in successful clomiphene-induced ovulatory cycles ranges between 18 and 30 mm (mean 25 mm).<sup>91,145,146</sup> Considering that the preovulatory follicle grows approximately 2 mm/day as it approaches maturity,<sup>95,96</sup> the corresponding interval may thus span up to 6 days. Normally, the preovulatory follicle triggers its own ovulatory stimulus at the peak of maturity by generating and maintaining the estrogen levels that are required to induce the LH surge. The timing of

the spontaneous LH surge is therefore always optimal, but that of hCG treatment can never be more than an educated guess.

**When combined treatment with clomiphene and IUI is required, insemination usually is best performed on the day after detection of the spontaneous LH surge, using one of the now widely available commercial kits designed for the purpose, because ovulation generally occurs 14–26 hours after urinary LH surge detection.**<sup>90,147</sup> However, the lower limit of LH detection usually is between 20 and 40 IU/L, and many ovulatory women exhibit peak LH levels below 40 IU/L or surges of brief duration that may escape detection<sup>92</sup>; false-negative results are therefore not uncommon and frustrating. **Exogenous hCG can be useful for the few women who require IUI but repeatedly fail to detect the LH surge despite other objective evidence of successful ovulation induction.** In such circumstances, we believe that hCG is best postponed until the preovulatory follicle reaches or exceeds 20 mm in mean diameter. Ovulation occurs 34–46 hours after hCG injection,<sup>148</sup> so IUI usually is performed approximately 36 hours later.

**When the LH surge can be detected, adjuvant hCG treatment has no value and only adds unnecessary expense and inconvenience.** A 2014 meta-analysis including two randomized controlled trials where anovulatory women undergoing ovulation induction with clomiphene citrate were given an ovulatory dose of hCG or not reported similar live birth, ovulation, pregnancy, and miscarriage rates.<sup>149</sup> Another meta-analysis including seven studies comparing hCG trigger with LH monitorization for timing IUI for women who were treated with clomiphene reported significantly lower pregnancy rates in the hCG group.<sup>150</sup> The idea that hCG may still serve to ensure or improve the quality of luteal function even if it is not required to trigger ovulation also is not supported by existing data. In spontaneous ovulatory cycles, hCG treatment superimposed on the endogenous LH surge has no effect on luteal phase duration or serum estrogen or progesterone concentrations<sup>151</sup>; the same is true in clomiphene-induced ovulatory cycles.<sup>152</sup> In sum, adjuvant hCG treatment is best limited to those few women who require IUI and ovulate but cannot reliably detect a midcycle LH surge.

## Clomiphene and Metformin

Insulin resistance and hyperinsulinemia are common features of PCOS and an important contributing cause of the hyperandrogenism and chronic anovulation that characterize the disorder. Anovulatory infertile women with PCOS and hyperinsulinemia also are typically more resistant to clomiphene treatment.

Recognition of the pathophysiologic importance of insulin resistance in PCOS stimulated intense interest in the use of insulin-sensitizing agents for the treatment of the

disorder. Metformin is a biguanide oral insulin-sensitizing agent that acts primarily by reducing hepatic gluconeogenesis but also decreases intestinal absorption of glucose and increases peripheral glucose uptake and utilization. The effects of metformin on insulin levels and sensitivity, androgen concentrations, and other metabolic and clinical measures are considered at length elsewhere in this text ([Chapter 11](#)); its adjunctive use as an ovulation-inducing agent is the focus here.

Treatment with metformin alone or with other insulin-sensitizing drugs (thiazolidinediones, D-chiro-inositol) can increase ovulation rates in some women with PCOS,<sup>153,154,155,156,157</sup> but there is no practical method for predicting those who will respond. The literature is mostly populated with small studies that include heterogeneous groups of patients, which vary in their BMI, insulin resistance (which has not been tested at all or tested using different methodologies), and prior treatment status (i.e., clomiphene resistant or treatment naïve). Moreover, different treatment regimens with regard to timing and dose have been employed across these studies. Finally, live birth rate, the most important outcome of treatment, has not been reported in many. As can be expected, results from such studies are often heterogeneous preventing reliable pooling of their data. As such, assessment of the role of metformin and other insulin sensitizers as adjuvants for ovulation induction is difficult, despite years of research.<sup>157</sup>

In the largest randomized trial, 626 women with PCOS from the United States with oligomenorrhea and hyperandrogenism and a mean BMI greater than 34 kg/m<sup>2</sup> were treated with clomiphene, metformin, or both.<sup>118</sup> Ovulation and live birth rates were significantly higher with clomiphene alone compared with metformin (49% vs. 29% and 22.5% vs. 7.2%, respectively;  $P < 0.001$ ). Addition of metformin did not significantly improve outcomes compared to clomiphene alone.

A 2017 meta-analysis evaluated the effectiveness and safety of insulin-sensitizing drugs in improving reproductive outcomes for women with PCOS undergoing ovulation induction and concluded that metformin is associated with significantly higher rates of ovulation, clinical pregnancy, and live birth rates compared to placebo or no treatment.<sup>156</sup> However, the analysis for live birth rate included four trials with a total of 435 women and demonstrated only a marginal benefit with an odds ratio of 1.59 (CI = 1.0–2.51). When clomiphene was compared to metformin, live birth rates were similar between the groups (OR = 0.71, CI = 0.49–1.01), but data were very low quality and were found to be inconclusive and inconsistent. In subgroup analysis by obesity status, data from the nonobese group showed a possible benefit from metformin for live birth (OR = 1.71, 95% CI = 1.00–2.94) and pregnancy (OR = 1.56, 95% CI = 1.05–2.33) rate and no clear difference in ovulation rates (OR = 0.81, 95% CI = 0.51–1.28). Surprisingly, obese women treated with metformin had a lower ovulation (OR = 0.29, 95% CI = 0.20–0.43), clinical pregnancy (OR = 0.34, 95% CI = 0.21–0.55), and live

birth (OR = 0.30, 95% CI = 0.17–0.52) rate, compared to clomiphene. The same meta-analysis also concluded that combined treatment with metformin and clomiphene achieves higher ovulation (OR = 1.57, CI = 1.28–1.92) and pregnancy rates (OR = 1.59, CI = 1.27–1.99), compared to treatment with clomiphene alone.<sup>156</sup> There was no conclusive evidence that combined treatment with metformin and clomiphene can increase live birth rates over those achieved with clomiphene alone (OR = 1.21, CI = 0.92–1.59). The results for combined therapy did not vary across subgroups based on obesity status. The attempt in combining the two medications can be justified for women having few alternatives besides ovarian drilling or treatment with exogenous gonadotropins. Indeed, a sensitivity analysis based on six studies including clomiphene-resistant women showed a more pronounced increase in ovulation rate (OR = 4.89, CI = 2.62–9.13). However, clomiphene resistance was defined differently in all primary trials.

Limited evidence indicates that combined treatment with metformin and rosiglitazone,<sup>158</sup> or with clomiphene and rosiglitazone,<sup>159</sup> is no more effective than metformin alone. Combined with the safety alert issued by the U.S. Food and Drug Administration concerning a possible increased risk of ischemic cardiovascular events in patients receiving treatment with thiazolidinediones,<sup>160</sup> these data argue against their adjuvant use for ovulation induction. **In summary, combined treatment with metformin and clomiphene deserves consideration in women who prove to be clomiphene resistant.**

A 2010 randomized trial compared combined treatment with metformin and clomiphene with aromatase inhibitors in 250 clomiphene-resistant women.<sup>161</sup> Combination treatment involved 500 mg metformin 3 times daily for 6–8 weeks followed by 150 mg/day clomiphene for 5 days. Despite significantly higher ovulation rates with clomiphene-metformin than with letrozole (69.6% vs. 64.9%), clinical pregnancy rates were similar between groups (14.4% vs. 14.7%).

Metformin treatment is commonly associated with gastrointestinal side effects including nausea, vomiting, abdominal cramps, and diarrhea that can be severe enough to limit the dose administered or require discontinuation of treatment.<sup>162,163,164,165</sup> Because side effects tend to be dose-dependent and diminish with time, it is usually best to begin with a low daily dose (500 mg), increasing gradually at weekly intervals to a daily dose of 1,500–2,000 mg, as tolerance allows. Lactic acidosis can be a rare complication of metformin treatment, although recent systematic reviews have questioned whether there is a true causal relationship.<sup>166,167</sup> Women at highest risk are those with chronic hypoxemic conditions related to cardiovascular, renal, hepatic, and pulmonary disease and advanced age.

Although some have advocated metformin treatment to reduce the increased risk for

miscarriage in women with PCOS,<sup>168,169,170</sup> available data suggest otherwise. Miscarriage rates were similar between women treated with metformin compared to no treatment and between women treated with metformin compared to clomiphene; women who received combination therapy with metformin and clomiphene had significantly higher rates of miscarriage than women who received clomiphene alone (OR = 1.59, CI = 1.03–2.46). Metformin treatment during pregnancy also has been advocated to reduce the risk for developing gestational diabetes and other pregnancy complications in women with PCOS.<sup>171,172</sup> In diabetic women, treatment with metformin during pregnancy has been associated with an increased prevalence of preeclampsia and increased perinatal mortality in some studies,<sup>173</sup> but not in others.<sup>174,175</sup> Therefore, although there is no evidence that metformin treatment during pregnancy is associated with any increased risk for major fetal malformations,<sup>176</sup> and metformin is currently classified as U.S. Food and Drug Administration pregnancy category B, routine metformin treatment during pregnancy is not recommended for women with PCOS.

## **Preliminary Suppressive Therapy**

Considering that anovulation reflects a dysfunctional hypothalamic-pituitary-ovarian axis, it is reasonable to think that an interval of preliminary suppressive therapy might help to restore harmony and ovulatory function, at least temporarily. The idea is consistent with clinical observations of a few normal menstrual cycles immediately following discontinuation of estrogen-progestin contraception in some women who previously exhibited abnormal menstrual patterns. Limited data suggest that a 2-month interval of continuous estrogen-progestin contraception can effectively suppress serum LH and androgen levels and that ovulation rates up to 70% and cumulative pregnancy rates over 50% can be achieved with clomiphene treatment immediately thereafter in women who were previously clomiphene resistant.<sup>177,178</sup>

A long-acting GnRH agonist, alone or in combination with an estrogen-progestin contraceptive, can be used for the same purpose. Combined suppressive therapy with a GnRH agonist and an estrogen-progestin contraceptive (3–6 months) achieves a greater and longer-lasting reduction in serum LH and androgen concentrations than treatment with estrogen-progestin contraception alone and also prevents the otherwise inevitable estrogen deficiency symptoms associated with the use of a GnRH agonist. Spontaneous resumption of ovulatory cycles can follow,<sup>179,180,181</sup> potentially eliminating even the need for clomiphene treatment. GnRH antagonists would likely have a similar effect and allow the use of oral medication.

# AROMATASE INHIBITORS

---

Aromatase inhibitors, which were used primarily in the treatment of postmenopausal breast cancer, emerged as a new class of ovulation-inducing agents. Even though the use of aromatase inhibitors for ovulation induction has been controversial since their first introduction in 2001,<sup>182</sup> letrozole is now considered the first-line therapy for ovulation induction in women with PCOS,<sup>183</sup> as it provides significantly higher live birth rates compared to clomiphene.<sup>184</sup>

# Pharmacology and Mechanism of Action

Anastrozole and letrozole are triazole (antifungal) derivatives that act as potent, competitive, nonsteroidal inhibitors of aromatase,<sup>185,186</sup> the enzyme that catalyzes the rate-limiting step in estrogen production. They block estrogen production both in the periphery and in the brain, resulting in a compensatory increase in pituitary gonadotropin secretion that stimulates ovarian follicular development.<sup>187,188,189</sup> In this regard, their mechanism of action is similar to, but also distinct from, that of clomiphene. Although both stimulate increased gonadotropin secretion by decreasing the negative feedback effects of estrogen during treatment, clomiphene does so via depletion of central estrogen receptors, whereas aromatase inhibitors decrease estrogen production directly (**Figure 27.3**).

**FIGURE 27.3**

At least in theory, the different actions of aromatase inhibitors and clomiphene may have functional, and clinical, importance. Lower estradiol levels and higher luteal phase progesterone levels attained in letrozole-stimulated cycles than clomiphene-stimulated cycles may be the mechanism behind higher live birth rates with letrozole.<sup>22</sup> Gonadotropin secretion is anticipated to promptly decrease due to negative feedback by rapidly rising estrogen production by growing follicles following the cessation of aromatase inhibitor. To the contrary, the lack of immediate negative feedback following cessation of clomiphene, due to the depletion of central estrogen receptors, results in a more sustained increase in gonadotropin levels that is more likely to support multifollicular development. However, number of growing follicles and mono-ovulatory cycles are similar between women stimulated with clomiphene and letrozole.<sup>190</sup> Likewise, multiple pregnancy rates are also at least as low in letrozole as in clomiphene-induced cycles.<sup>184</sup> The transient accumulation of androgen substrate during treatment with aromatase inhibitors also may increase FSH receptor expression<sup>191,192</sup>

and production of insulin-like growth factor-1 (IGF-1),<sup>193,194,195</sup> amplifying the actions of FSH.

# Peripheral Actions

Despite lower serum estradiol levels in letrozole-stimulated cycles than in clomiphene-stimulated cycles, letrozole could have been expected to have less of an adverse effect on endometrial growth, since it does not block estrogen receptors. Indeed, a 2018 systematic review comparing the effect of clomiphene citrate and other ovulation induction drugs on endometrial thickness in women with WHO group 2 anovulation reported significantly higher endometrial thickness in letrozole-induced cycles (15 RCTs, 1,957 women, 3,892 cycles; weighed mean difference, 1.39 mm; 95% CI = 2.27–0.51).<sup>196</sup> However, the results in individual studies demonstrated high heterogeneity and comprise low-quality evidence. Whether the effect of letrozole on endometrial thickness has a significant effect on treatment outcome in terms of pregnancy and live birth rates is controversial. Few studies investigated molecular markers or endometrial growth and receptivity in letrozole-stimulated cycles. In general, letrozole was found to be associated with a more favorable molecular profile than clomiphene.<sup>197</sup> Clomiphene is associated with significantly decreased protein expression of active B-catenin, inactive glycogen synthase kinase-3 beta, and estrogen receptor 1.<sup>198</sup> A retrospective study involving women undergoing IVF reported increased integrin  $\alpha\beta3$  expression following stimulation with letrozole.<sup>199</sup> However, whether integrin expression is different between letrozole- and clomiphene-stimulated cycles is controversial.<sup>200</sup>

Limited data suggest that letrozole does not have a clinically relevant direct effect on oocytes or embryos. In a mouse model of PCOS, superovulation with letrozole was not found to affect meiotic spindle assembly or blastocyst development, compared with FSH-stimulated superovulation.<sup>201</sup>

# Clinical Indications

Following publication of large randomized controlled trials demonstrating higher live birth rates with letrozole than with clomiphene, it is now regarded the drug of choice for ovulation induction in anovulatory infertile women with PCOS.<sup>183</sup> The drug has also been tested in ovulatory women with unexplained infertility (in combination with IUI).<sup>202</sup>

Similar to clomiphene, letrozole is ineffective in women with hypogonadotropic hypogonadism (WHO Group 1), who already have low serum estrogen concentrations and a dysfunctional hypothalamic-pituitary-ovarian axis.

Despite evidence of effectiveness and safety in well-designed large randomized controlled trials, letrozole is still used off-label for ovulation induction in the United States, since it has not been approved by the U.S. Food and Drug Administration (FDA) for this indication.

# Aromatase Inhibitor Treatment Regimens

In almost all studies conducted to date, letrozole (2.5–7.5 mg daily) and anastrozole (1 mg daily) have been administered for a 5-day interval. Early on, a phase II randomized controlled trial comparing a single-dose therapy with anastrozole and 5-day course of clomiphene reported significantly lower ovulation rates with anastrozole and the sponsoring company stopped the development of the drug.<sup>203</sup> Thus, letrozole is the most studied and the most commonly used aromatase inhibitor in ovulation induction.

Letrozole is administered orally, typically beginning on the third to fifth day after the onset of a spontaneous or progestin-induced menses. Ovulation and conception rates and pregnancy outcomes are similar when treatment starts anywhere between cycle days 3 and 5.<sup>204</sup> In women with amenorrhea, treatment can begin immediately, without inducing endometrial shedding; however, pregnancy must be excluded. The starting dose for letrozole is 2.5 mg a day for 5 days. If 2.5 mg/day fails to induce ovulation, the dosage can be increased by 2.5 mg increments up to a maximum of 7.5 mg/day for 5 days. Despite the absence of published evidence with letrozole, dose increments can be done in the same cycle without inducing bleeding, like the stair-step protocol with clomiphene.<sup>99</sup> One trial comparing outcomes achieved with 5 or 10 days of letrozole treatment (5 mg and 2.5 mg daily, beginning on cycle day 1, respectively) in clomiphene-resistant women (100 mg daily) observed significantly more preovulatory follicles (3.0 vs. 1.8) and higher pregnancy rates (17.4% vs. 12.4%) in women receiving the longer course of treatment.<sup>205</sup>

The same methods used for diagnosis of a spontaneous or clomiphene-induced ovulation can be used to determine the response to letrozole. Whether monitoring and triggering of ovulation is necessary and improves results over that achieved without monitoring and fertility-oriented intercourse is controversial. However, it may be prudent to monitor during the follicular phase of the first cycle to confirm ovulation or to allow timely dose increments to achieve ovulation.

# Results of Treatment with Aromatase Inhibitors

Several trials have compared letrozole and clomiphene in anovulatory women without documented clomiphene resistance. The largest involved 750 patients who were randomized to receive letrozole (2.5 mg daily increased up to a maximum of 7.5 mg/day in case of anovulation) or clomiphene (50 mg daily increased up to a maximum of 150 mg/day), without ovulation trigger, up to five treatment cycles. In the letrozole group, a significantly higher proportion of women achieved ovulation (88.5% vs. 76.6%, RR = 1.16; 1.08–1.24), and the proportion of ovulations over total treatment cycles was significantly higher (61.7% vs. 48.3%, RR = 1.28; 1.19–1.37). Cumulative pregnancy (27.3% vs. 21.5%) and live birth (27.5% vs. 19.1%, RR = 1.44; 1.10–1.87) rates were also significantly higher with letrozole treatment.<sup>22</sup> One randomized trial, which recruited 100 anovulatory women with PCOS who had never received ovulation induction, also reported significantly higher ovulation (60% vs. 32%) and a nonsignificant increase in pregnancy rate (26% vs. 14%) with letrozole (5 mg/day) than clomiphene (100 mg/day).<sup>206</sup> A 2018 systematic review reported significantly higher live birth rates with letrozole than clomiphene (OR = 1.79; 1.42–2.25).<sup>184</sup> The beneficial effect of letrozole seems independent of body mass index, that is, despite decreasing overall live birth rates with increasing BMI, letrozole outperforms clomiphene across categories of BMI.<sup>22,184</sup> Miscarriage per pregnancy (OR = 0.96; 0.65–1.42) and multiple pregnancy rates (OR = 0.61; 0.41–1.16) are also similar between letrozole- and clomiphene-induced cycles.<sup>184</sup> **Available evidence suggests that letrozole should be considered the first-line agent for ovulation induction in anovulatory women with PCOS.**

In an early proof of concept trial involving anovulatory clomiphene-resistant women, 9/12 of patients (75%) ovulated after treatment with letrozole (2.5 mg daily) and hCG (lead follicle > 20 mm), three conceived (resulting in two singleton births), and normal endometrial proliferation was observed in all.<sup>182</sup> **Aromatase inhibitors can also be effective in anovulatory women who fail to ovulate in response to clomiphene treatment.**

Aromatase inhibitors also might be considered for women who respond to clomiphene but exhibit grossly poor endometrial proliferation. Indeed, letrozole is associated with a significantly thicker endometrium; however, the mean difference is small at 1.39 mm (95% CI = 2.27–0.51).<sup>196</sup> **All studies have included monitoring with ultrasonography and the vast majority used adjuvant treatment with hCG, so it is unclear whether these additions to the treatment regimen are necessary to achieve success. If not, the substantially lower complexity, risks, and costs of treatment, compared to the alternative of gonadotropin therapy, make it easy to justify a trial**

**of treatment with an aromatase inhibitor for clomiphene-resistant anovulatory women.**

## Side Effects

Letrozole is generally well tolerated, and the most common side effects of letrozole are headaches and cramps. Women on letrozole report more fatigue (20%) and dizziness (12%) than women on clomiphene.<sup>22</sup> However, hot flushes are less common with letrozole (20.3% vs. 33.0%).<sup>22</sup>

## Risks

The major risk of ovulation induction is the occurrence of a multiple pregnancy. Even though a rapid decline in serum FSH level is anticipated following the cessation of letrozole, the incidence of monofollicular development and the risk of multiple pregnancy are similar with clomiphene.<sup>184</sup> The risk of multiple pregnancy is about 3–7%. While the vast majority of multiples are limited to twins, a case of sextuplets has been reported following ovulation induction with letrozole at a dose of 7.5 mg/day.<sup>207</sup> It would be prudent to monitor ovarian response and cancel cycles when the patient is regarded to be at risk of multifollicular development, for example, with prior multifollicular development or requiring high dose of letrozole.

Despite initial concerns regarding increased risk of fetal anomalies following ovulation induction with aromatase inhibitors, there is no evidence suggesting letrozole is any more teratogenic than clomiphene. One case series comparing the incidence of congenital malformations in 911 newborns of women who conceived after treatment with letrozole (14/514, 2.4%) or clomiphene (19/397, 3.0%) found no difference.<sup>208</sup> Another comparing the incidence of birth defects in children born to mothers treated with letrozole or clomiphene to that in pregnancies conceived without treatment also observed no difference.<sup>209</sup>

The risk of clinically significant OHSS (massive ovarian enlargement, progressive weight gain, severe abdominal pain, intractable nausea and vomiting, gross ascites, oliguria) is very low when letrozole is used cautiously in an incremental manner.

**In sum, the available data suggest that letrozole is more effective than clomiphene as a first-line treatment for ovulation induction in anovulatory women with PCOS, without a significant increase in complications or side effects.**

# LAPAROSCOPIC OVARIAN DRILLING

---

Surgical treatments aimed at restoring ovulatory function in anovulatory infertile women date back to the classic bilateral ovarian wedge resection described originally by Stein and Leventhal in 1935.<sup>210</sup> The procedure understandably fell out of favor after the introduction of clomiphene citrate and gonadotropins for ovulation induction. Advances in laparoscopic surgery sparked renewed interest in the procedure, with ovarian “drilling” now representing the modern equivalent of the classical wedge resection and another treatment option for anovulatory women who are resistant to oral ovulation induction agents.

Several methods for ovarian drilling have been described, including electrocautery or laser vaporization (three to six sites per ovary, avoiding surfaces near the tubo-ovarian interface to minimize the risk for adhesions that might adversely affect ovum capture).<sup>211,212,213</sup> All are intended to cause focal destruction of the ovarian stroma in efforts to decrease both intraovarian and systemic androgen concentrations. There is no evidence for the superiority of any one method, but the most common technique involves electrocautery using a unipolar needle electrode insulated above the distal 1–2 cm. Unilateral ovarian drilling seems comparable with bilateral drilling for the majority of women, perhaps except for clomiphene-resistant patients.<sup>214,215,216</sup>

Postoperative serum concentrations of androstenedione and testosterone decrease, at least for a time,<sup>217,218,219,220</sup> and inhibin concentrations also decline.<sup>221,222</sup> Both changes likely contribute to an associated increase in FSH levels. As with the classical surgical procedure, the principal risk associated with laparoscopic ovarian drilling is postoperative adnexal adhesion formation that may decrease overall fertility, although the risk and severity of adhesions are lower<sup>223,224,225,226</sup>; second-look laparoscopy and adhesiolysis do not appear necessary or useful.<sup>227,228</sup> There is one report of unilateral ovarian atrophy after ovarian drilling with electrocautery<sup>229</sup>; however, the energy levels applied in that case were almost 40 times higher than the currently recommended dose. Whether ovarian drilling might adversely affect ovarian reserve and predispose to early menopause is controversial. Despite a significant decline in serum AMH levels and ovarian volume after drilling, 6 months after the procedure, postoperative levels were still higher than age- and BMI-matched ovulatory fertile women in a retrospective study<sup>230</sup>; other data indicate that reductive ovarian surgery, including ovarian wedge resection, increases risk for early menopause.<sup>231</sup>

In numerous uncontrolled observational studies, 40–90% of women have ovulated after laparoscopic ovarian drilling and approximately half of those have conceived.<sup>211,212,213,224,232</sup> In truly clomiphene-resistant women, ovarian drilling can

improve clomiphene sensitivity or response to exogenous gonadotropins when it does not restore spontaneous ovulatory cycles.<sup>233</sup> When considering laparoscopic ovarian drilling as a treatment option in clomiphene-resistant anovulatory infertile women, the most relevant data derive from randomized controlled trials comparing surgical treatment with ovulation induction using exogenous gonadotropins.<sup>227,234,235</sup> A 2012 systematic review and meta-analysis including 25 trials found no evidence of a difference in live birth (OR = 0.97, CI = 0.59–1.59) or pregnancy rate (OR = 1.01, CI = 0.72–1.32).<sup>216</sup> After 12 months, the ovulation rate achieved with drilling (52%) was similar to that with gonadotropin therapy (62%). However, as might be expected, laparoscopic ovarian drilling yields far fewer multiple pregnancies than gonadotropin treatment (1% vs. 16%; OR = 0.13, CI = 0.03–0.52); the miscarriage rates associated with surgical and medical treatment are comparable.<sup>216</sup>

The ideal candidates for ovarian drilling are women who are not obese and have no other infertility factors. The procedure often is unsuccessful in obese women (BMI > 30 kg/m<sup>2</sup>),<sup>236,237</sup> and whereas over 80% of women can be expected to conceive after surgery when clomiphene-resistant anovulation is the sole cause of infertility,<sup>236,238</sup> only 15–30% achieve pregnancy when there is a coexisting tubal, male, or other infertility factors.<sup>219,238</sup>

**Laparoscopic ovarian drilling can be an effective therapeutic option for anovulatory infertile women who are resistant to oral ovulation induction agents, but the temporary effects of treatment, the risk of postoperative adhesions, and the theoretical risk of adverse effects on ovarian reserve deserve careful consideration and discussion. The procedure is perhaps best reserved for women who are unable or unwilling to accept the costs and risks associated with gonadotropin therapy.**

# EXOGENOUS GONADOTROPINS

---

Exogenous gonadotropins have been used to induce ovulation in gonadotropin-deficient women and those who fail to respond to other, less complicated forms of treatment for nearly 50 years. They are highly effective but also very costly and associated with substantial risks including multiple pregnancy and OHSS. **Consequently, exogenous gonadotropins should be used only by clinicians having the training and experience necessary to provide safe and effective treatment.**

# Gonadotropin Preparations

Gonadotropin preparations have evolved gradually over the years, from relatively crude urinary extracts to more highly purified urinary extracts to the recombinant preparations in common use today.<sup>239,240</sup>

For almost 30 years, the only exogenous gonadotropins available were human menopausal gonadotropins (hMG, menotropins), an extract prepared from the urine of postmenopausal women containing equivalent amounts (75 IU) of FSH and LH per ampule or vial and requiring intramuscular injection. Originally, the urinary source was a single convent in Italy, but later, collections were expanded to a number of centers in other countries.<sup>241</sup> Urinary menotropins also contain small but measurable and varying amounts of hCG, most of it added intentionally during the manufacturing process to provide the appropriate amount of LH activity.<sup>242</sup> Clinical use of hMG began in 1950 but the clinical trials did not begin until after 1960.<sup>243,244</sup> Relatively crude gonadotropin extracts like traditional hMG also contained significant amounts of uncharacterized urinary protein that may be antigenic.<sup>245</sup> Contemporary hMG preparations are more highly purified than in the past and can be administered subcutaneously.<sup>246</sup>

Beginning about 25 years ago, more purified urinary FSH preparations (urofollitropin) were developed by removing LH from urinary extracts using immunoaffinity columns containing polyclonal anti-hCG antibodies.<sup>247</sup> Early preparations of purified urinary FSH (75 IU) contained less than 1 IU LH but a considerable amount of other urinary protein and still required intramuscular administration. Further purification using monoclonal antibodies specific for FSH yielded a preparation containing less than 0.1 IU LH and less than 5% unidentified protein. The even more highly purified products now in use contain less than 0.001 IU LH, very low levels of urinary protein, and can be administered subcutaneously.

Just over 20 years ago, the in vitro production of recombinant human FSH was achieved through genetic engineering. Briefly summarized, the process involves introduction of the genes encoding the  $\alpha$ - and  $\beta$ -FSH subunits into the genome of a Chinese hamster ovary cell line, which then synthesizes and secretes a glycosylated bioactive dimeric FSH that is purified by immunochromatography using a specific anti-FSH monoclonal antibody. Recombinant FSH preparations contain less acidic FSH isoforms that have a shorter half-life than those derived from human urine but stimulate estrogen secretion as or even more efficiently.<sup>248</sup> The advantages of recombinant FSH preparations include the absence of urinary protein, more consistent supply, and less batch-to-batch variation in biologic activity. The two recombinant FSH preparations currently available are marketed as follitropin alfa and follitropin beta. They are both structurally identical to native FSH and contain 1 alpha and 1 beta glycoprotein chain,

but the posttranslational glycosylation process and purification procedures for the two are different.<sup>249</sup> Despite the subtle differences in structure, they are functionally the same. The biologic activity of all FSH preparations, including recombinant formulations, is ultimately confirmed using the classic Steelman-Pohley ovarian bioassay.<sup>250</sup>

Recombinant technology has also been used to create a new chimeric gene containing the coding sequences of the FSH  $\beta$ -subunit and the C-terminal peptide of the hCG  $\beta$ -subunit (containing additional glycosylation sites). Coexpression of the  $\alpha$ -subunit and the chimeric FSH  $\beta$ -subunit produces a new molecule called corifollitropin alfa, which has a prolonged half-life and enhanced in vivo bioactivity compared with wild-type FSH. Early studies in women suppressed by treatment with a long-acting GnRH agonist have confirmed the extended half-life of the compound, and clinical trials have demonstrated that corifollitropin alfa can induce and sustain multifollicular growth for a week in women receiving ovarian stimulation for IVF. Corifollitropin alfa provides the means for simpler and more convenient treatment compared with conventional treatment regimens involving daily injections with FSH and GnRH agonist. However, this recombinant gonadotropin with extended half-life is designed to induce multifollicular development, and it is not well suited for ovulation induction where unifollicular development is the objective.<sup>251,252</sup> This product is widely available outside of the United States.

Most recently, follitropin delta, the first recombinant FSH protein that is expressed in a human cell line (PER.C6), has been available for use in assisted reproductive technologies (ART). Follitropin delta has the same amino acid FSH sequence as follitropin alfa, but the glycosylation patterns of the two molecules are different. Follitropin delta has distinct pharmacokinetics and pharmacodynamics, with higher exposure and lower serum clearance than follitropin alfa.<sup>253</sup> Similar to corifollitropin alfa, follitropin delta is also licensed for use in ART cycles aiming at multifollicular development and is currently not suitable for induction of monofollicular development.

A recombinant form of human LH having physicochemical, immunologic, and biologic activities comparable to those of human pituitary LH also is available, supplied in vials with syringes designed to deliver 75 IU.<sup>254,255,256</sup> Combined use of recombinant LH and FSH (or hMG) helps to promote follicular development in women with hypogonadotropic hypogonadism who have a profound LH deficiency<sup>257</sup> but otherwise does not appear necessary.<sup>258,259</sup>

Traditionally, and still today, by virtue of its structural and biologic similarity to LH, hCG is used to simulate the LH surge and induce ovulation in gonadotropin-stimulated cycles once follicle development reaches maturity. LH/hCG promotes the final stages of follicular and oocyte maturation (from prophase I, the germinal vesicle

stage, through meiotic maturation and metaphase II), which requires approximately 36 hours to complete, and ovulation generally occurs approximately 4 hours later. A recombinant form of hCG, produced using techniques similar to those described earlier for recombinant FSH,<sup>260</sup> has widely replaced hCG extracted from human pregnancy urine and placental tissue. Studies indicate that 250 mcg of the recombinant product yields results comparable to those achieved with 5,000–10,000 IU of urinary hCG.<sup>260,261,262,263,264,265</sup>

The availability of recombinant FSH, LH, and hCG has done much to further our understanding of the specific actions of individual gonadotropins in follicular development and oocyte maturation.<sup>266,267,268</sup> Recombinant gonadotropins provide the capability to tailor ovarian stimulation regimens to the needs of the individual woman in an effort to optimize oocyte quality and cycle fecundity. Unfortunately, we still do not yet have the ability to accurately define what those specific needs are. It may someday be possible to design combinations of recombinant gonadotropins that will vary with the hormonal milieu of the individual, perhaps even within a cycle of stimulation, but for the present, our existing more generic treatment regimens must suffice.

# Indications for Gonadotropin Treatment

Any discussion of ovulation induction with exogenous gonadotropins must first define the different clinical situations in which they may be used because the choice of gonadotropin preparation and treatment regimen vary with the type of ovulatory disturbance.

## Hypogonadotropic Hypogonadism

Women with hypogonadotropic hypogonadism (hypothalamic amenorrhea, WHO Group I) are the most obvious candidates for ovulation induction with exogenous gonadotropins. Oral antiestrogens typically are ineffective because their actions require an intact and functional hypothalamic-pituitary-ovarian axis. In a sense, gonadotropin therapy in women with hypogonadotropic hypogonadism may be viewed as hormone therapy intended to stimulate normal folliculogenesis and ovulation once fertility becomes a priority.

**In women with hypogonadotropic hypogonadism, ovulation induction regimen must contain both FSH and LH.** Although follicular growth and oocyte maturation can be successfully stimulated with FSH alone,<sup>269</sup> LH also is required for normal steroidogenesis, luteinization, and ovulation<sup>257,270,271,272,273</sup>; endogenous LH levels typically are inadequate. Traditionally, menotropins are the drug of choice. One small randomized controlled trial including 35 women with hypogonadotropic hypogonadism compared 150 IU/day of menotropin with a combination of 150 IU/day of rFSH and 75 IU/day of rLH.<sup>274</sup> Following three cycles, ovulation rates were similar with hMG and rFSH/rLH combination (88% vs. 70%), but women receiving rFSH/rLH combination had higher pregnancy rates (23.3% vs. 55.6%). The study has multiple limitations, that is, lack of sample size calculation, blinding, unclear allocation concealment, and inclusion of each woman with more than one cycle, and as such should be regarded as providing low-quality evidence. The multiple pregnancy rate was 5/25 (20%) in this study using a starting dosage of 150 IU/day. **Women with hypogonadotropic hypogonadism may respond to relatively low doses of gonadotropin stimulation, although treatment must nonetheless be carefully monitored and adjusted according to response. The objective, unifollicular ovulation, must be kept clearly in mind because hypogonadal women are otherwise normally fertile and at high risk for multiple pregnancy.**

The quality of luteal function after exogenous gonadotropin-induced ovulation in women with hypogonadotropic hypogonadism merits specific consideration. **Although not always required,<sup>275</sup> luteal phase support with supplemental hCG (2,000–2,500 IU every 3–4 days)<sup>276</sup> or progesterone<sup>277</sup> generally is needed to compensate for low**

**levels of endogenous LH secretion that can prove insufficient to support normal luteal function.** Premenstrual spotting or a grossly short luteal phase suggests the possibility. Some have observed that supplemental hCG treatment can improve cycle fecundity,<sup>276,278</sup> but its value has not been conclusively demonstrated, probably because endogenous LH levels vary in women with hypogonadotropic hypogonadism and only those with profoundly low LH concentrations (< approximately 3 IU/L) may benefit from luteal phase support.<sup>257,279</sup> Because supplemental hCG also increases the risk for OHSS, treatment with hCG is best reserved for women who exhibit evidence of poor luteal function after ovulation induction; empiric treatment with progesterone is the obvious alternative.

Some women with secondary hypogonadotropic hypogonadism related to hyperprolactinemia become candidates for treatment with exogenous gonadotropins because they cannot tolerate dopamine agonist therapy. Consequently, it is important to know that hyperprolactinemia has no apparent adverse effect on the response to exogenous gonadotropins.<sup>280</sup>

## **Oral Antiestrogen-Resistant Anovulation**

When oral antiestrogen treatments such as clomiphene or aromatase inhibitors fail to achieve ovulation, exogenous gonadotropins are an obvious option. Any of the alternative and adjuvant therapies discussed above also might be chosen in efforts to avoid the costs, logistical demands, and risks of gonadotropin treatment, but failure with other such strategies is not a prerequisite for the use of gonadotropins.

In women with hypogonadotropic hypogonadism, endogenous gonadotropin secretion is extremely low, and menotropin (hMG) therapy provides the necessary gonadotropin stimulation. In contrast, serum gonadotropin concentrations in oral antiestrogen-resistant anovulatory women with PCOS (WHO Group II) generally are normal and, in many, LH levels are relatively high. In this population of women, treatment with exogenous gonadotropins is superimposed on a background of erratic endogenous FSH and LH secretion. Purified or recombinant FSH preparations offer a theoretical advantage over conventional menotropins because they avoid the risk of amplifying endogenous LH hypersecretion. However, in practice, there is no evidence that purified or recombinant FSH has greater efficacy than hMG and either may be used. Numerous randomized controlled trials have compared urinary FSH, recombinant FSH, and hMG for ovulation induction in clomiphene-resistant anovulatory women with PCOS. A meta-analysis including 14 such trials found no differences in the ovulation rate, pregnancy rate, miscarriage rate, multiple pregnancy rate, or incidence of OHSS.<sup>281</sup>

Like women with hypogonadotropic hypogonadism, clomiphene-resistant

anovulatory women with PCOS generally respond to relatively low doses of gonadotropin stimulation. **In many who are exquisitely sensitive, the therapeutic range is extremely narrow; doses that are only slightly higher than those proving ineffective can cause hyperstimulation.** Treatment again must be carefully monitored and frequently requires small adjustments. Unifollicular ovulation remains the objective but often can be difficult to achieve. The risk for multiple pregnancy is high and risk of ovarian hyperstimulation is greater than in hypogonadal women.

Luteal phase support seldom is necessary after gonadotropin-induced ovulation in women with PCOS because endogenous LH levels typically are more than sufficient to support normal luteal function. However, in women also receiving treatment with a GnRH agonist to suppress endogenous gonadotropin secretion (discussed below)<sup>282</sup> and in others who may exhibit evidence of poor luteal function after otherwise successful ovulation induction, luteal phase support generally should be provided; considering the higher risk of OHSS associated with hCG, progesterone therapy is preferable.<sup>241,283</sup>

## Unexplained Infertility

Exogenous gonadotropins can be used intentionally to stimulate the development and ovulation of more than one mature ovum in efforts to increase cycle fecundity in older subfertile women and those with otherwise unexplained infertility; superovulation is most effective when combined with timely IUI ([Chapter 25](#)). In this context, higher initial daily doses of exogenous gonadotropins are typically employed,<sup>282</sup> and because such women already ovulate normally and have no endocrinopathy, any of the available gonadotropin preparations can be used. Although superovulation is intended, careful monitoring is still required to avoid obviously excessive stimulation. The risk of multiple pregnancy is even greater than with ovulation induction in clomiphene-resistant anovulatory women, not surprising considering that superovulation is specifically intended. A 2017 meta-analysis including 11 trials found that luteal support with vaginal progesterone increased clinical pregnancy (RR = 1.56, 95% CI = 1.21–2.02) and live birth rates (RR = 1.77; 95% CI = 1.30–2.42) significantly.<sup>284</sup>

# Gonadotropin Treatment Regimens

Careful counseling and instruction are essential to the success of gonadotropin treatment. Couples must be thoroughly familiar with the medications prescribed, the methods for their preparation and injection, the need for frequent office visits to monitor response and reliable lines of communication, and the costs, prognosis, and risks associated with exogenous gonadotropin therapy.

Early retrospective studies established that daily treatment, frequently adjusted according to the clinical response, is the most effective treatment regimen.<sup>285,286</sup> The dose and duration of gonadotropin treatment required to induce ovulation successfully vary among women, sometimes even among cycles within women, and must be determined empirically. Whereas many women are extremely sensitive to relatively low doses of gonadotropins (75 IU daily), others require substantially greater stimulation (300–450 IU daily). Although there is a direct relationship between body weight and dose requirement, the response threshold for a specific individual cannot be predicted reliably, even in the obese.<sup>287</sup> The treatment plan also must consider the intended goal, unifollicular ovulation, or purposeful superovulation. **Safe and effective ovulation induction with exogenous gonadotropins depends heavily on the experience and clinical judgment of the treating clinician.**

In both women with hypogonadotropic hypogonadism (WHO Group I) and those with oral antiestrogen-resistant anovulation (WHO Group II), initial attempts to induce ovulation generally should begin with a low daily dose (75 IU daily) in a “**step-up**” **treatment regimen** designed to define the effective threshold of response. After 4–7 days of stimulation, a serum estradiol level, with or without transvaginal ultrasonography, provides the first measure of response. Thereafter, the dose of gonadotropins may be maintained or increased, as indicated. Once the serum estradiol level begins to rise, ovarian ultrasonography to determine the number and size of developing follicles becomes essential and the frequency of evaluation increases to every 1–2 days. When the mean diameter of the lead follicle reaches 16–18 mm, hCG is administered to trigger ovum release; ovulation generally may be expected to occur approximately 36–48 hours later. In subsequent stimulation cycles, the initial dose of gonadotropins should consider the response threshold and pattern of follicular development observed in previous cycles.

Because women with PCOS often are exquisitely sensitive to low doses of gonadotropin stimulation, early and frequent monitoring generally is wise. Such women typically have a larger number of small antral follicles (recruitable follicles) poised to respond to FSH stimulation.<sup>288</sup> Ovarian hyperstimulation, higher risks of multiple pregnancy, and the expense and frustration associated with canceled cycles usually can

be avoided by using a **“low-slow” treatment regimen** involving low doses (37.5–75 IU daily), small increments, and a longer duration of stimulation.<sup>289,290,291,292,293</sup> Although most gonadotropin stimulations span an interval of 7–12 days, low-dose stimulations in women with PCOS can take longer. Insulin-resistant women may be less sensitive to gonadotropin stimulation than those who have normal insulin response.<sup>294</sup> In some such women, metformin treatment before and during gonadotropin stimulation can help to improve response, limit the number of smaller developing ovarian follicles,<sup>295</sup> and reduce the likelihood of cycle cancellation for excessive stimulation.<sup>165</sup>

The alternative **“step-down” treatment regimen** is designed to more closely approximate the pattern of serum FSH concentrations observed in spontaneous ovulatory cycles. Treatment begins with a higher dose (150–225 IU daily) and decreases gradually thereafter in an effort to promote continued development of only the more sensitive dominant follicle while withdrawing support from the less sensitive smaller follicles in the cohort. Considering that many anovulatory women are quite sensitive to low doses of exogenous gonadotropin stimulation, the step-down method generally is best applied only after the response threshold has been established in one or more previous stimulation cycles. However, the two approaches can be effectively combined, first gradually increasing the dose of gonadotropins until a response is observed and then decreasing the dose once a dominant follicle has emerged.

Recognition of the role that LH plays in the latter stages of follicular development, when FSH levels decline steadily, has suggested other approaches to ovulation induction with gonadotropins that may have particular value for women with PCOS, in whom standard treatment regimens too often result in multifollicular development and ovarian hyperstimulation. Although the selected dominant follicle is more sensitive to FSH than smaller follicles in the cohort, by virtue of its greater granulosa cell mass, FSH receptor content, and advanced microvascular development, the final stages of maturation are equally, if not more, dependent on low levels of LH.<sup>267,268,296,297</sup> Whereas LH stimulates the theca (to produce androgens as substrate for estrogen synthesis) in all follicles, it also stimulates granulosa cells in larger follicles, via LH receptors induced by FSH and estrogen.<sup>298,299,300,301</sup> LH thus becomes the principal stimulus for the final stages of follicular maturation while declining concentrations of FSH starve the smaller, more FSH-dependent follicles into atresia.

Low doses of hCG<sup>302</sup> or recombinant LH<sup>257</sup> can selectively promote larger follicle growth while also hastening the regression of smaller follicles. To a limited extent, step-down gonadotropin treatment regimens, in which the amounts of FSH stimulation are gradually reduced, have exploited this phenomenon. The practice of “coasting,” wherein FSH stimulation is withdrawn altogether during the latter stages of follicle development, does so even more. In the latter instance, the largest follicles generally

continue to function, most likely because their LH receptor expression renders them receptive to prevailing low concentrations of endogenous LH,<sup>303</sup> whereas estrogen levels plateau or decline and smaller follicles arrest or begin to regress.<sup>304,305</sup> Continuing stimulation with low doses of hCG or recombinant LH after decreasing or discontinuing FSH treatment takes fullest advantage of the differential actions of LH in larger and smaller follicles by supporting continued development of the former<sup>267,297</sup> and selectively excluding the latter,<sup>296,306</sup> both by withdrawing FSH and by directly stimulating increased intrafollicular androgen concentrations.<sup>307</sup>

In women with hypogonadotropic hypogonadism or PCOS, recombinant LH treatment (225–450 IU daily) during the latter stages of follicular development can decrease the number of developing follicles.<sup>306</sup> In GnRH agonist-suppressed normal ovulatory women treated with 150 IU FSH daily for 7 days, a variety of treatment regimens involving combinations of decreasing FSH (50, 25, 0 IU) and increasing hCG (50, 100, 200 IU) have been observed to support the development of larger follicles and to speed the regression of smaller follicles.<sup>308</sup> Whereas either hCG or recombinant LH might be used, the longer half-life of hCG may help to provide a more stable level of LH activity between daily injections.<sup>308</sup> Interestingly, low-dose hCG treatment during the late stages of follicular development appears to have little effect on circulating progesterone or testosterone concentrations, at least in normal women, suggesting that the risk of causing premature luteinization or other adverse effects is low. By inducing the regression of smaller follicles, such treatment also may help to reduce the risk of ovarian hyperstimulation associated with exogenous gonadotropin therapy. The optimum sequence and relative amounts of FSH and LH/hCG to administer have not been defined and likely vary with the goals of treatment and the endocrinology of individual women.<sup>306,309,310</sup>

Some clomiphene-resistant anovulatory women can benefit from **sequential treatment with clomiphene and gonadotropins**. The typical cycle involves a standard course of clomiphene treatment (50–100 mg daily), followed by low-dose FSH or hMG (75 IU daily) beginning on the last day of clomiphene therapy or the next day; treatment is monitored and individualized thereafter as in standard gonadotropin-stimulated cycles. In most,<sup>311,312,313</sup> but not all studies,<sup>314</sup> cycle fecundity in sequential treatment cycles has approached or equaled that achieved with gonadotropins alone. In all, the dose and duration of gonadotropin therapy and the associated costs of monitoring were decreased significantly by 50% or more. Logically, sequential therapy generally is useful only in women who respond to clomiphene, at least to some extent. Otherwise, treatment does not effectively begin until gonadotropin therapy starts.

The elevated endogenous LH levels in many clomiphene-resistant anovulatory women with PCOS predispose to premature follicular luteinization during exogenous

gonadotropin stimulation<sup>282,315,316</sup> and have been implicated as a contributing factor in the higher incidence of spontaneous miscarriage observed in those who conceive.<sup>317,318,319,320</sup> **Adjuvant treatment with a long-acting GnRH agonist** before exogenous gonadotropin stimulation suppresses endogenous LH levels, and continued GnRH agonist treatment during gonadotropin stimulation can prevent premature luteinization.<sup>282,316,321</sup> The risk that residual GnRH agonist-induced LH suppression might result in poor luteal function after ovulation induction appears more theoretical than real.<sup>322</sup>

Nonrandomized clinical trials have suggested that combined treatment with a GnRH agonist and exogenous gonadotropins can improve cycle fecundity in clomiphene-resistant anovulatory women.<sup>316,321,323</sup> However, randomized controlled trials comparing combined treatment with a GnRH agonist and exogenous gonadotropins to stimulation with gonadotropins alone have failed to demonstrate any differences in cycle fecundity or the incidence of ovarian hyperstimulation.<sup>282,322,324,325</sup> Adjuvant GnRH agonist therapy also has no proven benefits for unselected subfertile women receiving gonadotropins to induce superovulation<sup>326</sup> and may even increase the amount and duration of gonadotropin stimulation required, at least in some.<sup>282,324</sup> **Although combined treatment with a GnRH agonist/antagonist and exogenous gonadotropins is the established standard for controlled ovarian hyperstimulation in IVF cycles, it has no proven advantage over gonadotropin stimulation alone for ovulation induction.**

# Monitoring Gonadotropin Therapy

To achieve ovulation but also avoid ovarian hyperstimulation and minimize the risk for multiple pregnancy, gonadotropin therapy must be carefully monitored with serial serum estradiol measurements and transvaginal ultrasonography. In effect, the clinician replaces the hypothalamus and pituitary in the feedback loop during treatment with exogenous gonadotropins. The chosen dose is administered, the ovarian response is measured and judged according to needs and expectations, and the gonadotropin dose is maintained or adjusted, reevaluated, and readjusted as needed. Under normal circumstances, the hypothalamic-pituitary-ovarian axis performs the same task, constantly and repeatedly refining and coordinating the level of gonadotropin stimulation with the ovarian response. By contrast, the clinician can make no more than one such assessment daily, at most. Not surprisingly, the results achieved are relatively crude by comparison.

## Serum Estradiol Levels

To best reflect the ovarian response to stimulation and provide for an efficient flow of information, gonadotropins generally are administered in the evening, typically between 5:00 and 8:00 P.M., and serum estradiol measurements are obtained early in the morning. Results usually are available for review by midday, and new instructions regarding the dose and duration of treatment and the next scheduled evaluation are communicated before the evening dose of that day is due. In general, follicles less than approximately 10 mm in mean diameter produce relatively little measurable estrogen, and larger follicles secrete progressively more as they grow and approach maturity. Usually, estradiol levels rise at a constant exponential pace, doubling approximately every 2–3 days over the days before peak follicular development is achieved. A shallower or steeper slope of increase suggests the need to increase or decrease the level of stimulation.

In the natural ovulatory cycle, estradiol levels peak between 200 and 400 pg/mL just before the LH surge. Comparable levels of estradiol should be expected in gonadotropin-stimulated cycles, for each mature follicle observed. Clinical judgments also must consider the number and size of smaller follicles and their lesser but collective contributions to the serum estradiol concentration. **Not surprisingly, cycle fecundability increases with serum estradiol levels; unfortunately, so do the risks of multiple pregnancy and ovarian hyperstimulation. With existing gonadotropin stimulation regimens, best results generally are obtained when estradiol concentrations peak between 500 and 1,500 pg/mL; pregnancies are uncommon at levels below 200 pg/mL.** <sup>327,328,329,330,331</sup>

## Ultrasonography

Ovarian ultrasonography defines the size and number of follicles contributing to the measured estradiol level. In the normal ovulatory cycle, the recruited cohort of antral follicles can be identified by cycle days 5–7, and the dominant follicle emerges by days 8–12, grows approximately 1–3 mm/day thereafter (most rapidly over the 1–2 days immediately preceding ovulation), and measures approximately 20–24 mm in mean diameter when the LH surge occurs; lesser follicles rarely exceed approximately 14 mm in diameter.<sup>95,96</sup> In 5–10% of spontaneous cycles, two preovulatory follicles may develop.

In exogenous gonadotropin-stimulated cycles, dominant follicles exhibit a similar linear growth pattern but reach maturity at a smaller mean diameter and over a wider range of sizes. **The likelihood of ovulation increases with follicular diameter.** As judged by serial ultrasonography after hCG administration, follicles 14 mm and smaller occasionally ovulate, but about 40% of those measuring 15–16 mm, 70% measuring 17–18 mm, 80% measuring 19–20 mm in size, and virtually all larger follicles will ovulate.<sup>332</sup> The larger range of follicle size at maturity complicates clinical judgments. **The risk of multiple gestation rises with the number of follicles likely to ovulate. Consequently, hCG generally should not be administered when the risk of multiple ovulation is high and the goal of treatment is unifollicular ovulation.** A large number of intermediate and small follicles also increase the risk for OHSS.<sup>333</sup>

Baseline ovarian ultrasonography is prudent between consecutive cycles of stimulation with exogenous gonadotropins. In the absence of any significant residual ovarian cysts or gross enlargement, treatment can begin again immediately without the need for an intervening rest cycle. Higher cycle fecundability and cumulative pregnancy rates have been observed in consecutive treatment cycles than with alternating cycles of stimulation and no treatment.<sup>334,335</sup> When baseline ultrasonography reveals one or more residual ovarian cysts, it is usually best to briefly postpone further treatment. Stimulation cycles in the presence of ovarian cysts are less often successful,<sup>336</sup> possibly because newly emerging follicles can be difficult to distinguish from regressing cystic follicles, leading to errors in interpretation. Although many believe that suppressive therapy with a cycle of oral contraceptives helps to speed the regression of residual ovarian cysts, there is no evidence that such treatment is more successful than observation alone.

Studies of endometrial growth in exogenous gonadotropin-induced ovulatory cycles suggest that ultrasonographic measurements of endometrial thickness also have value. Cycle fecundity increases with endometrial thickness,<sup>337</sup> which correlates with serum estradiol concentrations.<sup>338</sup> While a 2017 systematic review and meta-analysis,

including 23 studies and 3,846 women undergoing ovarian stimulation and IUI, report similar endometrial thickness between women who achieved a pregnancy and who did not,<sup>338</sup> few pregnancies result from cycles in which endometrial thickness is less than approximately 7 mm on the day of hCG-induced ovulation.<sup>328,337,339,340</sup>

# Results of Gonadotropin Treatment

Although exogenous gonadotropin therapy can successfully induce ovulation in over 90% of women with either hypogonadotropic hypogonadism (WHO Group I) or clomiphene-resistant anovulation (WHO Group II), the pregnancy rates achieved in the two populations differ significantly.<sup>234,341,342,343</sup> **In women with hypogonadotropic hypogonadism, cycle fecundity is approximately 25%, equal to or even greater than that observed in normal fertile women; cumulative pregnancy rates after up to six cycles of gonadotropin stimulation approach 90%. By comparison, cycle fecundity is significantly lower in clomiphene-resistant anovulatory women. Overall, cycle fecundity ranges between 5% and 15%, and cumulative conception rates range between 30% and 60%; within the group, those with hyperandrogenic chronic anovulation have the poorest prognosis.**<sup>234,341,342,343,344</sup> Although results generally do not vary with the duration of infertility or parity, pregnancy rates are significantly lower in women 35 years or older than in younger women.<sup>343,344</sup>

**The incidence of multifetal gestation is greatly increased in pregnancies resulting from exogenous gonadotropin-induced ovulation, even in anovulatory women where the goal of treatment is unifollicular ovulation.** Whereas approximately 1 in 80 (1.25%) spontaneous pregnancies and 5–8% of those following clomiphene treatment are multiples,<sup>107,108,109,345</sup> in anovulatory women undergoing gonadotropin-induced ovulation, the rate of multiple pregnancy is reported to be approximately 15%.<sup>341,343</sup> Not surprisingly, the incidence of multiple gestation among subfertile women receiving gonadotropin stimulation for intentional superovulation is even higher and may approach 30% with nearly one-third being high-order multiple pregnancies (approximately 10% overall).<sup>346</sup> The higher frequency of multiple pregnancy after gonadotropin treatment obviously results from inadvertent or intentional multiple ovulation. However, when the cycle is canceled by withholding the hCG injection and abstinence from intercourse, or selective follicular aspiration is undertaken in the presence of multifollicular growth (i.e.,  $\geq 3$  follicles  $\geq 14$ – $16$  mm), multiple pregnancy rates are decreased to 4.4% and 6.5%, while pregnancy rates are maintained between 10% and 14% per stimulation cycle.<sup>347,348</sup> **It is prudent to take necessary measures, including cycle cancellation, to prevent multiple pregnancy in women undergoing ovarian stimulation since they are usually young and have good ovarian reserve, both of which are assuring for a better adjusted response in a subsequent cycle. The complications and costs of high-order multiple pregnancies would be significantly more than the cost and inconvenience associated with forfeited gonadotropin injections.** Interestingly, however, there is some evidence to suggest that the normal frequency of monozygotic twinning (0.3–0.4%)<sup>345</sup> may be

increased as much as threefold in pregnancy resulting from ovulation induction with exogenous gonadotropins.<sup>349</sup>

**The overall incidence of spontaneous miscarriage in gonadotropin-induced conception cycles is approximately 20–25%,<sup>224,341,342,343</sup> moderately higher than is generally observed (15%).** A higher prevalence of advanced maternal age and obesity among women who receive gonadotropin therapy appear to contribute to the higher incidence,<sup>350</sup> but miscarriage rates also differ with the indication for treatment. In general, miscarriage rates are low in those with hypogonadotropic hypogonadism and significantly higher in clomiphene-resistant anovulatory women,<sup>341,342,343</sup> but not in all studies.<sup>234</sup> **As with clomiphene, there is no evidence that gonadotropin therapy is associated with any increased prevalence of congenital anomalies.<sup>351</sup>**

# Risks of Gonadotropin Treatment

In addition to the obviously greater costs and logistical demands involved, exogenous gonadotropin treatment also poses significant risks. Chief among these are the risks of multiple pregnancy and OHSS. Neither can be avoided altogether, even by the most experienced clinician, but both risks can be reduced with careful management. As with any complicated form of treatment having significant intrinsic risks, thorough pretreatment counseling is essential.

## Multiple Pregnancy

Twin births rose by 76% between 1980 and 2009 (from 18.9 to 33.2 per 1,000 births), plateaued between 2009 and 2012, rose to a record high of 33.9 per 1,000 births in 2014, and have been declining since, reaching 33.4 per 1,000 births in 2016.<sup>352</sup> Births of triplet and higher-order multiple pregnancies more than quadrupled between 1980 and 1998 but declined to 101.4 per 100,000 total births in 2016, reaching the lowest level in more than two decades.<sup>352</sup> About 20% of the increase in multiple births, overwhelmingly twins, can be attributed to advanced maternal age and the societal trend toward older age at childbearing (older women are more likely to conceive a multiple pregnancy). The remainder, including almost all high-order multifetal gestations, results directly from the use of exogenous gonadotropins for ovulation induction, superovulation, and ART.<sup>353</sup> The number of multiple pregnancies conceived is even greater because spontaneous and intentional multifetal pregnancy reductions do not appear in birth statistics.

**Multiple pregnancies are high-risk pregnancies at any age because they are frequently complicated by preterm delivery, low birth weight, gestational diabetes, preeclampsia, and associated with high infant morbidity and mortality.**<sup>354,355,356,357</sup>

Their clinical management often requires extended hospitalization, cesarean delivery, and neonatal intensive care; the associated health care costs are enormous, for both individual couples and society. **In fact, evidence indicates that the combined costs associated with multifetal pregnancies and their complications exceed those of all the treatments from which they derive.**<sup>358,359</sup> The less obvious social “costs” associated with multiple births also are high and include increased levels of parental stress, a higher incidence of maternal depression and child neglect or abuse, and a greater likelihood of behavioral problems among siblings.<sup>360</sup> Several factors contribute to the risks of multiple pregnancy associated with exogenous gonadotropin therapy. Although much of the attention in recent years has focused on embryo transfer practices in ART centers, less than half of all treatment-related multiple pregnancies results from IVF.<sup>361,362</sup> The majority of multiple pregnancies, and the focus here, results from

exogenous gonadotropin therapy for ovulation induction and superovulation.

Exogenous gonadotropins are an essential part of the therapeutic armamentarium with specific indications, and very real risks, including multiple pregnancy. **Gonadotropins should be reserved for ovulation induction in infertile women with hypogonadotropic hypogonadism and oral antiestrogen-resistant anovulation and for intentional superovulation in subfertile women and those with otherwise unexplained infertility, including women who ovulate in response to treatment but ultimately fail to conceive.** If unnecessary risk is to be avoided, the objective (unifollicular ovulation vs. intentional superovulation) must be kept clearly in mind; there is seldom an indication for superovulation in anovulatory but presumably otherwise fertile women.

Many infertile women seek the most aggressive forms of treatment simply because they offer the greatest chance for success, finding it hard to believe that any treatment could be too successful. Even those committed to avoiding excessive risks can find it very difficult to accept recommendations to cancel a treatment cycle, thereby forfeiting their investment of time and resources.<sup>363</sup> Financial pressures weigh heavily on the minds of even the most risk-averse patients and physicians. Cost considerations color perspectives and influence treatment decisions, tempting all involved to accept risks they otherwise would choose to avoid and later may regret. Some childless couples actually may hope for twins, but most are more circumspect when thoroughly counseled,<sup>364</sup> and none should want triplets or more.

Multiple pregnancy is an intrinsic risk of intentional superovulation. In IVF cycles, the risk of multiple pregnancy relates to the number of embryos transferred, which the physician and patient control. However, the number of embryos that may implant is difficult to predict or control in superovulation cycles. Logically, risk might be reduced if ovulation simply was not triggered when the estradiol level or number of maturing follicles was excessive. Unfortunately, the response parameters that offer the best balance between increased cycle fecundity and the risks of multiple pregnancy and ovarian hyperstimulation have not been clearly defined and remain controversial.<sup>365,366</sup> **The risk of multiple pregnancy increases with serum estradiol concentrations, with the total number of developing ovarian follicles, and with decreasing maternal age but does not correlate well with the number of larger preovulatory follicles.**<sup>49,346,367,368,369,370</sup> Some have suggested varying cycle cancellation criteria that might be used to guide treatment and limit risks of multiple pregnancies.<sup>346,367,368</sup> Whereas there is little doubt that withholding hCG when serum estradiol levels rise above approximately 900–1,400 pg/mL or ultrasonography reveals more than four to six follicles larger than 10–14 mm, or more than three follicles  $\geq 15$  mm, application of such criteria also would dictate cancellation up to one-third of all exogenous gonadotropin-

stimulated cycles.<sup>105,370</sup>

With relatively few exceptions among anovulatory women, exogenous gonadotropin therapy can be refined to achieve unifollicular ovulation with limited risk of multiple pregnancy and minimal risk of high-order multiple pregnancy. Conservative superovulation strategies likely can reduce the risk of multiple pregnancy associated with gonadotropin treatment, but any therapy wherein the specific objective is multifollicular ovulation logically cannot avoid the consequence. It is important to acknowledge that superovulation treatment exists primarily because practical considerations effectively prevent so many from pursuing the obvious alternative of IVF. In all likelihood, superovulation would fade into obsolescence if IVF was available to all those who need it, and few physicians or patients would lament its passing.

When ovarian stimulation exceeds its targeted goals, management options other than cycle cancellation include conversion to IVF and transvaginal aspiration of “excess” follicles. Unfortunately, the first of these is available only in centers where IVF also is offered. While, based on limited evidence, “rescue” IVF can provide equally good clinical outcome with “regular” IVF,<sup>371,372,373</sup> most couples are unprepared for the change in plan and the substantial additional costs involved. Limited experience with the second option of aspirating excess follicles before hCG is administered to prevent ovulation of more than three ova suggests the strategy can effectively reduce the risk of multiple pregnancy and may be a legitimate alternative to cycle cancellation.<sup>374,375</sup>

## **Multifetal Pregnancy Reduction**

Women who conceive a high-order multiple pregnancy despite all efforts to avoid the complication must choose from among three difficult options. Termination of the entire pregnancy generally is unacceptable, particularly for those who have overcome infertility. Continuing the pregnancy carries the inherent risks of preterm birth and associated complications of increased neonatal morbidity and mortality and longer-term disability. Multifetal pregnancy reduction sacrifices a portion of the pregnancy in efforts to save the whole, but for many, it is no option at all, for a variety of personal, moral, ethical, or religious reasons. For most, a choice between the risks of carrying a high-order multiple pregnancy and those associated with pregnancy reduction presents a most difficult dilemma. Couples that ultimately choose pregnancy reduction experience a rapidly shifting tide of strong emotions. Anxiety falls with the diagnosis of pregnancy, rises to very high levels with recognition of a multiple pregnancy, decreases to some extent after consultation before reduction, increases sharply during the procedure, and falls to lower levels after its completion.<sup>376</sup> In retrospect, two-thirds of couples recall acute emotional pain, stress, and fear, and almost 20% report feelings of guilt and anger.<sup>377</sup>

In most cases, multifetal pregnancy reduction is performed under transabdominal ultrasound guidance between 10 and 14 weeks of gestation. By then, the possibility of spontaneous reduction has passed,<sup>378</sup> and a limited screen for gross structural anomalies and features of aneuploidy can be performed to guide selection of fetuses for reduction.<sup>379</sup> There have been no randomized controlled trials comparing maternal and neonatal outcomes in high-order multiple pregnancies managed expectantly with those in which a multifetal reduction was performed, and it is unlikely that there will be.<sup>380</sup> A 2001 report from an international registry including over 3,500 reductions performed at 11 centers indicated that multifetal pregnancy reduction had an overall pregnancy loss rate of nearly 10% with approximately 4% of subsequent deliveries occurring between 25 and 28 weeks of gestation (severe prematurity).<sup>381</sup> Both results compare favorably with published outcomes for series of unreduced high-order multiple pregnancies.<sup>382,383,384,385</sup> Outcomes correlated with the number of fetuses both before and after reduction and improve with the experience of the operator.<sup>386,387</sup> Outcomes were better for triplet pregnancies (6% pregnancy loss rate, 3% severe prematurity) than for quadruplet and higher-order pregnancies (12–22% and 4–11%) and improved as the number of fetuses remaining after reduction decreased from three (20% and 6.5%) to two (9% and 4%) to one (9% and 1.6%).<sup>381</sup> A 2017 systematic review and meta-analysis showed that, when compared with unreduced triplets, reduction from triplets to twins was associated with a significantly lower risk of preterm birth (RR = 0.36, 95% CI = 0.28–0.48) and similar risk of miscarriage (RR = 1.08, 95% CI = 0.58–1.98).<sup>388</sup> Another systematic review of prospective studies comparing outcomes from multifetal pregnancy reduction with those from twin pregnancies (conceived spontaneously or after ART) found no differences between women having a multifetal reduction and women with a twin pregnancy for pregnancy loss (RR = 1.32, CI = 0.42–4.16), preterm birth (before 34 weeks; RR = 0.20, CI = 0.01–3.18), stillbirth (RR = 0.86, CI = 0.05–13.48), or neonatal death (RR = 0.86, CI = 0.05–13.45).<sup>389</sup> Limited available information suggests that reduction to a singleton is associated with fewer pregnancy losses and preterm deliveries than reduction to twins.<sup>390</sup> **Multifetal pregnancy reduction is an effective management tool for the complication of high-order multiple pregnancy, but one which all would prefer to avoid.**

There's very limited information on the outcome of elective reduction from twins to a singleton between 10 and 14 weeks of gestation. Available data suggest that elective reduction to a singleton can be associated with lower rates of preterm delivery less than 37 weeks and low birth weight, however, with similar rates of serious neonatal morbidity or perinatal death, very preterm birth, and small-for-gestational-age live birth, at the cost of an overall increased risk of loss of the entire pregnancy.<sup>391,392</sup>

# Ovarian Hyperstimulation Syndrome

OHSS is an iatrogenic complication of ovulation induction with exogenous gonadotropins. The disorder also can be observed occasionally in clomiphene-induced cycles. However, to date, OHSS is not reported following ovulation induction with letrozole alone. To the contrary, one study including women at high risk of OHSS following ovarian stimulation for IVF reports decreased risk of OHSS when letrozole is given during the luteal phase.<sup>393</sup>

Rare cases of OHSS in spontaneous pregnancies generally have been associated with conditions characterized by supraphysiologic concentrations of hCG (multiple gestations, molar pregnancy). Cases of recurrent OHSS in spontaneous singleton pregnancies in individuals and families have been described and linked to germline mutations in the FSH receptor resulting in the loss of ligand specificity that permits activation by hCG.<sup>394,395,396</sup>

OHSS has a broad pathophysiologic spectrum ranging from mild illness to severe disease. The syndrome normally is self-limited and resolves spontaneously within several days but may persist for longer durations in conception cycles. The hallmark of OHSS is an increase in capillary permeability resulting in a fluid shift from the intravascular to extravascular spaces,<sup>283,397,398</sup> mediated by increased secretion of vasoactive substances including vascular endothelial growth factor (VEGF), elements of the renin-angiotensin system, and other cytokines.<sup>399,400,401,402,403</sup> Resultant hypovolemia leads to hemoconcentration and increased risk of thrombosis.

**Risk factors for OHSS include young age, low body weight, high ovarian reserve as indicated by high serum AMH levels or antral follicle count, PCOS, higher doses of gonadotropins, and previous episodes of hyperstimulation.**<sup>333,404,405,406,407,408,409,410,411</sup> **Risk increases with serum estradiol levels and the number of developing ovarian follicles and when supplemental doses of hCG are administered after ovulation for luteal phase support.**<sup>412,413,414</sup> OHSS has been classified as mild, moderate, severe, or critical but is perhaps best viewed as a continuum with a widely varying number and severity of symptoms.<sup>415</sup>

Mild illness is characterized by ovarian enlargement, lower abdominal discomfort, and mild nausea and vomiting, diarrhea, and abdominal distention and occurs in up to one-third of superovulation cycles.<sup>405</sup> In general, only oral analgesics and counseling to alert affected women to the signs and symptoms of progressive illness are required; intercourse may be painful and is best avoided to limit the risk of ovarian rupture.

Persistent or worsening symptoms or ascites signal progressing illness and require treatment with antiemetics and more potent oral analgesics. Outpatient management

usually is still feasible but must include careful monitoring of daily weights and urinary frequency, serial clinical examinations to detect increasing ascites, and laboratory evaluation of hematocrit, electrolytes, and serum creatinine.<sup>416</sup> Oral fluid intake should be maintained at no less than 1 L/day; electrolyte-supplemented commercial drinks generally are well tolerated and can help to maintain electrolyte balance. Strenuous physical activity is best avoided to reduce the risk of ovarian torsion,<sup>417</sup> but light physical activity is preferable to bed rest, which can increase the risk for thromboembolism. Weight gain greater than approximately 2 lb daily and decreasing urinary frequency are indications for prompt clinical and laboratory reevaluation. **Pregnant women with OHSS merit particularly close monitoring because rapidly rising hCG levels increase the risk for progression to severe illness.** The severity of symptoms, inadequate pain relief, or social considerations may require hospitalization.

Serious illness is uncommon but not rare, having an incidence of approximately 1%. Characteristic features include severe pain, rapid weight gain, tense ascites, hemodynamic instability, respiratory difficulty, progressive oliguria, and laboratory abnormalities. Hypotension can result from vascular volume depletion, oliguria from reduced renal perfusion due to low vascular volume or tense ascites, and dyspnea from ascites or hydrothorax. Hemoconcentration, reduced peripheral perfusion, and inactivity increase the risk of thromboembolism. Renal failure, adult respiratory distress syndrome, hemorrhage from ovarian rupture, and thromboembolic phenomena are potential life-threatening complications of OHSS.<sup>418,419,420,421</sup>

**Hospitalization for more careful monitoring and aggressive treatment warrants serious consideration in women with severe abdominal pain or peritoneal signs, intractable nausea and vomiting, severe oliguria, tense ascites, dyspnea or tachypnea, dizziness or syncope, severe hyponatremia (sodium < 135 mEq/L) or hyperkalemia (potassium > 5 mEq/L), hemoconcentration (hematocrit > 55%), or abnormal renal functions (serum creatinine > 1.2 mg/dL; creatinine clearance < 50 mL/min) or abnormal liver functions (elevated transaminases).**<sup>283,415,416,419,420</sup>

Recommended inpatient care for hospitalized women includes frequent evaluation of vital signs, daily weights, measurements of abdominal circumference and fluid intake and output, chest x-ray and echocardiogram when pleural or pericardial effusion is suspected, pulse oximetry for those with pulmonary symptoms, and serial hematocrits, electrolytes, and renal and liver function studies.<sup>416</sup> Intravenous fluid management must restore an effective plasma volume but not contribute unnecessarily to the accumulation of extravascular fluid. After initial rehydration, fluids should be administered judiciously in the lowest volumes necessary to maintain adequate urine output and relieve hemoconcentration; because of the tendency to develop hyponatremia, saline is preferable to lactated Ringer solution. When saline fails, slow infusions (over 4 hours)

of albumin (25%; 50–100 g at 4–12 hours intervals) can effectively expand plasma volume.<sup>422</sup> Premature or excessive use of diuretics is counterproductive and should be avoided as they cause further volume depletion. Intravenous fluid support can be reduced substantially after diuresis begins and oral intake is reestablished. Hyperkalemia may require specific treatment to move potassium into the intracellular space (insulin/glucose, sodium bicarbonate) or to prevent cardiac dysrhythmias (calcium gluconate).

Ultrasound-guided transabdominal or transvaginal paracentesis can be very helpful in women with painful ascites, pulmonary symptoms, or oliguria that does not respond to fluid management.<sup>421,423,424,425,426</sup> In rare women with persistent bilateral or severe pleural effusions, thoracentesis also may be required to relieve pulmonary symptoms.<sup>427</sup> Full-length venous support stockings are recommended, and prophylactic anticoagulation is warranted in cases of severe OHSS and should be continued at least until the end of the first trimester in case of pregnancy.<sup>428,429</sup> When symptoms prevent ambulation, the use of an intermittent pneumatic compression device can help to reduce the risk of thrombosis. Clinical signs and symptoms suggesting thromboembolism demand prompt additional diagnostic measures and therapeutic anticoagulation when the diagnosis is confirmed or strongly suspected.

In critical cases of OHSS, intensive care may be required for management of thromboembolism, renal failure, or deteriorating pulmonary function. Women with severe hyperstimulation and ovarian torsion or a ruptured ovarian cyst with hemorrhage who require surgical management present a challenge to anesthesiologists who are understandably seldom familiar with the pathophysiology of OHSS.<sup>430</sup>

**Knowledge and prompt recognition of the risk factors for ovarian hyperstimulation are essential for its prevention. Rapidly rising serum estradiol levels, concentrations over 2,500 pg/mL, and observations of a large number of small- and intermediate-sized ovarian follicles are high-risk indicators and signal to cancel or proceed with great caution.** Cycle cancellation and less aggressive stimulation in a subsequent cycle warrant strong consideration. Coasting without further gonadotropin stimulation and delaying administration of hCG for 1–3 days until estradiol levels plateau or decline can reduce the risk of hyperstimulation.<sup>431,432,433,434,435</sup> A lower dose of hCG (5,000 IU) also may help to reduce risk.<sup>283</sup> Alternatively, a GnRH agonist (leuprolide 0.5–1.0 mg) to trigger an endogenous LH surge can be administered,<sup>436</sup> thereby avoiding the longer duration of action and further stimulation of hCG.<sup>437</sup> However, GnRH agonist trigger without any hCG is associated with decreased pregnancy and increased miscarriage risk and does not ensure complete prevention of OHSS.<sup>438</sup> Evidence from a trial involving 69 oocyte

donors at high risk for developing OHSS suggests that treatment with a dopamine agonist (cabergoline 0.5 mg) may decrease vascular permeability (mediated via VEGF) and decrease the risk for OHSS.<sup>439</sup> When luteal support is judged necessary, exogenous progesterone administered by injection (50 mg daily) or vaginally (suppositories 100 mg or 8% gel, daily) are preferable to supplemental doses of hCG.<sup>412</sup>

## **Breast and Ovarian Cancer**

The evidence suggesting that ovulation-inducing drugs might be associated with an increased risk of breast or ovarian cancer was reviewed when discussing the potential risks associated with clomiphene treatment earlier in this chapter. In brief summary, although most studies have found no evidence that fertility drug use increases overall breast cancer risk, some studies suggest that prolonged or repeated use of exogenous gonadotropins (six cycles or more) may increase risk.<sup>135,440,441</sup> Overall, the available data are quite reassuring. **No causal relationship between exogenous gonadotropin treatment and breast or ovarian cancer has been established, although longer-term studies are warranted and prolonged treatment is best avoided, especially when there is little hope for success.**

# PULSATILE GONADOTROPIN-RELEASING HORMONE

---

Exogenous pulsatile GnRH therapy has been used successfully to induce ovulation since 1980.<sup>442,443</sup> Compared to gonadotropin therapy, GnRH treatment has both advantages and disadvantages. Once established, the method is relatively simple to use, requires no extensive and costly monitoring, and is associated with low risks for both multiple pregnancy and ovarian hyperstimulation. However, because GnRH therapy requires maintenance of an indwelling intravenous catheter for an interval of 2–3 weeks or longer, many women fear needle displacement or other technical problems and are reluctant to use the method or reject the option outright. Pulsatile GnRH therapy is currently unavailable in the United States and is not used widely elsewhere in the world.

Where it is available, synthetic GnRH comes in a crystalline form that remains stable for at least 3 weeks at room temperature after reconstitution in aqueous diluent. GnRH is administered in a continuous pulsatile fashion using a portable, programmable mini-pump that must be worn constantly, around the clock, requiring some logistical ingenuity during bathing and sleep. Although the drug may be administered intravenously or subcutaneously, the intravenous route requires lower doses involving less cost (2.5–5.0 vs. 15–20 µg/pulse, depending on body weight) and is more physiologic and more effective. The drug is metabolized rapidly and has a terminal half-life of 10–40 minutes after intravenous administration. Compared to the brief spikes in serum levels that result from intravenous administration and effectively mimic the normal pattern of pulsatile hypothalamic GnRH secretion, subcutaneous treatment creates a more continuous low level of GnRH stimulation without definite peaks.

In effect, pulsatile intravenous exogenous GnRH therapy represents an artificial hypothalamus. In women with hypogonadotropic hypogonadism who have absent or low levels of endogenous pulsatile GnRH secretion, treatment restores a normal pulsatile GnRH rhythm. In those with other forms of ovulatory dysfunction, treatment superimposes a normal rhythm on an existing but disorganized pattern of endogenous GnRH secretion. **Importantly, exogenous pulsatile GnRH treatment generally stimulates only normal physiologic levels of pituitary gonadotropin secretion and allows normal feedback modulation of the pituitary response by ovarian steroids and peptides to operate. Consequently, follicular recruitment, selection, growth, and development in women using the GnRH pump progress as they do in the normal menstrual cycle.**<sup>444,445,446</sup>

# Indications for Pulsatile GnRH Treatment

Anovulatory infertile women with hypogonadotropic hypogonadism are the best candidates for ovulation induction with exogenous GnRH because treatment is specific, physiologic, and highly effective; the GnRH pump provides the only instructional signals the pituitary gonadotropes are likely to receive. Although the drug also can be used in women with other ovulatory disorders, it is much less often effective, probably because the pituitary has more difficulty interpreting the mixed signals of endogenous and exogenous GnRH stimuli. As often may be observed in women with PCOS, an increased BMI (>24), serum LH (>15 IU/L), serum testosterone (> approximately 100 ng/dL), and fasting serum insulin (> approximately 15 units/mL) are associated with lower ovulation rates in response to exogenous GnRH and lower pregnancy rates per ovulatory cycle.<sup>447,448</sup> The GnRH pump also can be effective in women with hyperprolactinemia and offers an alternative to exogenous gonadotropins when dopamine agonist treatment fails or cannot be tolerated.

# Exogenous GnRH Treatment Regimens

**Exogenous GnRH is most effective when administered intravenously in low doses (2.5–5.0 µg/pulse) at a constant interval (every 60–90 minutes).**<sup>447</sup> Those who fail to ovulate may respond to a higher dose (10–20 µg).<sup>449,450</sup> As with oral antiestrogens and exogenous gonadotropins, treatment should begin with a low dose and gradually increase to meet the needs of the individual because the risk of multiple pregnancy increases with the pulse dose.<sup>451</sup> To a large extent, the dose and duration of exogenous GnRH treatment required to induce ovulation depend on the underlying endocrine milieu.<sup>447,452,453</sup>

In women with primary hypogonadotropic hypogonadism, a low dose (2.5 µg/pulse) can induce ovulation effectively, but follicular phase LH concentrations may remain lower than normal and luteal phase progesterone concentrations often are reduced; both are typically normal when a higher dose of GnRH (5.0 µg/pulse) is used. Longer durations of treatment typically are required because available stores of pituitary gonadotropins are markedly reduced due to the historically low levels of endogenous GnRH secretion. In women with secondary idiopathic hypogonadotropic hypogonadism, treatment should begin with a low dose of GnRH (2.5 µg/pulse); the higher dose (5.0 µg/pulse) is associated with higher follicular and luteal phase LH and estradiol levels, a short follicular phase, multiple folliculogenesis, and a higher risk of multiple pregnancy, possibly because previous pituitary or ovarian priming confers a greater sensitivity to GnRH therapy.<sup>447,454</sup>

**The endocrine response of women with PCOS to pulsatile exogenous GnRH (5.0 µg/pulse) is markedly abnormal but can be normalized by pretreatment with a long-acting GnRH agonist (daily subcutaneous administration) for 6–8 weeks immediately before starting pulsatile exogenous GnRH treatment.**<sup>445,447,455</sup> Without GnRH agonist pretreatment, follicular phase FSH, LH, and estradiol levels and luteal phase estradiol concentrations all are abnormally elevated. After preliminary down-regulation with a GnRH agonist, the endocrine characteristics of induced cycles are much improved and closer to those observed in spontaneous ovulatory cycles in normal women. Unless similar down-regulation with a GnRH agonist also precedes subsequent cycles, the response to exogenous GnRH therapy again becomes abnormal. The benefits of GnRH agonist pretreatment probably result from suppression of intraovarian androgen levels<sup>456</sup> and improved (higher) FSH/LH ratios before GnRH therapy begins.<sup>457</sup>

After ovulation has been achieved, GnRH therapy can continue at the same or a slower pulse frequency (every 120–240 minutes).<sup>447,449</sup> Whereas either can stimulate sufficient endogenous LH secretion to support normal corpus luteum function, a slower

frequency more closely approximates the reduced endogenous pulse frequency observed in normal cycles during the luteal phase and may help to reduce the cost of treatment. However, it is simpler, much less costly, and just as effective to discontinue the pump after ovulation has occurred and to support the luteal phase with small doses of hCG (2,000 IU every 3 days)<sup>447</sup> or exogenous progesterone.

One of the advantages that GnRH pump therapy has over exogenous gonadotropin treatment is that monitoring is not required once an effective treatment regimen has been established. Serial estradiol measurements and ovarian ultrasonography certainly can be used to monitor ongoing treatment but are not necessary. Objective evidence of ovulation can be obtained by periodic progesterone measurements. If needed, the time of ovulation can be estimated more accurately by monitoring urinary LH excretion as in spontaneous or clomiphene-induced ovulatory cycles.

# Results of Exogenous GnRH Treatment

A 2018 systematic review and meta-analysis, including 35 studies and 1,002 women with hypothalamic amenorrhea, reported ovulation rates of 75% (95% CI = 64.91–84.44%, based on 3 RCTs) and 85% (95% CI = 81.35–88.68%, based on 32 observational studies).<sup>458</sup> Pooled estimates of pregnancy rate per ovulatory cycle were 38% (95% CI = 14.54–65.85%, 3 RCTs) and 31% (95% CI = 27.77–35.63%, 27 observational studies). Pooled estimates of live birth rates per ovulatory cycle were 35% (95% CI = 15.61–58.12%, 3 RCTs) and 25% (95% CI = 22.27–29.58%, 27 observational studies).<sup>458</sup> **Overall, results are best in women with hypogonadotropic hypogonadism and worse in those with PCOS.**<sup>447,450,459,460</sup> In the former, cycle fecundity equals that observed in normal fertile women, and cumulative pregnancy rates can reach 80% or higher after 6–12 cycles of treatment.<sup>447,449,459,461</sup> In the latter, cycle fecundability and cumulative pregnancy rates are moderately lower, when ovulation can be successfully induced, and pretreatment with a GnRH agonist improves ovulation rates.<sup>447,449,459</sup>

Overall, pulsatile GnRH therapy can achieve ovulation and pregnancy rates that compare with or even exceed those observed with exogenous gonadotropin treatment in women with PCOS,<sup>460</sup> but how the two treatments might compare in eugonadotropic clomiphene-resistant anovulatory women, arguably the more clinically relevant question, is much less clear because no studies have examined their relative efficacy in such a selected population. One small randomized controlled trial in which pulsatile GnRH therapy (10–20 µg/90 minutes) after GnRH agonist suppression (nafarelin 400 mg daily for 3 weeks or longer) was compared directly with clomiphene citrate treatment (50–150 mg daily, cycle days 3–7) as first-line ovulation induction strategy over two to three cycles observed similar ovulation and pregnancy rates in the two groups.<sup>450</sup> These data serve to emphasize again that more complicated and costly ovulation induction regimens involving GnRH pump therapy or exogenous gonadotropin treatment are best reserved for those who fail to ovulate in response to oral antiestrogens.

**In addition to requiring less or no monitoring after an effective treatment regimen has been established, another advantage that pulsatile GnRH therapy has over exogenous gonadotropin treatment is that it rarely results in multiple follicular development and ovulation; the risk for multiple gestation is therefore substantially lower and that for serious ovarian hyperstimulation is eliminated almost entirely.** The aforementioned 2017 systematic review reported a pooled incidence of multiple pregnancy to be 3.35% (95% CI = 0.03–20.44%, 3 RCTs) and 5.67% (95% CI = 3.96–7.8%, 29 observational studies).<sup>458</sup> In the largest single

collected series including over 100 pregnancies in 600 GnRH-stimulated cycles in nearly 300 women with a variety of ovulatory disorders, only four multiple pregnancies (4% incidence, one triplet and three twin pregnancies) and no cases of moderate or severe ovarian hyperstimulation were observed.<sup>447</sup> Overall, the risk of multiple pregnancy in GnRH-induced conception cycles is comparable to that associated with clomiphene treatment (5–8%) and 40–75% lower than that associated with exogenous gonadotropin therapy in anovulatory women (approximately 15%). Based on a meta-analysis of 29 studies including 2,029 cycles, the pooled estimate of incidence of OHSS is 1.86% (95% CI = 0.79–3.37%).<sup>458</sup>

The overall incidence of spontaneous miscarriage in exogenous GnRH-induced conception cycles is approximately 30%.<sup>447,459</sup> As has been observed in most studies of pregnancies resulting from exogenous gonadotropin treatment,<sup>341,342,343</sup> miscarriage rates are lowest in women with hypogonadotropic hypogonadism (<20%) and highest in those with PCOS (over 40%).<sup>445,447,459</sup>

**Taken together, the results achieved with pulsatile exogenous GnRH therapy support its use as the drug of choice for treatment of anovulatory infertile women with hypogonadotropic hypogonadism.<sup>447,459</sup> Unfortunately, few clinicians have experience with the method and relatively few women judge it as an attractive choice after considering the available alternatives.**

# DOPAMINE AGONISTS

---

Hyperprolactinemia and its treatment with dopamine agonists are considered at length elsewhere in this text in the context of their association with amenorrhea ([Chapter 10](#)). Relevant details from that discussion are summarized briefly again here in an expanded discussion focused on the use of dopamine agonists for ovulation induction.

The two most common dopamine agonists in clinical use are bromocriptine and cabergoline. Both are ergot alkaloids that mimic the actions of dopamine via their binding to dopamine receptors. Serum concentrations peak 1–3 hours after an oral dose of bromocriptine, and very little remains in the circulation 14 hours after administration; an oral dose of 2.5 mg generally lowers prolactin concentrations for up to 12 hours.<sup>462</sup> When administered vaginally, the same dose of bromocriptine has peak effects approximately 10–12 hours later that are sustained for up to an additional 12 hours.<sup>463</sup> Cabergoline is a longer-acting dopamine agonist with high affinity for the dopamine receptor. A single dose of cabergoline effectively inhibits prolactin secretion for 7 days or longer.<sup>464</sup>

Like endogenous hypothalamic dopamine, the agonists inhibit pituitary lactotrope prolactin secretion directly. By lowering serum prolactin levels into the normal range, dopamine agonist treatment allows the hypothalamic-pituitary-ovarian axis to escape from the suppressive influence that hyperprolactinemia has on pulsatile GnRH secretion and to resume normal operation, thereby restoring ovulatory function. Because even prolactin-secreting pituitary adenomas remain sensitive to the actions of dopamine, the agonists are effective in hyperprolactinemic women with and without a pituitary adenoma.<sup>465</sup>

# Indications for Dopamine Agonist Treatment

**Dopamine agonists are the treatment of choice for hyperprolactinemic infertile women with ovulatory dysfunction who wish to conceive.** Although some hyperprolactinemic women will respond to clomiphene treatment, most do not, because the neuroendocrine consequences of hyperprolactinemia generally disrupt the mechanism by which clomiphene exerts its therapeutic action.

Dopamine agonist treatment can be highly effective in women who have galactorrhea but normal serum prolactin levels.<sup>466</sup> With few exceptions, the presence of galactorrhea can be regarded as a reliable indicator of excess prolactin secretion. Possible explanations for occult hyperprolactinemia include excess production of biologically active forms of prolactin not detected in all immunoassay systems and transient but exaggerated nocturnal prolactin secretion that goes unrecognized in randomly drawn blood samples.<sup>466,467,468,469,470</sup>

Up to 30% of women with PCOS can exhibit mild hyperprolactinemia.<sup>471,472</sup> Reduced levels of dopaminergic inhibition also have been implicated as a contributing cause of the elevated serum LH concentrations observed in women with the disorder.<sup>471,473</sup> Consequently, dopamine agonists also have been advocated as adjuvant therapy for hyperprolactinemic anovulatory women with PCOS who require exogenous gonadotropin treatment. Limited evidence suggests that pretreatment with a dopamine agonist can temper the ovarian response to exogenous gonadotropins and may thereby help to decrease the risks of multiple pregnancy and ovarian hyperstimulation associated with such treatment.<sup>472</sup>

# Dopamine Agonist Treatment Regimens

Because many hyperprolactinemic women are very sensitive to low doses of dopamine agonists, treatment generally should begin with a low dose and increase gradually until the dose required to restore and to maintain euprolactinemia has been established. Although the dose ultimately required roughly correlates with the degree of hyperprolactinemia, many women with very high prolactin levels respond to relatively low doses of dopamine agonists. The dose of dopamine agonist required to maintain euprolactinemia very often is lower than that needed to achieve it initially.<sup>474</sup>

**Cabergoline has widely replaced bromocriptine as the first-choice treatment because it seems more effective in decreasing serum prolactin concentration and has a better side effect profile.** Treatment with cabergoline usually begins with a dose of 0.25 mg twice weekly, increasing gradually thereafter about every 4 weeks until the effective dose is established. Most women achieve normal prolactin levels with 0.5–1.0 mg weekly, and doses greater than 2.0 mg weekly rarely are required.<sup>11,474</sup>

With bromocriptine, treatment usually begins with a dose of 1.25–2.5 mg, administered at bedtime to more effectively suppress the normal nocturnal increase in prolactin secretion. A low initial dose also helps to minimize the frequency and severity of gastrointestinal and cardiovascular side effects related to dopamine receptor stimulation.<sup>475</sup> **Prolactin levels decrease and stabilize shortly after treatment begins, and a repeated serum prolactin measurement will demonstrate the effectiveness of any given dose in as little as a week.** If needed, a second dose can be added, administered with breakfast or lunch. Although most women respond to 2.5–5.0 mg bromocriptine daily, some may require as much as 10 mg daily.<sup>11</sup>

Exogenous gonadotropins are an effective alternative for the few who do not respond to a dopamine agonist, alone or in combination with clomiphene.

# Results of Dopamine Agonist Treatment

**Overall, dopamine agonist treatment normalizes and maintains normal prolactin levels in approximately 60–85% of hyperprolactinemic women. Cyclic menses are restored in 70–90%, usually within 6–8 weeks after treatment begins, and ovulatory cycles return in 50–75% of treated women with or without tumors.**<sup>11,12,474</sup> The probability of successful treatment is modestly lower in women with markedly elevated prolactin levels (>100 ng/mL) than in those with lesser degrees of hyperprolactinemia. Breast secretions typically diminish noticeably within approximately 6 weeks, and complete cessation of galactorrhea generally takes about twice as long to achieve. After discontinuation of dopamine agonist therapy, hyperprolactinemia and associated menstrual dysfunction return in 75–80% of women.

A 2012 systematic review and meta-analysis including nine studies found that cabergoline was more effective than bromocriptine in reducing the risk of persistent hyperprolactinemia (RR = 2.88; 95% CI = 2.20–3.74), amenorrhea/oligomenorrhea (RR = 3.41, 95% CI = 1.40–2.36), and galactorrhea (RR = 3.41, 95% CI = 1.9–5.84).<sup>476</sup> Moreover, cabergoline has proven effective in 70–85% of hyperprolactinemic women who are resistant to or cannot tolerate bromocriptine treatment.<sup>11,474,477</sup> Compliance with a twice weekly treatment (cabergoline) is also better than with a twice-daily regimen (bromocriptine).<sup>11</sup>

# Side Effects of Dopamine Agonists

Overall, side effects of dopamine agonist treatment are common, are most severe during the first 2 weeks of therapy, but generally are well tolerated. Because bromocriptine stimulates both D1 and D2 dopamine receptors, most women will experience mild adrenergic side effects<sup>475</sup>; dizziness, nausea, vomiting, nasal stuffiness, and orthostatic hypotension are the most common. Although cabergoline has similar side effects, they generally are less frequent and severe because of the drug's higher affinity to D2 dopamine receptors. Side effects are severe enough to require discontinuation of treatment in approximately 12% of women treated with bromocriptine and in 3% of those treated with cabergoline.<sup>11,476</sup>

Side effects can be minimized by starting with a low dose, increasing gradually thereafter as needed and tolerated. Taking the medications with a snack or meal also improves tolerance. When necessary, vaginal administration of bromocriptine or cabergoline can help to reduce side effects and improve compliance.<sup>478,479,480</sup> Whereas much of an orally administered dose is not absorbed or rapidly metabolized in the first pass through the liver, vaginal absorption is more complete and avoids immediate hepatic metabolism. Consequently, therapeutic results often can be achieved with lower doses when the drugs are administered vaginally.

# Risks of Dopamine Agonist Treatment

There is no evidence that dopamine agonists pose any increased risk for spontaneous miscarriage or birth defects. Numerous studies of women who have conceived during treatment have found no increase in the incidence of spontaneous miscarriage or congenital anomalies in pregnancies resulting from treatment with bromocriptine<sup>11,481,482,483,484</sup> or cabergoline.<sup>11,463,474,477</sup>

Treatment for Parkinson disease with cabergoline or another dopamine agonist, pergolide, has been associated with a four- to sevenfold increased risk for valvular heart disease (mitral, aortic, or tricuspid regurgitation).<sup>485,486</sup> The risk appears to result from mitogenic stimulation of normally quiescent valve cells via activation of serotonin (5-hydroxytryptamine, 5-HT) receptors (specifically, the 5-HT<sub>2B</sub> receptor).<sup>487</sup> Bromocriptine, which has no 5-HT<sub>2B</sub> agonist activity, has not been associated with any increased risk for valvular heart disease. Although the doses of cabergoline used for treatment of hyperprolactinemia are less than 10% of those used for the treatment of Parkinson disease and have not been associated with the development of heart disease, it seems prudent to use the lowest effective dose of cabergoline for the shortest time required to achieve the goals of treatment. Current evidence does not support a recommendation for echocardiography before or during treatment with low doses of cabergoline in asymptomatic women.

# Assisted Reproductive Technologies

**Assisted reproductive technologies (ART)** encompass all techniques involving direct manipulation of oocytes outside of the body. The first and still most common form of ART is in vitro fertilization (IVF), but other related techniques also reside within the realm of ART. The success of modern ART has completely revolutionized both the evaluation and treatment of infertility. Some traditional diagnostic methods and treatments have been rendered obsolete, and others have only limited applications because ART is simply more effective. The trend is clear and certain to continue.

IVF involves a sequence of highly coordinated steps beginning with ovarian stimulation with exogenous gonadotropins, followed by retrieval of oocytes from the ovaries under the guidance of transvaginal ultrasonography, fertilization and embryo culture in the laboratory, and transcervical transfer of embryos into the uterus. The first pregnancy resulting from IVF was reported in 1976 and was ectopic.<sup>1</sup> The first child resulting from IVF was born in 1978.<sup>2</sup> Over the subsequent 40 years, ART has been greatly refined and expanded, resulted in millions of births worldwide, and now accounts for 1–4.5% of all births in the United States and Europe.<sup>3,4</sup> ART includes methods for assisted fertilization by intracytoplasmic sperm injection (ICSI) using sperm isolated from the ejaculate or obtained by microsurgical epididymal sperm aspiration (MESA) or testicular sperm extraction (TESE), assisted embryo hatching, and preimplantation genetic testing (PGT) for aneuploidy (PGT-A; previously called preimplantation genetic screening, PGS) and/or PGT for monogenic disease (PGT-M; previously called preimplantation genetic diagnosis, PGD). In most cases, IVF is used to help an infertile couple conceive their own biologic child; however, donor sperm, donor oocytes, and gestational surrogates also play an important role in modern ART. Medically indicated or elective fertility preservation ([Chapter 29](#)) is another area where ART is increasingly being used.

Other forms of ART include tubal transfer of oocytes and sperm (gamete intrafallopian transfer, GIFT), zygotes (zygote intrafallopian transfer, ZIFT), or embryos (tubal embryo transfer, TET) via laparoscopy. Whereas these more invasive techniques once had certain advantages over traditional IVF for some infertile couples, they now have only very limited, if any, indications.

A truly comprehensive discussion of ART is well beyond the scope of any single book chapter. The objective here is to provide an overview of the indications for ART,

the most common methods for ovarian stimulation, oocyte retrieval, sperm recovery, fertilization, and gamete/embryo transfer, and the results and complications of ART, with emphasis on newly developing technologies and areas of controversy.

# INDICATIONS FOR IVF

---

IVF was first developed as a method to overcome infertility resulting from irreparable tubal disease but now is applied much more broadly for the treatment of almost all causes of infertility. IVF is most clearly indicated when infertility results from one or more causes having no other effective treatment; severe tubal disease relating to previous infection or advanced endometriosis and severe male factor infertility are the most obvious examples. IVF also is often the best treatment for couples with multifactor infertility because it can address or overcome all contributing causes at the same time. IVF is a legitimate treatment option for women with age-related or otherwise unexplained infertility and also represents the treatment of last resort when other treatments fail.

In women with premature ovarian failure or reproductive aging and healthy women beyond normal reproductive age, IVF using oocytes from a young donor is highly successful. For women with normal ovaries but no functional uterus (müllerian agenesis, severe intrauterine adhesions, previous hysterectomy) and those with medical disorders that preclude pregnancy due to serious health risks, IVF with embryo transfer to a gestational surrogate still offers the possibility of genetically related offspring. IVF using oocytes from a donor and embryos transferred to a gestational carrier also allows male same-sex couples to pursue parenthood. In couples who carry autosomal or sex-linked genetic disorders or balanced chromosomal translocations, IVF with PGT can avoid the risk of delivering an affected child.

# Tubal Factor Infertility

Before the advent of IVF, women with irreparable bilateral tubal obstruction were essentially sterile, and the prognosis for those with less severe distal disease was only fair. In the modern era of ART, surgical treatments are declining in importance, and the prognosis for women with tubal factor infertility has improved dramatically. Approximately 14% of patients using ART have a primary diagnosis of tubal factor infertility.<sup>5</sup> The relative advantages and disadvantages of surgery and IVF for the treatment of tubal factor infertility and the factors bearing on a choice between the two are discussed in-depth in [Chapter 25](#) and summarized here.

**Reconstructive surgery remains a viable option for young women with mild distal tubal obstruction or peritubular adhesions (because postoperative live birth rates can exceed 50%),<sup>6,7,8</sup> but IVF is the treatment of choice for women with severe distal disease.** Results achieved with surgery have varied, but success rates (10–35%) are generally lower than with IVF, and the risk of ectopic pregnancy is higher (5–20%).<sup>5,9,10,11,12</sup> In 2015, the overall IVF live birth rate (per cycle start) for U.S. women with tubal factor infertility (all ages) was 24%; however, this rate increases with decreasing age.<sup>5</sup> IVF is also the best treatment for women who remain infertile for more than a year after tubal surgery (the likelihood for success diminishes progressively with time after operation), for older women with significant distal tubal disease (cycle fecundity is low after distal tubal surgery and time is limited), and for women with recurrent distal tubal obstruction (repeated attempts to correct distal tubal occlusive disease are rarely successful).

Although not candidates for reconstructive surgery, women with severe distal tubal disease still can benefit from surgery prior to IVF. **A substantial body of evidence indicates that** pregnancy, implantation, and delivery rates are decreased by approximately 50% and abortion rates are increased in the presence of **communicating hydrosalpinges (proximal patency and distal occlusion)**. The mechanism for the adverse effect of hydrosalpinges on IVF outcomes could involve mechanical interference with implantation or toxic effects on the embryo or endometrium.<sup>13,14,15,16,17,18</sup> A 2010 systematic review including five randomized trials involving 646 women observed that the odds of achieving an ongoing pregnancy were twice as great after laparoscopic salpingectomy for hydrosalpinges before IVF (OR = 2.14, CI = 1.23–3.73).<sup>19</sup> Laparoscopic proximal occlusion of the tubes also increased the odds of clinical pregnancy compared to no intervention (OR = 4.66, CI = 2.47–10.01), and neither surgical procedure was superior.<sup>19</sup> **This is likely to be true even when only one tube is affected.** Moreover, removal or proximal occlusion of unilateral hydrosalpinx seems to improve chances of spontaneous pregnancy.<sup>19,20,21</sup>

**Proximal tubal occlusion** observed during hysterosalpingography (HSG) often is a reaction to the procedure itself and results from “cornual spasm” or other technical pitfalls of the procedure ([Chapter 25](#)). **Efforts to confirm the diagnosis are justified; otherwise, many women may needlessly undergo IVF.** Common methods include repeated HSG<sup>22</sup> and laparoscopic “chromotubation.”<sup>23,24,25</sup> Fluoroscopic or hysteroscopic selective tubal cannulation both establish the diagnosis and provide the means for successful treatment.<sup>22,23,26,27,28,29,30</sup> Microsurgical segmental resection and anastomosis is another proven treatment for true proximal tubal obstruction<sup>31,32,33,34</sup> but requires uncommon technical expertise. IVF is the obvious alternative when cannulation is contraindicated (salpingitis isthmica nodosa) or technically unsuccessful and when infertility persists for more than 6–12 months after the procedure.

Approximately 1 million U.S. women have an elective **tubal sterilization** procedure each year; up to 30% regret the decision, and about 1% later request its reversal.<sup>35,36,37,38</sup> The most commonly cited reasons for regret include new relationships, changes in family planning goals, and death of a child. Regrets are more common in younger women, those who were unaware of the spectrum of contraceptive options, women whose decision for sterilization was influenced by a third party (partner, other family member, friend, or physician), and in those sterilized postpartum or after an abortion.<sup>36,37,39,40</sup> Women 30 years old or younger are twice as likely as older women to express regret, 3.5–18 times more likely to request information about reversal of the procedure, and approximately 8 times more likely to have a sterilization reversal or IVF.<sup>37,38,41</sup>

**Young women sterilized using rings or clips and women having no other infertility factors have the best surgical prognosis; success rates are lower for older women, those sterilized by cautery (particularly multiple-burn techniques), and women with other infertility factors.**<sup>42,43,44,45,46,47,48,49</sup> **Although conception rates are quite good (45–82%) after microsurgical tubal anastomosis in properly selected candidates, IVF is a legitimate alternative to surgery, particularly for older women, those with a poor surgical prognosis or preferring to avoid surgery, and women who desire only one additional pregnancy.**

# Endometriosis

The association between endometriosis and infertility and the pathogenic mechanisms involved are considered at length in [Chapter 32](#). In brief summary, 20–40% of infertile women have endometriosis, and accumulated evidence indicates that fertility decreases with the severity of the disease. Endometriosis may cause infertility by distorting adnexal anatomy and interfering with ovum capture<sup>50</sup> or possibly by impairing oocyte development, early embryogenesis, or endometrial receptivity.<sup>51,52,53,54,55,56,57,58</sup> IVF should be expected to overcome any anatomical obstacles, and although the mechanisms by which IVF can conquer functional disorders of oocyte, embryo, or endometrial development are not clear, outcomes in women with endometriosis suggest it can. Endometriosis is the primary diagnosis in approximately 9% of patients using ART, although this number is likely an underestimate as not all patients with infertility undergo a diagnostic test for endometriosis.<sup>5</sup>

Treatment options for infertile women with advanced stages of endometriosis include conservative surgical treatment and IVF. For those with severe pain symptoms, surgery is the most logical treatment. However, whether surgical treatment of advanced endometriosis improves IVF outcome beyond symptom relief is controversial.<sup>59</sup> Data from uncontrolled case series suggest that cumulative pregnancy rates 1–3 years after surgical treatment are approximately 50% for women with endometriomas<sup>52,53,54,55</sup> and about 30% for women with complete cul-de-sac obliteration.<sup>60,61,62</sup> Patient selection and careful surgical technique are important because ovarian function can be compromised by excision of excessive tissue or damage to hilar vessels<sup>63,64</sup>; the risk of ovarian failure after excision of bilateral ovarian endometriomas is approximately 2.5%.<sup>65</sup> Preoperative oocyte or embryo cryopreservation should be considered prior to surgery in women at high risk of ovarian failure, for example, those with bilateral endometrioma and already low ovarian reserve. **After surgical treatment, the choice between expectant management, empirical treatment, and IVF should be based on age, surgical results, and the severity of any other coexisting infertility factors. The endometriosis fertility index, an externally validated staging system, incorporating female age, duration of infertility, history of a prior pregnancy, tubal and ovarian status at conclusion of surgery, and American Fertility Society score can aid in identification of couples with a poor prognosis for non-IVF conception and avoid loss of time without effective treatment.**<sup>66,67,68,69,70</sup>

Asymptomatic infertile women with advanced endometriosis, including those with ovarian endometriomas, can be treated surgically or proceed directly to IVF. Even though endometriomas can grow during ovarian stimulation and prevent access to some follicles during oocyte retrieval, there is no evidence to indicate that endometriomas

have any important adverse effect on the response to ovarian stimulation or IVF outcomes.<sup>71,72,73</sup> Consequently, endometriomas can be left untreated before IVF. Aspiration of endometriomas before ovarian stimulation or at time of oocyte retrieval has been associated with an increased risk for developing an ovarian abscess and is not recommended,<sup>74,75,76,77</sup> although the risk appears quite low.<sup>73,78</sup>

Treatment options for asymptomatic women with known or suspected minimal or mild endometriosis and no other infertility factors include expectant management, surgical treatment, empiric treatment with clomiphene or exogenous gonadotropins and IUI, and IVF. In older women, those with other coexisting infertility factors, and women who have failed other forms of treatment, IVF is often the best overall choice.

Results of a 2006 systematic review including three randomized trials involving 165 infertile women with endometriosis of varying severity suggest that treatment with a GnRH agonist for 3–6 months before IVF can increase the odds of clinical pregnancy (OR = 4.28, CI = 2.0–9.15).<sup>79</sup> However, because prolonged treatment with a GnRH agonist also can decrease response to ovarian stimulation, this regimen should be used cautiously in those with diminished ovarian reserve (DOR). Indeed, some retrospective series suggest similar IVF outcome with GnRH agonists or antagonists in women with endometriosis.<sup>80,81</sup> Therefore, long-term GnRH antagonist use in endometriosis may be used to achieve similar IVF results; however, they have not yet been tested in clinical trials.

# Male Factor Infertility

Poor semen quality is the sole cause of infertility in approximately 20% of infertile couples and an important contributing factor in another 20–40%.<sup>82,83</sup> Many infertile men have disorders that can be corrected medically or surgically if properly diagnosed and treated, allowing them to achieve natural conception with their partners. In others, mild but important semen abnormalities can be overcome by IUI. **When treatment is not possible or fails, IVF and ICSI, using sperm isolated from the ejaculate or extracted from the epididymis or testis, offers realistic hope for success.** The evaluation and treatment of male factor infertility are the focus of [Chapter 26](#). Discussion here is limited to the indications for ART.<sup>83</sup>

The likelihood of male factor infertility is increased in men whose ejaculates consistently exhibit a sperm concentration under 15 million sperm/mL, less than 32% progressive motility, or fewer than 4% morphologically normal sperm (strict criteria, WHO III standard).<sup>84</sup> The overall odds of male infertility increase with the number of abnormal parameters in the subfertile range; the probability is 2–3 times higher when one is abnormal, 5–7 times higher when two are abnormal, and approximately 16 times greater when all three parameters are abnormal.<sup>85</sup> **Additional genetic evaluation is indicated for men with severe oligospermia (sperm concentration <5 million/mL) (Chapter 26).**

Medical or surgical treatment to improve or normalize poor semen quality is always the first and best option, when that is possible. When treatment is not feasible or proves unsuccessful, timely IUI can help to improve cycle fecundity in some couples with male factor infertility. **Best results with IUI are achieved when the number of total motile sperm in the insemination specimen exceeds a threshold of approximately 10 million.**<sup>86,87,88</sup> Higher counts do not further increase the likelihood for success,<sup>86</sup> and IUI is seldom successful when fewer than 1 million total motile sperm are inseminated.<sup>89,90</sup> The effect of sperm morphology on IUI success is controversial, and predictive value of percentage of morphologically normal sperm is low, yet most studies suggest lower pregnancy rates with lesser than 4% sperm with normal morphology.<sup>91,92,93,94,95,96</sup> However, a low percentage of morphologically normal sperm alone does not necessitate omitting IUI in favor of IVF. The likelihood of success with IUI also decreases with increasing female partner age and with coexisting infertility factors (ovulatory dysfunction, uterine and tubal factors).

**When IUI is not possible, the prognosis for success with IUI is poor, or IUI proves unsuccessful, IVF is the logical alternative.** Approximately 35% of patients using ART have a primary diagnosis of male factor infertility.<sup>5</sup>

Conventional fertilization rates in IVF cycles are decreased when the total motile sperm count is less than 2–3 million (postwash).<sup>97,98</sup> Similarly, conventional fertilization rates also are decreased when less than 4% of sperm are morphologically normal (also called teratospermia).<sup>97,99,100,101,102</sup> Although severe teratospermia is widely accepted as an indication for assisted fertilization by ICSI, some, after observing no differences in fertilization, pregnancy, and live birth rates achieved with ICSI, compared with conventional fertilization, do not regard isolated teratospermia as an indication for ICSI.<sup>103,104,105,106</sup>

# Ovulatory Dysfunction

For women with ovulatory disorders (hypogonadotropic hypogonadism, polycystic ovary syndrome (PCOS), thyroid disorders, hyperprolactinemia), ovulation induction alone generally restores fertility ([Chapter 27](#)), but for some who require exogenous gonadotropins, ovulation induction proves difficult to achieve or consistently results in excessive ovarian stimulation and cycle cancellation for undue risk of ovarian hyperstimulation syndrome (OHSS) and high-order multiple gestation. For these difficult patients, IVF is an obvious treatment alternative, making their high sensitivity to gonadotropin stimulation an asset instead of a liability. Ovulatory dysfunction is the primary diagnosis in approximately 14% of patients using ART.<sup>5</sup>

# Unexplained Infertility

The incidence of unexplained infertility ranges from 10% to as high as 30% among infertile populations, depending on diagnostic criteria.<sup>107,108,109</sup> For women with unexplained infertility, treatment options (cycle fecundability in parentheses) include expectant management (2–4%),<sup>110</sup> combined treatment with IUI and clomiphene (5–10%)<sup>111,112,113</sup> or gonadotropins (7–10%),<sup>111,114,115</sup> and IVF (25–45%).<sup>5,116</sup> As might be expected, success rates with all forms of treatment decline progressively with increasing age of the female partner.

Among couples with unexplained infertility, IVF is the preferred treatment for some and the treatment of last resort for others. **In either case, there is no question that IVF is the most effective treatment for couples with unexplained infertility.** A higher incidence of fertilization failure has been observed in several, but not all, studies of IVF outcomes in couples with unexplained infertility,<sup>117,118,119,120</sup> prompting many to recommend ICSI when IVF is planned. However, whether ICSI improves fertilization rate in the absence of male factor infertility remains controversial. It also seems unlikely that ICSI improves clinical outcome over that achieved with IVF in unexplained infertility.<sup>121,122,123</sup> Approximately 14% of patients using ART have a diagnosis of unexplained infertility.<sup>5</sup>

# Diminished Ovarian Reserve and Ovarian Failure

Increasing number of women undergo ART due to DOR. In the United States, DOR was the primary diagnosis for 10% of ART cycles in 2003, 14% in 2008, and 19% in 2015; the number of fresh IVF cycles using nondonor oocytes performed for women with DOR almost doubled reaching over 13,000 cycles during the same time period (Figure 28.1).<sup>5</sup>

**FIGURE 28.1**

IVF using oocytes from a known or anonymous young donor was first developed for women with premature ovarian failure or menopause.<sup>124</sup> Now, oocyte donation is most commonly performed in women over age 42, those with grossly abnormal ovarian reserve test results, and women whose IVF cycles consistently yield poor quality embryos. Similar to the trend observed with DOR, the number of women undergoing oocyte donation in the United States almost doubled in the past decade.<sup>5</sup>

# Other Indications for IVF and Related Technologies

Although less commonly encountered, there are a number of other legitimate indications for IVF and related ART procedures.

**Fertility preservation** is fast becoming a common indication for ART. Women with cancer or other illnesses requiring treatments (chemotherapy, radiation therapy) that pose a serious threat to future fertility may be candidates for urgent IVF and cryopreservation of embryos before treatment begins, if time and health allow.<sup>125</sup> Oocyte cryopreservation is a viable option for women in similar circumstances having no male partner<sup>126</sup> and is an option for young women at risk for premature ovarian failure, healthy aging women, and others who anticipate delayed childbearing.<sup>127,128</sup>

For women with normal ovaries but no functional uterus, due to a developmental anomaly (müllerian agenesis), advanced disease (multiple myomas, severe intrauterine adhesions), or a previous hysterectomy, and for women with medical conditions that preclude pregnancy due to serious health risks, **gestational surrogacy** offers the opportunity to have their own genetic offspring.<sup>129,130</sup>

Male same-sex couples utilize egg donation and gestational surrogacy to achieve parenthood. IVF may also be utilized by female same-sex couples to achieve pregnancy using eggs retrieved from one partner, fertilized by donor sperm, and transferred to the other partner, in a process termed reciprocal IVF.

For couples at risk for transmitting a specific genetic disease or abnormality to their offspring, IVF with **preimplantation genetic testing for monogenic diseases (PGT-M, also called preimplantation genetic diagnosis or PGD)** provides the means to identify and exclude affected embryos and thereby avoid that risk. PGT-M is applied most commonly in couples who carry autosomal recessive and sex-linked disorders or harbor a balanced chromosomal translocation.<sup>131</sup> Women who carry a genetic disorder not amenable to diagnosis by PGT-M or who decline PGT-M may be candidates for oocyte donation. **Preimplantation genetic testing for aneuploidy (PGT-A, also called preimplantation genetic screening or PGS)** applies the same technology in couples having no known chromosomal or genetic abnormality in efforts to identify and exclude aneuploid embryos.<sup>132</sup>

# PROGNOSTIC FACTORS

---

The probability for success with IVF relates to several factors, many of which are unfortunately not known until the treatment cycle is well underway (response to stimulation) or even nearing completion (number and quality of embryos). Before an IVF cycle begins, the primary prognostic indicators are maternal age, ovarian reserve, diagnosis, and past reproductive performance.

# Maternal Age

The relationship between maternal age and fertility and the physiology of reproductive aging are discussed in detail in [Chapter 25](#) only briefly summarized again here, where the focus is on the relationship between maternal age and IVF outcomes.

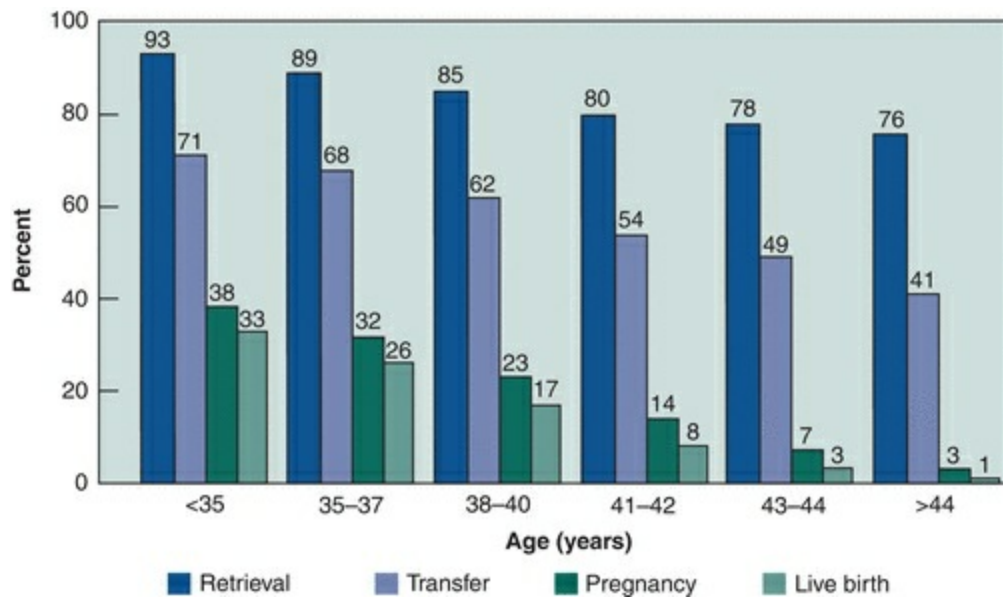

The average age of women using ART in the United States is 35 years.<sup>5</sup> **Maternal age is the one most important factor in determining the likelihood for success with IVF.** Although IVF can overcome most causes of infertility in younger women, it cannot negate or reverse the age-related decrease in biologic fertility in older women, particularly those over the age of 40.<sup>133</sup> The success rates achieved with IVF, like natural fertility rates, decline as maternal age increases.<sup>5</sup> **The pattern reflects a progressive decline in response to ovarian stimulation, resulting in fewer oocytes and embryos, and a decreased embryo implantation rate, due to declining oocyte quality and increasing embryo aneuploidy.**<sup>134,135,136,137,138</sup> In 2015, the percentage of cycles that resulted in a live birth from fresh nondonor oocytes, by maternal age, was 33% for women under age 35, 26% for ages 35–37 years, 17% for ages 38–40 years, 8% for ages 41–42 years, 3% for ages 43–44 years, and 1% for over 44 years.<sup>5</sup> The pattern of decreasing success rates achieved with IVF parallels that associated with other, less complex, forms of treatment for infertility ([Figure 28.2](#)).<sup>139</sup>

\* Total percentages are greater than 100% because more than one diagnosis can be reported for each cycle.

**FIGURE 28.2**

Evidence from numerous lines of investigation indicates that the age-dependent decrease in success rates achieved with IVF relates primarily to an increasing prevalence of aneuploidy in aging oocytes,<sup>140,141,142,143</sup> which is reflected in the incidence of miscarriage in pregnancies achieved with ART: less than 15% for women under age 35, 20% at age 38, 29% at age 40, and nearly 60% for women over age 44 (Figure 28.3).<sup>5</sup> In a case series of IVF cycles involving women aged 45–49, 70/231 cycles (30%) were cancelled before oocyte retrieval and 34/161 retrievals (21%) resulted in a pregnancy, but only 5/34 pregnancies (15%) and 5/231 cycles (2%) resulted in a live birth (Figure 28.4).<sup>144</sup>

**FIGURE 28.3**

**FIGURE 28.4**

# Ovarian Reserve

A retrospective analysis of all 400,135 IVF cycles performed in the United Kingdom over a 17-year period spanning 1991–2008, showed a strong association between the number of oocytes and live birth rate, which rose with an increasing number of eggs  $\approx 15$ .<sup>145</sup> In the same study, live birth rate plateaued between 15 and 20 eggs and steadily declined beyond 20 eggs. This decline is most likely due to impaired endometrial receptivity in a hyperstimulated cycle, rather than an adverse effect of stimulation on oocytes. The major determinant of number of oocytes collected is the ovarian reserve. The concept of ovarian reserve, generally defined as the size and quality of the remaining ovarian follicular pool, and the various methods for its measurement are discussed in detail in [Chapter 25](#). In brief summary, the total number of oocytes in any given woman is genetically determined and inexorably declines throughout life, from approximately 1–2 million at birth, to about 300,000 at puberty, 25,000 at age 40, and fewer than 1,000 at menopause.<sup>146,147,148</sup> The rate of follicular depletion is not constant but increases gradually as the number of follicles remaining decreases.<sup>149,150,151,152</sup> As the size of the remaining follicular pool decreases, circulating inhibin B levels (derived primarily from smaller antral follicles) decrease, resulting in lower levels of feedback inhibition and a progressive increase in serum follicle-stimulating hormone (FSH) levels, most noticeably during the early follicular phase.<sup>153,154,155,156,157,158,159,160,161</sup> Increasing intercycle FSH concentrations stimulate earlier follicular recruitment, resulting in advanced follicular development early in the cycle, an earlier rise in serum estradiol levels, a shorter follicular phase, and decreasing overall cycle length.<sup>162,163,164</sup>

The physiology of reproductive aging provides the foundation for all contemporary tests of ovarian reserve. Traditionally, the basal early follicular phase (cycle days 2–4) FSH level was the most common test; however, antimüllerian hormone (AMH) and antral follicle count (AFC) are being used increasingly more often.

As basal FSH levels increase, peak estradiol levels during stimulation, the number of oocytes retrieved, and the probability for pregnancy or live birth decline steadily.<sup>165,166,167,168,169,170,171</sup> **With current assays (using IRP 78/549), FSH levels greater than 10 IU/L (10–20 IU/L) have high specificity (80–100%) for predicting poor response to stimulation, but their sensitivity for identifying such women is generally low (10–30%) and decreases with the threshold value.**<sup>170</sup> Although most women who are tested have a normal result, including those with a DOR, the test is still useful because those with abnormal results are very likely to have DOR.

**The basal serum estradiol concentration, by itself, has little value as an ovarian reserve test**<sup>172,173,174,175</sup> **but can provide additional information that helps in the interpretation of the basal FSH level.** An early elevation in serum estradiol reflects

advanced follicular development and early selection of a dominant follicle (as classically observed in women with advanced reproductive aging) and will suppress FSH concentrations, thereby possibly masking an otherwise obviously high FSH level indicating DOR. When the basal FSH is normal and the estradiol concentration is elevated (>60–80 pg/mL), the likelihood of poor response to stimulation is increased and the chance for pregnancy is decreased.<sup>176,177,178,179</sup> When both FSH and estradiol are elevated, ovarian response to stimulation is likely to be very poor.

Antimüllerian hormone derives from preantral and small antral follicles. The number of small antral follicles correlates with the size of the residual follicular pool, and AMH levels decline progressively with age, becoming undetectable near the menopause.<sup>180,181,182,183</sup> Overall, lower AMH levels have been associated with poor response to ovarian stimulation and low oocyte yield, embryo quality, pregnancy rates, and cumulative live birth rates,<sup>184,185,186,187,188</sup> but studies correlating mean AMH levels with IVF outcomes have not yielded threshold values that can be applied confidently in clinical care.<sup>172,185,186,189,190,191,192,193,194,195,196,197,198</sup> **In the general IVF population, low AMH threshold values (0.2–0.7 ng/mL) have had 40–97% sensitivity, 78–92% specificity, 22–88% positive predictive value (PPV), and 97–100% negative predictive value (NPV) for predicting poor response to stimulation (<3 follicles or <2–4 oocytes) but have proven neither sensitive nor specific for predicting pregnancy.**<sup>184,199,200,201</sup> In women at low risk for DOR, values of 2.5–2.7 ng/mL have had 83% sensitivity, 82% specificity, 67–77% PPV, and 61–87% NPV for clinical pregnancy.<sup>173,202</sup> A study in women at high risk for DOR (involving older women, those with an elevated FSH, or history of poor response to stimulation) observed that an undetectable AMH had 76% sensitivity, 88% specificity, 68% PPV, and 92% NPV for three or fewer follicles.<sup>185</sup> In 2018, a large prospective cohort study of more than 2,000 women younger than 38 years old undergoing their first IVF cycle found that the odds of a given fertilized oocyte developing to a blastocyst, being aneuploid or leading to a live birth after euploid transfer were no different if the oocyte was retrieved from a cycle with AMH in the less than 10th percentile (corrected for age) compared to an oocyte retrieved in a cycle with those parameters in the 25–75th percentile. AMH level in the less than 10th percentile did more commonly result in cycle cancellation prior to retrieval and after retrieval prior to transfer due to global arrest of embryos. These findings suggest that while young women with evidence of quantitative depletion of ovarian reserve have lower live birth rates per stimulation cycle, this is not simply attributable to poor oocyte quality.<sup>198</sup>

The AFC is the total number of antral follicles measuring 2–10 mm in both ovaries during the early follicular phase and is a useful measure of ovarian reserve because it quantifies the number of follicles at the stage of development that responds to FSH

stimulation.<sup>203,204,205,206,207</sup> Several studies have observed a relationship between the AFC and response to ovarian stimulation in IVF cycles. In the general IVF population, including women at low and high risk for DOR, an AFC threshold value of three to four follicles has high specificity (73–100%) for predicting poor response to ovarian stimulation and failure to conceive (64–100%) but relatively low sensitivity for both end points (9–73% for poor response and 8–33% for failure to conceive).<sup>174,208,209,210,211,212,213,214</sup> **The PPV and NPV of AFC have varied widely in studies. A low AFC has high specificity for predicting poor response to ovarian stimulation and treatment failure, making it a useful test, but its low sensitivity limits its overall clinical utility.**

In summary, both AFC and AMH level are useful tools to identify patients who are likely to have a poor, normal, or hyperresponse to exogenous gonadotropin stimulation.<sup>211,215,216,217</sup> **However, none of the ovarian reserve tests currently in use is an accurate predictor of pregnancy in IVF cycles, unless extreme abnormal threshold values are applied, which results in very low sensitivity for identifying women having a poor prognosis.**<sup>218</sup> The tests are adequate for predicting poor response, which does have prognostic value, although not as great in young women as in older women.<sup>219,220,221</sup> Although ovarian reserve tests have become a routine element of pretreatment evaluation for couples planning IVF, it can be argued that routine testing has limited clinical utility in the large majority of patients and can be misleading, especially in women at low risk for having a DOR.<sup>222</sup>

Ovarian reserve tests always should be interpreted with caution. Rigid application of test results risks inappropriate recommendations for treatment or for no treatment, and both must be avoided. An abnormal test result does not preclude the possibility of pregnancy. **Except perhaps at the extremes, test results should not be used to deny treatment but only to obtain prognostic information that may help to guide the choice of treatment and best use of available resources. Although the probability of pregnancy may be low, many with abnormal test results will achieve pregnancy if afforded the chance. Ultimately, regardless of the prognosis, the success rate for any individual woman will be 0% or 100%.**

# Diagnosis and Past Reproductive Performance

Although the average overall IVF live birth rate per cycle is approximately 24% for all women in the United States, success rates vary, to some extent, with the cause of infertility. In 2015, the success rates for women with tubal factor infertility, ovulatory dysfunction, endometriosis, male factor, and unexplained infertility were above average, and those for women with multiple infertility factors, a uterine factor, and DOR were below average. Whereas these data are useful, it is important to note that criteria for the different diagnoses are not standardized and likely vary among treatment centers ([Table 28.1](#)).

## TABLE 28.1 Live Birth Rates in IVF Cycles, By Diagnosis, 2015<sup>5</sup>

**Infertility Diagnosis****Live Births/Cycle**

Unexplained infertility (Unknown factor)	29.0%
Ovulatory dysfunction	28.8%
Endometriosis	27.6%
Male factor	27.1%
Tubal factor	24%
Multiple factors, female and male	22%
Other factor	18.5%
Uterine factor	17.3%
Multiple factors, female only	17.3%
Diminished ovarian reserve	13.1%

Women with a previous live birth are more likely to succeed with IVF than nulliparous women. In all age categories, success rates for women having one or more previous live births are modestly higher (1–5%) than for women with no previous live births, while women with previous unsuccessful ART cycles attain lower live birth rates beginning after two previous failures.<sup>5</sup> A history of an earlier unsuccessful pregnancy has no effect on success rates.<sup>5</sup>

## Other Prognostic Factors

As discussed earlier in the section focused on indications for ART, there is substantial evidence indicating that hydrosalpinges adversely affect IVF outcomes and that salpingectomy or proximal tubal occlusion before IVF increases the likelihood for achieving a live birth by twofolds.<sup>19</sup> Laparoscopic salpingectomy before IVF is generally recommended for women with hydrosalpinges, even when only one tube is affected. A study evaluating the cost-effectiveness of preliminary salpingectomy concluded that the procedure decreases the average cost per live birth, compared to no treatment.<sup>223</sup> One concern with salpingectomy or even tubal occlusion or ligation is its impact on ovarian reserve. Despite contradictory results in early reports, salpingectomy does not impact ovarian reserve, except perhaps when it is done for ectopic pregnancy. Salpingectomy does not significantly decrease serum AMH concentration, ovarian response to stimulation or clinical pregnancy rates with IVF.<sup>224,225</sup> Ovarian stimulation parameters, implantation, and clinical pregnancy rates are similar in women who underwent salpingectomy or laparoscopic proximal tubal occlusion.<sup>226</sup>

Ultrasound-guided aspiration of hydrosalpingeal fluid at the time of oocyte retrieval has been suggested as an alternative treatment.<sup>227</sup> The procedure is effective in improving IVF outcome as compared to no intervention, simpler and less costly than surgical options. However, salpingectomy or proximal tubal occlusion improve success rates more than fluid aspiration with regard to ongoing pregnancy, clinical pregnancy, ectopic pregnancy, and miscarriage rates.<sup>228</sup> Moreover, the fluid reaccumulates rapidly.<sup>229</sup> Aspiration of hydrosalpingeal fluid should be reserved for women who are likely to have severe intra-abdominal adhesions prone to complications with pelvic surgery.

Essure is a 2-mm-thick and 4-cm-long microplug, primarily used as a contraceptive device. Essure coil inserts have been used for occlusion of hydrosalpinges prior to IVF. Hysteroscopic placement of Essure coils is relatively easy; however, clinical pregnancy, implantation, and live birth rates following Essure are significantly lower than those achieved with laparoscopic management (salpingectomy or proximal occlusion) of hydrosalpinges.<sup>230</sup> Some evidence suggest that miscarriage rate is higher following Essure blockage of hydrosalpinges, as compared with other interventions.<sup>231</sup> Similar to hydrosalpinx aspiration, currently, Essure can be regarded as a second-line intervention for women under high risk of intra-abdominal adhesions. It is noteworthy that, in late July of 2018, the manufacturer announced its plans to stop selling Essure in the United States, possibly as a result of injury and increasing safety restrictions from regulators.

The effect of uterine myomas on IVF outcomes depends on their location. They alter

global endometrial receptivity through the production of cytokines rather than simply a mechanical effect.<sup>232,233,234</sup> There is a clear consensus that submucous myomas have significant adverse effect on clinical pregnancy rates (OR = 0.3, CI = 0.1–0.7) and delivery rates (OR = 0.3, CI = 0.1–0.8).<sup>235,236,237,238,239,240</sup> Available data also support the conclusion that submucous myomas increase risk for miscarriage by more than threefolds,<sup>239,240</sup> while the effect of intramural myomas that do not distort the cavity on the risk of miscarriage is less clear.<sup>241</sup> Results of early studies examining the effect of intramural myomas on IVF outcomes are inconsistent, with some finding adverse effects,<sup>242,243,244,245,246</sup> and others not.<sup>239,247,248,249,250,251,252</sup> Large-scale prospective studies report significantly lower implantation, pregnancy, ongoing pregnancy, and live birth rates in women with intramural myomas.<sup>245,246</sup> A 2010 systematic review of the effect of intramural myomas without uterine cavity involvement on IVF outcome included 19 observational studies comprising 6,087 IVF cycles.<sup>253</sup> Live birth rate was significantly decreased (RR = 0.79, 95% CI = 0.70–0.88). It is noteworthy that when results from the only two prospective studies reporting live birth rate were pooled, the relative reduction in live birth was 40% (RR = 0.60, 95% CI = 0.41–0.87). Likewise, clinical pregnancy rate was decreased by 21% (RR = 0.79, 95% CI = 0.70–0.88), and implantation rate was decreased by a relative 13% (RR = 0.87, 95% CI = 0.73–1.03).<sup>253</sup> The effect appears to be related to both myoma size and proximity to the endometrium. All of the evidence concerning the effects of subserosal myomas is consistent in finding no evidence of adverse effects on IVF outcomes. **In sum, the accumulated body of evidence indicates that submucous myomas reduce IVF success rates by approximately 70%, intramural myomas by approximately 20–40%, and subserosal myomas have no adverse impact on outcomes. Submucous myomas increase risk for miscarriage after successful IVF at least threefolds and intramural myomas by more than half. Submucous and large proximal intramural fibroids should be removed prior to IVF.**<sup>254</sup>

## Tobacco Use

All smoking women should be strongly encouraged to stop smoking before IVF because smoking decreases the likelihood for success.<sup>255,256,257</sup>

# EVALUATION BEFORE IVF

---

Individuals and couples planning IVF require additional specific evaluation before a treatment cycle begins. At a minimum, evaluation generally includes a test of ovarian reserve, a current assessment of semen quality, infectious disease screening, and imaging of the uterine cavity.

**Ovarian reserve tests** (basal FSH, AMH, AFC) have value for predicting response to gonadotropin stimulation and therefore can be helpful in planning treatment. If a threshold value with high specificity for detecting DOR is applied, the test can accurately identify women at high risk for poor response and treatment failure.

**Semen quality** should be assessed shortly before the treatment cycle is scheduled to start, even when earlier diagnostic evaluation revealed normal semen parameters, to ensure there has been no appreciable change that might affect the choice between conventional fertilization and ICSI. Sperm cryopreservation is prudent when semen quality is severely abnormal or there is reason to anticipate difficulty with obtaining a fresh specimen on the day of oocyte retrieval. Although fertilization rates achieved with frozen-thawed sperm may be somewhat lower than when fresh sperm are used, pregnancy rates are comparable.<sup>258,259,260</sup>

**Infectious disease screening** recommended for both partners includes human immunodeficiency virus (HIV), hepatitis B (hepatitis B surface antigen), hepatitis C (hepatitis C antibody), and syphilis (rapid plasma reagin), for the protection of medical and laboratory staff, protection of any fetus that may result from IVF, and protection against the risk for cross-contamination of cryopreserved embryos in storage. Whereas some advocate routine testing for chlamydia and gonorrhea in the female partner, others choose to limit evaluation to women with tubal factor infertility or other risk factors. Testing for antibodies to rubella and varicella in women undergoing IVF should be performed for timely immunization, if indicated.

**Imaging of the uterine cavity** before a cycle of treatment identifies submucosal myomas or endometrial polyps that may interfere with implantation or have an adverse effect on pregnancy outcome. An HSG performed earlier during the diagnostic evaluation may suffice if entirely normal and relatively recent (within approximately 6 months), but sonohysterography and hysteroscopy are the more sensitive and preferred methods. Routine office hysteroscopy before IVF was expected to identify potentially significant abnormalities such as polyps, myomas, adhesions, or septa in 10–20% of patients without symptoms.<sup>261,262,263</sup> However, two multicenter randomized controlled trials suggest that routine hysteroscopy prior to an IVF cycle does not improve outcomes over routine imaging.<sup>264,265</sup> Many prefer sonohysterography to hysteroscopy because it is easier to perform, is highly sensitive, and also can detect hydrosalpinges and

unsuspected ovarian pathology.<sup>266,267,268</sup>

Many clinicians would also perform a **trial transfer** to determine the technique required to achieve an atraumatic embryo transfer and to identify women whose transfer may be difficult to accomplish, although the orientation of the uterus can change when the ovaries are enlarged after stimulation.<sup>269,270,271,272</sup>

# OVARIAN STIMULATION REGIMENS

---

The ideal ovarian stimulation regimen for IVF should have a low cancellation rate; minimize drug costs, risks, and side effects; require limited monitoring for practical convenience; and maximize cumulative live birth rate per oocyte retrieval procedure, that is, cumulative chances of one or more live births after exhausting all fresh and frozen embryos generated from a single oocyte retrieval. Singleton pregnancy delivered at term is the ultimate goal of ART.

There are three components of a typical ovarian stimulation regimen for IVF; the first is exogenous gonadotropins to stimulate multifollicular growth, the second is GnRH analogues (antagonist or agonist) to prevent spontaneous ovulation before oocyte retrieval, and the third is LH activity in the form of human chorionic gonadotropin (hCG) to induce oocyte maturation. The source and type of gonadotropin, for example, endogenous or exogenous, human menopausal gonadotropin or recombinant, the type of GnRH analogue, that is, agonistic or antagonistic, vary according to the selected protocol.

Numerous regimens have been described, ranging from no stimulation (natural cycles), to minimal stimulation (clomiphene citrate) or mild stimulation (sequential treatment with clomiphene citrate and low-dose exogenous gonadotropins), to aggressive stimulation (high-dose exogenous gonadotropins, alone or in combination with a gonadotropin-releasing hormone agonist or antagonist).

# Natural Cycle

The first birth resulting from IVF derived from a single oocyte collected in a natural ovulatory cycle.<sup>2</sup> Compared to stimulated IVF cycles, natural cycle IVF offers a number of attractive advantages. Natural cycle IVF involves only monitoring the spontaneous cycle and retrieving a single oocyte before the midcycle LH surge occurs. It is physically less demanding, requires little or no medication, decreases costs,<sup>273,274</sup> and all but eliminates risks for multiple pregnancy and OHSS. The chief disadvantages of natural cycle IVF are high cancellation rates due to premature LH surges and ovulation and the comparatively low success rate of approximately 7%.<sup>275</sup>

When oocyte retrieval is based on detection of the midcycle rise in LH, careful and frequent monitoring is required and procedures are difficult to schedule efficiently. Alternatively, exogenous hCG can be administered when the lead follicle reaches a size consistent with maturity, thereby better defining the optimum time for oocyte retrieval.<sup>274</sup> Adjuvant treatment with a GnRH antagonist also can be used to prevent a premature LH surge but requires “add-back” treatment with exogenous FSH, and success rates are still quite low, ranging up to 14% per cycle in nonrandomized trials.<sup>276,277,278,279</sup> In one large cohort study involving 844 treatment cycles in 350 good prognosis patients, the cancellation rate was 13%, the pregnancy rate was 8% per cycle, and the cumulative pregnancy rate after three “modified natural IVF cycles” was 21%.<sup>280</sup> In a cohort of infertile couples with male factor infertility, success rates in modified natural cycles have reached as high as 13% per cycle, with a cumulative pregnancy rate of 44% after six treatment cycles.<sup>281</sup> Since the number of oocytes retrieved is positively correlated with pregnancy rates,<sup>145</sup> natural or modified natural cycles are not the first choice for women who can produce multiple follicles with gonadotropin stimulation. However, they can be a reasonable compromise for women who are expected to grow one or two follicles despite gonadotropin stimulation.

# Clomiphene Citrate

Clomiphene citrate was the first method of ovarian stimulation used in IVF,<sup>282,283</sup> but now has been almost entirely replaced by more effective stimulation regimens using human menopausal gonadotropins hMG or FSH, in combination with a GnRH agonist or antagonist.<sup>284</sup>

Clomiphene (100 mg daily) usually is administered for 5–8 days, beginning on cycle day 3, and induces development of two or more follicles in most normally ovulating women,<sup>285,286,287</sup> although egg yields (1–3) are only slightly greater than in unstimulated cycles and substantially lower than in cycles stimulated with exogenous gonadotropins.<sup>287,288,289</sup> Cycle cancellation rates are somewhat lower than in natural cycles, and the numbers of oocytes retrieved, embryos transferred, and pregnancy rates are greater. As in natural cycles, exogenous hCG is administered when the lead follicle reaches mature size and a GnRH antagonist can be used to prevent a premature endogenous LH surge.

Sequential treatment with clomiphene (100 mg daily for 5 days) and modest doses of exogenous gonadotropins (150–225 IU daily beginning on the last day of clomiphene treatment or the day after) stimulates multifollicular development more effectively than treatment with clomiphene alone.<sup>290,291,292</sup> Drug costs and monitoring requirements are moderately higher but still substantially less than in standard stimulation regimens involving higher-dose gonadotropin treatment after down-regulation with a long-acting GnRH agonist (described below).<sup>293,294</sup> In one comparative trial, higher cancellation rates and lower pregnancy rates were observed in sequential clomiphene/gonadotropin compared to gonadotropin/GnRH agonist cycles.<sup>294</sup> In another, the sequential stimulation regimen yielded fewer oocytes and embryos, but pregnancy rates were similar and the risks of OHSS were lower.<sup>293</sup> Adding a GnRH antagonist to the treatment regimen can prevent premature LH surges and improve outcomes but also increases costs. In a randomized trial, sequential clomiphene/gonadotropin stimulation and GnRH antagonist treatment yielded a pregnancy rate comparable to that achieved with a more aggressive standard treatment protocol,<sup>295</sup> confirming the results of two earlier retrospective studies,<sup>296,297</sup> although contrasting with those of another observing lower pregnancy rates.<sup>298</sup>

Apart from its common use as a stimulant for ovaries, clomiphene can help prevent premature LH surges in IVF cycles. Clomiphene may be used continuously until the day of ovulation trigger; this simplifies the protocol and reduces the cost of medication, as GnRH analogues are not needed. Large retrospective case series of minimal ovarian stimulation with clomiphene reported premature ovulation rates around 2.5%, attesting

to effectiveness of clomiphene in preventing premature LH surges.<sup>299</sup> Overall protocols that use clomiphene both to stimulate ovaries and inhibit LH surge are reported to result in an average number of oocytes collected between 1.5 and 2.5, cycle cancellation rates between 49% and 66%, clinical pregnancy rates at the range of 15–17%, and live birth rates at the range of 9.5–12.2%.<sup>299,300,301,302</sup> Regardless of the details of the protocols, studies that use mainly CC for ovarian stimulation yield a relatively lower number of oocytes with comparable clinical pregnancy rates (albeit being about 10% lower) than conventional stimulation cycles.

# GnRH Agonist Down-Regulation Gonadotropin Stimulation—The “Long” Protocol

The introduction of long-acting GnRH agonists in the late 1980s revolutionized the approach to ovarian stimulation in ART by providing the means to suppress endogenous pituitary gonadotropin secretion and thereby prevent a premature LH surge during exogenous gonadotropin stimulation. Adjuvant treatment with a GnRH agonist eliminated the need for frequent serum LH measurements and assuaged fears of premature luteinization, which previously had required cancellation of approximately 20% of all IVF cycles before oocyte retrieval.<sup>303,304,305</sup> Because fewer than 2% of cycles are complicated by a premature LH surge after down-regulation with a GnRH agonist,<sup>269</sup> stimulation could continue until follicles were larger and more mature. Numerous clinical trials subsequently demonstrated that egg yields and pregnancy rates were significantly higher than in cycles stimulated with exogenous gonadotropins alone.<sup>306,307</sup> Moreover, GnRH agonist treatment offered the welcome additional advantage of scheduling flexibility, allowing programs to coordinate cycle starts for groups of women simply by varying the duration of GnRH agonist suppression. Not surprisingly, the “long protocol” quickly became the preferred ovarian stimulation regimen for all forms of ART. Its only disadvantages are that GnRH agonist treatment sometimes blunts the response to gonadotropin stimulation and increases the dose and duration of gonadotropin therapy required to stimulate follicular development. The combined costs of the additional gonadotropins and the agonist itself increase the total cost of treatment substantially. **Nevertheless, because GnRH agonists have more advantages than disadvantages, the long protocol became and has remained the standard ovarian stimulation regimen in IVF cycles until more patient-friendly protocols utilizing GnRH antagonists gained widespread acceptance.**

In the typical cycle, GnRH agonist treatment begins during the midluteal phase, approximately 1 week after ovulation, at a time when endogenous gonadotropin levels are at or near their nadir and the acute release of stored pituitary gonadotropins in response to the agonist, known as the “flare” effect, is least likely to stimulate a new wave of follicular development.<sup>308,309</sup> GnRH agonist treatment can be scheduled to begin on cycle day 21 (assuming a normal cycle of approximately 28-day duration), but many prefer to first confirm that ovulation has occurred by measuring the serum progesterone concentration. In women who do not cycle predictably, oral contraceptives (OC) can be used to control the onset of menses, starting GnRH agonist treatment 1 week before their discontinuation. In the United States, leuprolide acetate (administered by SC injection) is the most commonly used GnRH agonist. In Europe and elsewhere, buserelin acetate (administered by SC injection or intranasal spray) and triptorelin

(administered subcutaneously) are more commonly used<sup>310</sup>; all work equally well. For leuprolide, the usual treatment regimen begins with 1.0 mg daily for approximately 10 days or until onset of menses or gonadotropin stimulation, decreasing to 0.5 mg daily thereafter until the ovulation trigger. A single dose of a longer-acting depot form of GnRH agonist (leuprolide, goserelin) offers greater convenience, but evidence indicates the total dose and duration of gonadotropin stimulation required are increased significantly when depot forms of the agonists are used.<sup>311</sup>

Gonadotropin stimulation begins after confirming that effective pituitary down-regulation has been achieved (serum estradiol level <30–40 pg/mL, no follicles >10 mm in diameter). Some women require longer durations of treatment to achieve suppression or may develop an ovarian cyst.<sup>303</sup> The significance of an ovarian cyst has been controversial. Whereas some investigators have observed that baseline cysts are associated with a poorer response to gonadotropin stimulation, decreased numbers of oocytes and embryos, and lower overall IVF success rates,<sup>312,313,314</sup> others have not.<sup>315,316,317,318,319</sup> **Overall, the weight of available evidence suggests that women who develop cysts or require longer durations of GnRH agonist treatment to achieve suppression are more likely to respond poorly to gonadotropin stimulation and less likely to achieve pregnancy.** Cyst aspiration immediately before stimulation does not appear to effect rates of live birth, clinical pregnancy, number of follicles recruited, or number of oocytes collected. Since cyst aspiration requires anesthesia, extra cost, psychological stress, and risk of surgical complications, it is probably not warranted in the absence of another indication (**Figure 28.5**).<sup>320</sup>

**FIGURE 28.5**

The initial dose of exogenous gonadotropins is tailored to the needs of the individual woman. Typical starting doses range between 150 and 300 IU of urinary FSH (uFSH), recombinant FSH (rFSH), or urinary menotropins (hMG) daily, depending on age, the

results of ovarian reserve testing, body weight, and the response observed in any previous stimulation cycles. However, there is an ongoing discussion regarding individualized dosing versus administering a standard dose of 150 IU/day for all women undergoing ovarian stimulation for IVF.<sup>321,322,323,324</sup> A multicenter trial conducted in The Netherlands categorized 1,032 women according to anticipated ovarian response as assessed by AFC and compared cumulative live birth rates over 18 months between women who received either the standard starting dose of 150 IU/day or 450 IU/day (women with AFC  $\leq 8$ ), 225 IU/day (women with AFC 8–10), or 100 IU/day (women with AFC  $> 15$ ).<sup>321,323</sup> Women with AFC less than 11 had similar cumulative live birth rates (43.2% vs. 45.6%) and time to ongoing pregnancy (212 vs. 197 days) regardless of FSH dosing, despite women receiving higher doses had significantly more oocytes collected (7.6 vs. 6.4), significantly lower incidence of poor response (35% vs. 50%), and significantly higher incidence of hyperresponse (8.6% vs. 3.4%) and treatment costs. Likewise, cumulative live birth rates (66.3% vs. 69.5%) and time to ongoing pregnancy (185 vs. 191 days) were similar between women with AFC greater than 15, who received 100 IU/day or 150 IU/day doses, respectively. Critics suggest the use of more complex models for dose selection, which include other markers of ovarian reserve; for example, AMH, body weight, or collection of more oocytes can improve outcomes or decrease the risk of OHSS.<sup>325,326,327</sup>

Numerous clinical trials and meta-analyses have compared outcomes in cycles stimulated with uFSH, rFSH, or hMG, with or without GnRH agonist pretreatment, concluding that there is no compelling evidence to indicate the superiority of one gonadotropin preparation over others.<sup>328,329,330,331</sup> However, a 2011 systematic review including 11 trials comparing outcomes in cycles stimulated with rFSH or hMG, involving 3,179 patients, observed a significant difference in live birth rate (OR = 0.84, CI = 0.72–0.99) favoring hMG.<sup>332</sup>

Recombinant DNA technology has been used to develop a longer-acting form of rFSH. Corifollitropin alfa comprises a  $\alpha$ -subunit identical to that of FSH and a  $\beta$ -subunit produced by the fusion of the C-terminal peptide from the  $\beta$ -subunit of chorionic gonadotropin (hCG) to the  $\beta$ -subunit of FSH. Corifollitropin alfa has a half-life 3 times longer than standard rFSH (95 vs. 32 hours).<sup>333,334</sup> A single dose (100  $\mu$ g for women  $\leq 60$  kg, 150  $\mu$ g for those  $> 60$  kg) can induce and sustain multifollicular growth for a week in women receiving ovarian stimulation for IVF. Controlled ovarian stimulation with corifollitropin yields similar or significantly higher numbers of oocytes and good quality embryos, as well as similar ongoing pregnancy rates compared to women stimulated with daily rFSH injections. Stimulation characteristics, embryology and clinical outcomes are also similar, and multiple pregnancy or OHSS rates are not increased over daily FSH regimen. Corifollitropin alfa molecule does not seem to be

immunogenic and does not induce neutralizing antibody formation. Drug hypersensitivity and injection site reactions are not increased. Incidence and nature of adverse events, serious adverse events, and rate of congenital malformations are reported to be similar to daily FSH injections.<sup>335,336</sup> This product is not available in the United States.

The low levels of LH secretion remaining after down-regulation with a GnRH agonist are sufficient to support normal follicular development in most women stimulated with uFSH or rFSH alone,<sup>337</sup> because only about 1% of LH receptors must be occupied to sustain normal levels of steroidogenesis.<sup>338</sup> However, in some women treated only with FSH, LH levels are markedly suppressed (<1 IU/L) and may be inadequate.<sup>339,340</sup> In such cycles, the dose and duration of gonadotropin stimulation required is higher, peak estradiol levels are lower, and the numbers of oocytes and embryos may be reduced.<sup>341,342</sup> Extremely low LH levels also may adversely affect fertilization, implantation, and pregnancy rates<sup>343,344,345,346,347</sup> and have been associated with a higher incidence of biochemical pregnancy and early pregnancy loss.<sup>348,349</sup> Whether LH activity improves clinical outcome of ovarian stimulation is controversial. A 2014 meta-analysis comparing rFSH alone and rFSH with recombinant LH concluded that the addition of rLH did not increase the number of oocytes collected.<sup>350</sup> However, consistent with the above mentioned Cochrane review,<sup>332</sup> rLH was associated with a small but statistically significant improvement in clinical pregnancy rate (rate ratio [RR] = 1.09, 95% CI = 1.01–1.18).<sup>350,351</sup> Even though the authors concluded that addition of rLH was associated with a more prominent increase in clinical pregnancy rates in poor responders, as well as significantly higher number of oocytes collected, this was not confirmed in several subsequent RCTs.<sup>352,353,354,355,356</sup> In sum, the evidence indicates **there may be a subgroup of women who could benefit from supplemental rLH or hMG during ovarian stimulation.** In the absence of any reliable method for identifying such women, and in light of evidence suggesting that use of hMG may increase live birth rates,<sup>357</sup> many clinicians favor combined stimulation with FSH and hMG over stimulation with FSH alone.

The response to stimulation is monitored with serial measurements of serum estradiol and transvaginal ultrasonography. The first estradiol level usually is obtained after 3–5 days of stimulation to determine whether the chosen dose of gonadotropins requires adjustment. Thereafter, serum estradiol concentrations and sonography are obtained every 1–3 days, based on the quality of the response and the need to evaluate the impact of any further adjustments in the dose of gonadotropin treatment. In general, stimulation continues until at least two follicles measure 17–18 mm in mean diameter, when others typically measure 14–16 mm and the serum estradiol concentration reflects the overall size and maturity of the cohort. Most women require a total of 7–12 days of stimulation. It is important to emphasize that these parameters only approximate the

goals of stimulation. In clinical practice, follicle measurements vary among observers and estradiol assays vary in their performance characteristics.<sup>358</sup> Ultimately, each program must empirically establish its own thresholds, based on its own experience.

The endometrium is monitored during stimulation by measuring the endometrial thickness or “stripe” (the sum thickness of the two layers, measured in the midsagittal plane). Numerous studies have confirmed the prognostic value of endometrial thickness and pattern in ART cycles; however, the predictive value is modest. Many have suggested that results are best when endometrial thickness measures 8–9 mm or greater or appears “trilaminar” and poor when the endometrium is less than 6–7 mm in thickness or appears homogeneous on the day of hCG administration.<sup>359,360,361,362,363,364,365,366</sup> However, numerous others have failed to observe any absolute correlation between endometrial thickness or appearance and outcomes.<sup>367,368,369,370,371,372,373,374,375,376,377,378,379</sup> Some have suggested that excessive endometrial growth (>14 mm) also is a poor prognostic indicator,<sup>380,381</sup> but that too has been refuted.<sup>382,383</sup> Overall, although measurements of endometrial growth are routine, their utility remains unclear. Probably, there is no threshold that completely precludes pregnancy and live birth.<sup>384,385</sup> Consequently, changes in stimulation regimens and cycle cancellations based on endometrial thickness or appearance alone are difficult to justify except in the extreme.<sup>386,387</sup>

When the cohort of ovarian follicles reaches maturity, hCG (5,000–10,000 IU) is administered to stimulate the final stages of follicular development. The equivalent dose of the recombinant form of hCG now available is 250 µg. A 2016 systematic review including 15 trials comparing recombinant and urinary hCG observed no differences in clinical outcomes.<sup>388</sup> Oocyte maturation can also be triggered with a single bolus of a GnRH agonist in cycles without pituitary down-regulation. GnRH agonist injection triggers an endogenous LH surge, which is accompanied by an endogenous FSH surge as in the natural cycle.<sup>389</sup> The LH surge triggered by a GnRH agonist bolus is shorter in duration than the endogenous LH surge, is inadequate to support corpora lutea, and is associated with lower implantation, pregnancy, and live birth rates than the conventional hCG trigger. Since the agonist trigger results in rapid luteolysis, it is either used alone as a means of preventing OHSS, or in combination with the hCG trigger, dubbed as “dual trigger” in order to possibly improve oocyte quality by mimicking the simultaneous LH and FSH surges in the natural cycle.<sup>389,390</sup> However, whether dual trigger improves IVF outcome is yet controversial.<sup>391,392,393,394,395,396,397,398,399,400</sup>

It is clear that increased progesterone levels on the day of ovulation trigger are associated with decreased pregnancy rates.<sup>401,402,403,404</sup> Progesterone elevation is more common among women with a high response to stimulation and the adverse effect of

elevated progesterone levels seem to vary across categories of ovarian response. Based on a large sized study, pregnancy rates seem to decline when serum progesterone level exceeds 1.5 ng/mL in women with  $\leq 4$  oocytes, after 1.75 ng/mL in normoresponders, and 2.25 ng/mL for women with a high response.<sup>404</sup> **Elective cryopreservation of embryos for transfer in a subsequent natural or artificial cycle should be considered in cycles with follicular phase progesterone elevation.**<sup>405</sup>

In 2015, 11% of stimulation cycles were cancelled before oocyte retrieval, most for lack of adequate response, and some for excessive response.<sup>5,406</sup> When the ovaries become grossly enlarged, containing large numbers of follicles of all sizes, and serum estradiol concentrations are markedly elevated ( $>5,000$  pg/mL), the risk for OHSS increases substantially.<sup>407,408,409</sup> Options to decrease the risk of OHSS in “high responders” include all of the following:

- Cycle cancellation
- Administering a dopamine agonist for up to 7 days after the trigger
- “Coasting,” in which GnRH analogue treatment continues but without further gonadotropin stimulation for 1–3 days, triggering oocyte maturation after estradiol levels moderate
- In GnRH antagonist stimulation cycles, administering a GnRH agonist to trigger ovulation with or without a small dose of hCG, depending on the magnitude of ovarian response, for oocyte maturation
- Proceeding with oocyte retrieval and fertilization but freezing all embryos in lieu of transfer
- Delaying transfer until 5 days after retrieval while observing for clinical signs and symptoms of developing OHSS
- Administration of daily GnRH antagonist for a few days after egg collection, in order to induce rapid demise of corpora lutea by decreasing endogenous LH levels

With the current cryosurvival rates attained using embryo vitrification, there is little point in proceeding with fresh embryo transfer in women with high ovarian response. First and foremost, if pregnancy occurs, endogenous hCG can stimulate corpora lutea and induce the more severe “late OHSS”; secondly, endometrial receptivity is decreased in such hyperstimulated cycles leading to lower live birth rates.<sup>406,410,411</sup> Importantly, two or more of the above mentioned interventions can be combined for maximal prevention, especially when fresh embryo transfer is omitted.<sup>412</sup> Introduction of GnRH agonist trigger in GnRH antagonist cycles has almost provided OHSS-free practice; thus, GnRH antagonist stimulation (discussed below) should be the protocol of choice in anticipated high responders. However, no strategy ensures complete prevention of severe OHSS, and careful stimulation is always prudent.

The challenges presented by “poor responders” are far greater. Poor responders include women who develop few follicles (<3–5) despite high doses of gonadotropin stimulation or have relatively low peak estradiol levels (<500–1,000 pg/mL). A variety of definitions have been used to define poor response to stimulation. The European Society of Human Reproduction and Embryology published the Bologna criteria to define “poor ovarian response” in a standard and reproducible manner.<sup>413</sup> The Bologna Criteria includes age, ovarian reserve tests, and response to a prior stimulation cycle. As such, women with different characteristics can be defined as anticipated poor responders; however, whether these different subsets have similar prognosis is controversial, and the Bologna criteria have not gained wide acceptance.<sup>414,415,416</sup> Regardless, the prognosis is relatively poor for such women,<sup>145,351,417,418</sup> and the important decision centers on whether to attempt stimulation again using a different or more aggressive treatment regimen.<sup>419</sup> Some of the more commonly employed options include the following:

- The long protocol, beginning with higher doses of gonadotropin stimulation, if the patient was given submaximal dose in the index cycle
- Decreasing the doses of GnRH agonist or discontinuing agonist treatment immediately before or soon after gonadotropin stimulation begins
- A short follicular phase GnRH agonist treatment regimen using a standard or microdose “flare” protocol (described below)
- Using a GnRH antagonist (described below) instead of a long-acting agonist

**Different aspects of stimulation have been modified with the intention to increase the number and quality of eggs obtained for ART in poor responders. Suppression of the LH surge with a GnRH antagonist or short GnRH agonist flare protocol, such as microdose flare (described below), and stimulation with daily high-dose gonadotropins are appropriate first choices, and there is a strong need for well-designed RCTs investigating effects of addition of LH activity, estradiol priming, transdermal testosterone administration, and growth hormone supplementation.<sup>356</sup> High doses of gonadotropins may generate a somewhat more vigorous follicular response, but doses greater than 300 IU daily generally have no additional benefit. Given the lack of high-quality evidence showing effectiveness of one approach over another, other factors such as duration of stimulation, total gonadotropin consumption and cost of medication, patient friendliness, and possible side effect profiles must be considered in tailoring the stimulation protocol according to each individual’s needs and desires.**

# GnRH Agonist “Flare” Gonadotropin Stimulation Protocol

The “short” or “flare” protocol is an alternative stimulation regimen designed to exploit both the brief initial agonistic phase of response to a GnRH agonist and the suppression that results from longer-term treatment.<sup>420,421</sup> In a typical standard short protocol, leuprolide acetate (1.0 mg daily) is administered on cycle days 2–4, continuing thereafter at a reduced dose (0.5 mg daily), and gonadotropin stimulation begins on cycle day 3. Later adjustments in the dose of gonadotropin stimulation, if needed, are based on response, and indications for trigger are the same as in the long protocol (described above).

Decreased scheduling flexibility is a distinct disadvantage of the flare protocol, unless the onset of menses is controlled by preliminary treatment with an OC or estrogen. The regimen also can result in a significant increase in serum progesterone and androgen levels, presumably resulting from late corpus luteum rescue,<sup>422,423</sup> which may adversely affect oocyte quality and fertilization and pregnancy rates.<sup>424,425,426</sup>

The “OC microdose GnRH agonist flare” stimulation regimen is a variation of the standard short protocol involving 14–21 days of preliminary ovarian suppression with an OC (one pill daily), followed by microdose leuprolide treatment (40 µg twice daily) beginning 3 days after discontinuation of OC treatment and high-dose gonadotropin stimulation starting on day 3 of leuprolide therapy. Indications for later gonadotropin dose adjustments and trigger are the same as in other stimulation regimens. Its primary advantage over the standard short protocol is that it does not induce any increases in serum progesterone or androgen concentrations,<sup>427</sup> possibly because the doses of GnRH agonist administered are much lower, but likely also because preliminary OC treatment all but eliminates the possibility there may be a corpus luteum left to respond.<sup>428,429</sup>

Individual trials comparing stimulation protocols in women with poor response, as well as meta-analyses reported conflicting results.<sup>351,430,431</sup> While the long protocol takes longer and requires higher total gonadotropin consumption, whether it provides more or better quality oocytes is controversial, despite better synchronization of follicular cohort.<sup>351,356,430</sup> Given the absence of any clear benefit with regard to the number of oocytes collected or pregnancy rates, and a clear disadvantage with regard to gonadotropin consumption, the long protocol should not be the first choice for DOR, with the possible exception of patients with substantial asynchronous follicle development in repeated cycles.<sup>356</sup> Short GnRHa protocols seem to provide significantly higher number of oocytes, albeit as small as 0.5 oocytes more on average, with similar gonadotropin consumption compared to GnRH antagonist protocols.<sup>356</sup>

Hence, the preference between the two remains personal, taking into consideration the number of injections required and cost of medication.

# GnRH Antagonist Gonadotropin Stimulation Protocol

The introduction of GnRH antagonists into clinical practice provided another option for ovarian stimulation in ART. In contrast to the long-acting agonists, which first stimulate and later inhibit pituitary gonadotropin secretion by desensitizing gonadotrophs to GnRH via receptor down-regulation, the antagonists block the GnRH receptor in a dose-dependent competitive fashion and have no similar flare effect<sup>432,433</sup>; gonadotropin suppression is almost immediate.

GnRH antagonists offer several potential advantages over agonists. First, the duration of treatment for an antagonist is substantially shorter than for an agonist. Since its only purpose is to prevent a premature endogenous LH surge and its effects are immediate, antagonist treatment can be postponed until later in follicular development (after 5–6 days of gonadotropin stimulation), after estradiol levels are already elevated, thereby eliminating the estrogen deficiency symptoms that may emerge in women treated with an agonist.<sup>434</sup> Second, because any suppressive effects that agonists may exert on the ovarian response to gonadotropin stimulation also are eliminated, the total dose and duration of gonadotropin stimulation required is decreased.<sup>434,435</sup> For the same reason, GnRH antagonist stimulation protocols may benefit women who are poor responders when treated with a standard long protocol.<sup>356,434,436</sup> Third, by eliminating the flare effect of agonists, GnRH antagonists avoid the risk of stimulating development of a follicular cyst. Finally, the risk of severe OHSS associated with use of antagonists also appears lower than with agonists.<sup>437,438,439,440</sup> The risk of OHSS can be further diminished with the use of a GnRH agonist trigger in GnRH antagonist stimulated cycles, an option that is not available when GnRH agonists are used for pituitary suppression.

GnRH antagonists have some potential disadvantages. When administered in small daily doses, strict compliance with the prescribed treatment regimen is essential.<sup>434</sup> Antagonists suppress endogenous gonadotropin secretion more completely than agonists. While initial studies suggested modestly lower pregnancy rates in antagonist treatment cycles than in cycles using agonists in the long protocol, this could have been due to patient selection or lack of experience with the use of antagonists, and recent evidence suggests similar live birth and pregnancy rates in GnRH antagonist cycles.<sup>441,442,443</sup> **Overall, due to their ease of use and comparable outcomes, antagonist protocols are used more commonly than long GnRH agonist protocols worldwide.**

The two GnRH antagonists available for clinical use, ganirelix and cetrorelix, are

equally potent and effective. For both, the minimum effective dose to prevent a premature LH surge is 0.25 mg daily, administered subcutaneously.<sup>347,444</sup> The treatment protocol may be fixed and begin after 5–6 days of gonadotropin stimulation<sup>347,444,445</sup> or tailored to the response of the individual, starting treatment when the lead follicle reaches approximately 13–14 mm in diameter.<sup>446,447</sup> The individualized treatment regimen generally requires fewer total doses and may yield better overall results.<sup>446</sup> Alternatively, a single larger dose of cetrorelix (3.0 mg) will effectively prevent an LH surge for 96 hours. If given on day 6–7 of stimulation, the interval of effective suppression will encompass the day of hCG administration in most women (75–90%); the remainder may receive additional daily doses (0.25 mg) as needed, ending on the day of hCG treatment.<sup>448,449,450</sup> The single-dose antagonist treatment regimen also can be withheld until the lead follicle reaches 13–14 mm in diameter.<sup>451</sup>

A common variation of the antagonist stimulation regimen uses preliminary treatment with an OC to control the onset of menses, typically ending at least 5 days before the scheduled start, which also may help to synchronize the follicular cohort before stimulation begins. However, OC priming is associated with longer duration of stimulation and higher gonadotropin consumption without an increase in cumulus oocyte complexes and a significant decrease in ongoing pregnancy and live birth rates.<sup>452,453</sup> Based on a single retrospective study, micronized estradiol (2 mg three times daily, administered orally) starting from the 2nd or 3rd day of menstrual cycle can be used to schedule the start of gonadotropins in GnRH antagonist cycles. Estradiol suppresses endogenous FSH halting follicular growth and is stopped on the day of scheduled gonadotropin start.<sup>454</sup> Follicular phase estradiol scheduling does not seem to increase gonadotropin consumption or hamper clinical outcome. Another variation advocated for poor responders uses micronized estradiol (2 mg twice daily, administered orally, beginning on day 21 of the preceding cycle) to suppress FSH during the late luteal phase for the same purpose, ending on the day before gonadotropin stimulation begins<sup>451,455</sup> or continuing through the first 3 days of gonadotropin stimulation.<sup>418</sup> The improved follicular dynamics observed are similar to those achieved by down-regulation with a GnRH agonist in the long protocol. The rebound increase in endogenous FSH levels that follows the discontinuation of estradiol treatment also may synergize with exogenous gonadotropins to promote multifollicular development (**Figure 28.6**).<sup>456,457</sup>

**FIGURE 28.6**

Women with PCOS characteristically exhibit high tonic LH secretion and are predisposed to premature LH surges when treated with standard ovulation induction regimens. Women with PCOS also are at increased risk for developing OHSS when aggressively stimulated with exogenous gonadotropins. Whereas both GnRH agonists and antagonists can suppress elevated circulating LH concentrations, the smaller follicular cohorts observed in antagonist cycles may help to reduce the risk of OHSS in women with PCOS who tend to be high responders. **The use of antagonists, rather than agonists, provides the opportunity to use an agonist instead of hCG to induce final oocyte maturation, thereby possibly further decreasing the risk of OHSS.**<sup>458</sup> Whereas a single bolus injection of an agonist (leuprolide 0.5 mg, triptorelin 0.2 mg) triggers a physiologic LH surge that lasts less than 24 hours, hCG levels remain elevated for several days and stimulate markedly higher estradiol and progesterone concentrations.<sup>459</sup>

The antagonist treatment regimens currently in use have potential disadvantages for women with PCOS. Their tonically elevated LH levels will remain high until antagonist treatment begins. Consequently, LH levels may rise prematurely, particularly if antagonist treatment is withheld until the lead follicle reaches 14 mm or more. Moreover, evidence indicates that increased LH exposure during early follicular development may be detrimental and predispose to lower pregnancy rates.<sup>460,461,462,463</sup> In theory, pretreatment with an OC might prove quite useful by suppressing LH and androgen levels before stimulation begins, decreasing exposure during early follicular development and the risk of rising LH levels before antagonist treatment starts. Preliminary OC suppression and later antagonist treatment may help to limit the follicular response to gonadotropin stimulation while preserving the option to use an agonist to trigger final oocyte maturation. However, OC pretreatment can be associated

with lower pregnancy rates if a fresh transfer is attempted.<sup>452,453</sup>

Antagonist stimulation protocols are advocated for poor responders, primarily because they avoid the suppressive effects that agonists can have on follicular response and can prevent the premature LH surges observed commonly in women stimulated with gonadotropins alone.<sup>413</sup> However, evidence is insufficient to indicate they yield results consistently better than other stimulation regimens.<sup>351,464</sup>

# GnRH Agonist Triggering of Oocyte Maturation

The first to report of GnRHa trigger in human IVF was in 1990 and involved 18 women, who underwent ovarian stimulation without pituitary suppression and received GnRHa or hCG as the trigger to induce final follicular maturation. Similar numbers of oocytes were collected; fertilization rate, embryo development rates, and pregnancy rates were also similar with GnRHa as compared to hCG triggers.<sup>465</sup> However, soon after this report, pituitary suppression with GnRHa to prevent the LH rise prior to egg retrieval became the norm in ART and the use of GnRHa trigger was abandoned until the introduction of GnRH antagonists into IVF practice.

When reintroduced, GnRHa trigger was initially used to prevent OHSS in GnRH antagonist cycles.<sup>466</sup> The luteinizing hormone (LH) surge following GnRHa trigger lasts even shorter than natural LH surge. In addition, the half-life of LH is much shorter than that of hCG.<sup>389,459</sup> These two characteristics serve to decrease the luteinizing stimulus on the granulosa cells, limiting the production of vascular endothelial growth factor, which is responsible for increased vascular permeability, the hallmark of OHSS.<sup>467,468,469</sup>

GnRHa trigger is associated with decreased size and number of corpora lutea, decreased expression of steroidogenic enzymes, and consequently lower estradiol and progesterone production during the luteal phase.<sup>470,471</sup> Initial clinical trials confirmed findings of similar oocyte yield and embryo quality following GnRHa trigger. However, significantly lower pregnancy rates accompanied by higher rate of pregnancy loss compared to conventional hCG trigger were alarming.<sup>459,472,473</sup> A randomized trial demonstrated similar implantation and pregnancy rates in oocyte recipients from donors triggered with hCG or GnRHa, suggesting the adverse effect being on the endometrium rather than the oocytes.<sup>474</sup> Two uncontrolled case series of oocyte and embryo freezing following GnRHa trigger reported cryosurvival, implantation, and pregnancy rates within expected range of hCG trigger. Altogether, these data provided convincing evidence for a suboptimal luteal phase impacting on birth rates following GnRHa trigger.<sup>475,476</sup>

Initial studies of rescuing luteal phase by “intensive luteal support” through administration of high doses of exogenous progesterone and estrogen yielded contradictory results.<sup>477,478</sup> High endogenous LH level is an important factor contributing to the observed success of intensive luteal support in some studies.<sup>479</sup> The magnitude of the LH peak induced with GnRHa bolus, which is related with early follicular phase serum LH levels, is a determinant of pregnancy rates following GnRHa trigger and intensive luteal support.<sup>480</sup> Overall, intensive luteal support can be a viable

option for women with PCOS, the very same patients who comprise the highest risk group for OHSS following hCG injection.

Rescuing the luteal phase with a small dose of hCG after GnRHa trigger is another option. A series of randomized controlled trials suggested equivalent ongoing pregnancy rates with GnRHa trigger followed by 1,500 IU hCG injection 35 hours later and luteal phase support with vaginal progesterone and oral estradiol.<sup>472,481,482,483</sup> Not only luteal phase serum estradiol and progesterone levels but also ongoing pregnancy rates were statistically similar to hCG trigger, despite a trend toward lower rates with GnRHa + 1,500 hCG. The success of hCG rescue in maintaining pregnancy rates were confirmed in several uncontrolled case series, and it was suggested that severe early OHSS could be successfully prevented with this method.<sup>484,485</sup> However, several reports of severe early OHSS following GnRHa trigger with or even without any hCG rescue proved it an elusive goal to completely prevent OHSS.<sup>486,487,488</sup> Therefore, it seems prudent to completely avoid hCG support in women with predicted high ovarian response, although precise markers of ovarian reserve and threshold levels remain to be determined.

Another setting where GnRHa triggering could prove useful is oocyte collection cycles for the purpose of fertility preservation in patients with hormone sensitive tumors, such as breast cancer. The rapid decline in serum estradiol and progesterone levels following GnRHa trigger limits tumor exposure to these hormones.<sup>489</sup> Clearly, GnRHa trigger should be the norm in fertility preservation cycles, as it does not affect oocyte yield or quality.

Overall, GnRHa trigger enables collection of similar number of oocytes as with the conventional hCG trigger. It is the ovulation trigger of choice for women at risk of OHSS and in fertility preservation cycles. The decision to proceed with a fresh or frozen transfer should be individualized, as well as the method of luteal phase rescue in fresh transfers.

# UNCONVENTIONAL STIMULATION

# OVARIAN

Traditionally, ovarian stimulation is started in the early follicular phase. The rationale for this timing includes stimulation of a synchronous cohort of antral follicles recruited during the luteofollicular transition and inducing timely endometrial development to synchronize blastocyst development with the implantation window. However, synchronizing endometrial and follicular development is not required if the aim of the cycle is oocyte or embryo cryopreservation without a fresh embryo transfer. This is particularly relevant when time is a constraint, such as in women with malignancy awaiting gonadotoxic chemotherapy. Increasing evidence suggests that multiple waves of antral follicles develop during one menstrual cycle, challenging the concept of a single recruitment episode during the follicular phase.<sup>490</sup> Among different theories of follicular recruitment, the wave theory forms the basis of ovarian stimulation during the luteal phase. While the dominant follicle formed in the final wave of the interovulatory interval reaches ovulation, the preceding waves are anovulatory.<sup>490</sup> However, follicles that are in the anovulatory waves that precede and follow the ovulatory wave can reach ovulatory stage if exposed to FSH stimulation. Based on this concept, ovarian stimulation may be started at any time during the menstrual cycle; the so-called random start ovarian stimulation.<sup>491</sup>

Initially, the random start stimulation was used for fertility preservation in women with cancer.<sup>492,493</sup> More recently, encouraging results have been reported with luteal phase start ovarian stimulation in women with normal or poor ovarian reserve.<sup>494,495</sup> Stimulating the ovaries twice during a single menstrual cycle has been done as an alternative strategy that aims rapid accumulation of embryos in poor responders. The initial stimulation is commenced in the follicular phase with a GnRH antagonist protocol, usually followed by a GnRH agonist trigger, and another cycle of stimulation is initiated after egg collection.<sup>494</sup> Already elevated progesterone levels from the corpora lutea prevent the endogenous LH surge, and the luteal phase stimulation can be completed even without using GnRH antagonist in many cases. A 2016 meta-analysis reports that the luteal phase stimulation takes significantly longer (on average 1.5 days), despite consumption of more gonadotropins (on average 817 IU), but may yield a higher number of mature oocytes.<sup>496,497</sup> Based on limited data, oocytes collected in the luteal phase develop into blastocyst at a similar rate with oocytes from follicular phase, euploidy rates of these blastocysts are similar, and, when transferred in an artificial cycle, they yield similar pregnancy rates.<sup>497,498</sup> Limited data on obstetric outcome of and congenital anomalies in pregnancies derived from frozen-thawed transfer of embryos derived from luteal phase stimulation ovaries suggest similar results with follicular

phase oocyte retrievals.<sup>499</sup>

# OOCYTE RETRIEVAL

---

Oocyte retrieval is generally performed approximately 34–36 hours after hCG administration. Slightly longer intervals do not substantially increase the risk of ovulation or adversely affect oocyte quality, fertilization rates, or overall results in GnRH agonist down-regulated stimulation cycles,<sup>500,501,502,503</sup> but earlier retrievals yield fewer mature oocytes.<sup>504</sup>

Whereas oocyte retrieval once was performed via laparoscopy, transvaginal aspiration guided by ultrasonography under intravenous sedation is now the standard technique. Deep sedation (propofol) is most common, but most women tolerate the procedure very well with “conscious sedation” using short-acting narcotics (fentanyl) and benzodiazepines (midazolam), administered in small doses, as needed. There is no compelling evidence to indicate any difference in patient satisfaction or outcomes.<sup>505</sup> Continuous monitoring by automated blood pressure recordings and pulse oximetry is essential to ensure that the proper plane of sedation is maintained and not exceeded. Specific reversal agents for narcotics (naloxone) and benzodiazepines (flumazenil) should be readily available.

Prophylactic antibiotic treatment (doxycycline 100 mg or cefoxitin 2 g), administered intravenously 30–60 minutes before retrieval is common but controversial because of the low incidence of infectious complications following retrieval (0.3–0.6%).<sup>506,507</sup> Alternatively, oral antibiotics may be started immediately following the procedure (tetracycline, doxycycline), reserving prophylactic intravenous antibiotics for women at increased risk for infection (history of pelvic inflammatory disease, endometrioma).

Antiseptics (povidone-iodine) are toxic to oocytes, and limited evidence suggests their use may be associated with lower pregnancy rates.<sup>508</sup> When used to prepare the vagina before retrieval, thorough irrigation with sterile saline should follow, but repeated irrigation with saline alone is generally sufficient to cleanse the vagina. The bladder can become distended as a result of intravenous fluid administration but can be drained immediately before retrieval; an indwelling catheter is unnecessary.

A vaginal probe (5–7 MHz) in a sterile plastic sheath with an attached needle guide is used to image the ovaries and to align the guide with the follicles in their largest diameter. A specially designed disposable 16- to 17-gauge needle is used to enter each follicle, in turn, and to aspirate the follicular fluid and oocytes. At the proper vacuum pressure (approximately 100 mm Hg), the follicle walls collapse but do not obstruct the needle lumen. Whereas some have observed that flushing and reaspiration of follicles using a double-lumen needle can increase oocyte yield,<sup>509</sup> the majority of evidence

shows similar oocyte yield, fertilization, and pregnancy rates while increasing operating time and analgesic requirements.<sup>510,511,512</sup> This holds true for even in women with few follicles.<sup>513</sup> As such follicular flushing seems unnecessary and has been largely abandoned. Efforts to minimize the arc swept by the needle within the ovary help to limit discomfort and ovarian trauma. In general, all follicles within the ovaries greater than 10 mm in diameter can be aspirated with no more than one to three separate entries on each side. Flushing the needle and attached tubing with media after each withdrawal helps to maximize oocyte yield. Abdominal pressure can sometimes stabilize a mobile ovary or move an ovary into a more convenient location for aspiration. Ovaries adherent to the posterior uterus often are more easily approached from the contralateral side but may be difficult to enter without traversing a portion of the uterus.<sup>514</sup> It may be more prudent to simply abandon some follicles, particularly when the number of oocytes already retrieved is sufficient.

The “empty follicle syndrome,” characterized by a failure to retrieve oocytes despite apparently normal multifollicular development, occurs in up to 0.5–1% of cycles.<sup>515,516,517</sup> The phenomenon can be observed when hCG is administered later than scheduled<sup>518</sup> or forgotten altogether<sup>516</sup> and might rarely result from reduced biologic activity in some lots of commercially prepared hCG.<sup>519,520,521</sup> The serum hCG concentration 36 hours after injection generally ranges between 100 and 300 IU/L.<sup>520</sup> Despite increasing use of recombinant hCG and agonist trigger, empty follicle syndrome occurs at similar rate.<sup>480,522</sup> In one series of women who received agonist trigger, all cases of empty follicle syndrome occurred in women with serum LH levels lesser than 15 IU/L measured 8–12 hours after agonist administration.<sup>480</sup>

Serious complications of oocyte retrieval are uncommon. Limited vaginal hemorrhage from a puncture site is relatively common (8%) and usually can be controlled with a brief interval of direct pressure but may require a suture.<sup>507</sup> Acute hemorrhage from the ovary and hemorrhage or hematomas resulting from injury to the uterine, ovarian, or iliac vessels are rare (0.04–0.07%).<sup>507</sup> The incidence of postoperative pelvic infections is quite low even without prophylactic antibiotic treatment (0.3–0.6%), and, of those, almost half present as tuboovarian abscesses, 1–6 weeks after retrieval.<sup>77,506,507</sup> Women with ovarian endometriomas and those with past history of salpingitis are at highest risk.<sup>73,74,75,77,523,524,525</sup> Higher number of oocytes retrieved, longer duration of the procedure and the mean time per oocyte retrieved, inexperience of the surgeon, and younger age with lesser BMI are other risk factors.<sup>526</sup> Other rare reported complications include the rupture of a dermoid cyst,<sup>527</sup> laceration of a sacral vein,<sup>528</sup> and lumbosacral osteomyelitis.<sup>529,530</sup>

# Oocyte Maturation

Up to 20–30% of retrieved oocytes may be immature at the time of retrieval, reflecting the varying size and maturity of follicles in the cohort at the time hCG is administered. An accurate assessment of oocyte maturity is important to the timing of fertilization, even more so when ICSI is to be performed.

Like the LH surge in natural cycles, hCG triggers the resumption of meiosis in primary oocytes previously arrested at prophase I of the first meiotic division. Oocyte maturity generally can be judged by the expansion of the cumulus mass, radiance of the corona cells, the size and cohesiveness of granulosa cells, and the shape and color of the oocyte. When the cumulus mass is removed, as it is in preparation for ICSI, the oocyte can be further evaluated according to the presence or absence of the first polar body and germinal vesicle (nuclear membrane).

A mature (metaphase II) oocyte has extruded the first polar body and is in the resting phase of meiosis II. The cumulus cells are typically expanded and luteinized and the corona radiata exhibits a sunburst pattern. A metaphase I oocyte of intermediate maturity has no polar body and denser cumulus cells, but the germinal vesicle and nucleolus have faded. Metaphase I oocytes require additional time in culture before fertilization and must be examined periodically to document extrusion of the first polar body. A prophase I oocyte is grossly immature and exhibits a compact corona containing relatively few cumulus cells and a prominent germinal vesicle (GV) and nucleolus; dissolution of the germinal vesicle signals the resumption of meiosis I.

## In Vitro Maturation

Human oocytes reach full size (100–200  $\mu\text{m}$ ) during the early antral stage of follicular development. The ability of an oocyte to resume and complete meiosis relates to follicular diameter.<sup>531,532,533</sup> Although immature oocytes collected from small antral follicles can mature with time in culture (the majority within 46–48 hours), even those that reach meiosis II do not necessarily acquire developmental competence, which requires synchronous maturation of both the nucleus and cytoplasm. Consequently, although they frequently fertilize, immature oocytes yield embryos that often develop poorly and exhibit low implantation potential.<sup>534,535</sup> Nuclear maturation involves germinal vesicle breakdown, normally induced by the LH surge, followed by resumption of meiosis and, finally, extrusion of the first polar body. Cytoplasmic maturation is more difficult to define but involves a number of factors that prepare the cytoplasm for fertilization and subsequent embryonic development.<sup>536</sup> Epigenetic processes are involved in both nuclear and cytoplasmic maturation and influence development after fertilization.<sup>537,538</sup>

Despite the existence of different opinions among clinicians regarding what constitutes an in vitro maturation (IVM) cycle, technically, the term IVM describes the maturation of immature oocytes in culture after their retrieval.<sup>539</sup> The conventional definition implies collection of GV oocytes from small follicles **not** exposed to exogenous LH or hCG in vivo. In efforts to improve the relatively low efficiency of classical IVM, “follicular priming” has been developed.<sup>540,541,542</sup> One method involves FSH treatment for 3–6 days, followed by retrieval on cycle day 9–10. Another involves a single injection of hCG (10,000 IU), administered when the largest follicle reaches 10–12 mm in size and 36 hours before retrieval. A third method combines the two techniques, involving sequential treatment with FSH and hCG before oocyte retrieval.

Numerous studies have explored methods for IVM using oocytes obtained from normal women<sup>543,544,545,546,547,548</sup> and from women with PCOS.<sup>543,544,548,549,550,551,552,553,554,555</sup> Studies examining the effects of follicular priming in vivo have yielded inconsistent results, but embryos derived from primed oocytes generally have yielded higher implantation and pregnancy rates than those derived from oocytes collected from unstimulated antral follicles.<sup>551,553,555</sup> In one large trial examining the efficiency of IVM in women with normal ovaries, 400 women were randomly allocated to receive no priming or priming with hCG, FSH, or FSH followed by hCG.<sup>556</sup> The overall maturation rate and total number of available metaphase II oocytes were significantly higher in the groups receiving hCG than in those not receiving hCG. The overall clinical pregnancy rate per transfer was 18.3% and the implantation rate was 10.6%. Among the groups, the clinical pregnancy rate was higher in the group receiving both FSH and hCG priming (30%) than in all others.<sup>556</sup> However, a 2016 meta-analysis shows that hCG priming alone does not seem to improve live birth rates in IVM cycles.<sup>557</sup>

The best timing and method for efficient retrieval of immature oocytes from small follicles (<10 mm in diameter) have not been established.<sup>553,558,559</sup> Aspiration of follicles greater than 13 mm in size generally has yielded fewer oocytes, possibly because such follicles are already atretic.<sup>560</sup> A variety of aspiration vacuum pressures (80–300 mm Hg) and needles (16–20 gauge) have been described.<sup>558,561</sup> Whereas evidence is insufficient to warrant recommendation of any one method, extremely high vacuum pressures appear to adversely affect oocyte development in vitro.<sup>562</sup> The culture media composition that best supports IVM and the best method for fertilization of oocytes subjected to IVM also remain to be established; ICSI has achieved similar or higher fertilization rates, and embryos derived from oocytes fertilized by conventional methods have exhibited similar or higher implantation rates and yielded higher clinical pregnancy rates,<sup>544,563</sup> suggesting that ICSI is not required.

Although the clinical pregnancy rates achieved in IVM trials have been reasonably good, they do not approach those of standard IVF and have been achieved by transfer of a larger number of embryos. Implantation rates for embryos derived from IVM oocytes (5–22%) also are lower than those expected in similar women (age <35 years) receiving treatment with conventional IVF (34%).<sup>564</sup> Limited number of studies report similar aneuploidy rates of embryos derived from in vivo matured and in vitro matured oocytes; therefore, factors other than aneuploidy seem to be responsible for lower efficiency of IVM.<sup>565,566</sup> A retrospective study including 178 cycles in 121 women compared live birth rates following fresh and frozen embryo transfers (FETs) in IVM and IVF cycles. While live birth rate was significantly lower following fresh blastocyst transfers in IVM cycles, live birth rate was similar between the two groups following frozen blastocyst transfers.<sup>567</sup> This suggests that embryo-endometrium asynchrony can be a factor limiting effectiveness of IVM. Although the number of children derived from oocytes subjected to IVM is still quite small, preventing confident conclusions, the incidence of malformations and developmental abnormalities has thus far not differed from those in children resulting from traditional IVF or ICSI.<sup>568</sup>

**In summary, the results achieved thus far with IVM after follicular priming in vivo suggest the methods have clinical promise. However, numerous questions must be answered before IVM can be recommended for wider clinical application.**<sup>569</sup> Women with PCOS having large numbers of antral follicles and greatest risk for developing OHSS represent a population that could benefit from IVM, because purposeful retrieval of immature oocytes would require fewer days of gonadotropin stimulation. However, the widespread introduction of agonist trigger has limited the risks and hence the indication for IVM. Women with cancer represent another group that can benefit from such treatment; many require immediate treatment that does afford them the time to pursue established methods of fertility preservation, which require ovarian stimulation, oocyte retrieval, and oocyte or embryo cryopreservation.

# FERTILIZATION

---

Fertilization can be achieved by conventional microinsemination or by ICSI when there is a known or suspected male factor and concern for poor or failed fertilization. In fact, male factor infertility is the one most common diagnosis among couples who undergo IVF. In the U.S. national ART summary for 2015, 35% of all cycles were performed for male factor indications, and a male factor was one of multiple infertility factors in another 18% of cycles.<sup>5</sup>

A semen sample should be obtained by masturbation immediately before or after retrieval. The two methods most commonly used for sperm preparation before fertilization, the “swim-up” procedure and density gradient centrifugation, are described in detail in [Chapter 26](#). Whereas both methods can successfully isolate a population of highly motile sperm for insemination, density gradient centrifugation also appears to select sperm with normal morphology and is widely regarded as the better choice when semen parameters are abnormal.<sup>570,571,572,573</sup> The isolated sperm are then incubated in media supplemented with a high concentration of protein for 0.5–4.0 hours to achieve capacitation. A combination of both methods, density gradient centrifugation followed by swim up, is reported to decrease the number of sperm with ultrastructural abnormalities in the head and tail.<sup>574</sup> Recently, microfluidic chips have been introduced for sorting motile sperm from unprocessed semen sample. While some studies show decreased DNA fragmentation in sperm selected by microfluidic chips, convincing evidence demonstrating improved live birth rates with their use is lacking.<sup>575,576,577</sup>

In general, each oocyte is incubated with 50–100 thousand motile sperm for an interval of 12–18 hours at 37°C in 5–20% oxygen and 4–7% carbon dioxide in air at 94–98% relative humidity. The acrosome reaction, which enables sperm to penetrate the zona pellucida, is initiated by contact between the sperm and the zona. In turn, sperm penetration triggers the cortical reaction, which involves exocytosis of cortical granules from the ooplasm and renders the zona pellucida relatively refractory to penetration by more than a single sperm (block to polyspermy). Conventional IVF typically achieves fertilization rates ranging between 50% and 70%.

Sperm penetration also activates the oocyte and stimulates the second meiotic division, resulting in segregation of chromatids between the fertilized oocyte and the second polar body. Oocytes are evaluated for evidence of fertilization at approximately 18 hours after insemination. A normally fertilized oocyte exhibits two distinct pronuclei, one derived from the oocyte and the other from the sperm, and two polar bodies in the perivitelline space. The zygotes must be carefully inspected for the presence of extra pronuclei because polyploid embryos may cleave normally and go unrecognized at later stages of development. Polyploidy can be observed in up to 5–10% of embryos overall

but is far more prevalent in immature oocytes (up to 30%) than in mature oocytes (1–2%).<sup>578,579</sup> Besides polyspermy, polyploidy may result from digyny (fertilization of a diploid oocyte), due to meiotic spindle errors or failure to extrude a polar body, which are more commonly associated with immature, aging, or postmature oocytes.<sup>580,581</sup> The fertilization process requires approximately 24 hours and ends with the first mitotic division (cleavage).

Past failure of fertilization or severe male factor infertility requires ICSI, which yields pregnancy rates in couples with male factor infertility that compare favorably with those in couples without a male factor.<sup>582</sup> In the absence of a male factor, ICSI offers no clinical advantage over conventional IVF<sup>583,584</sup>; in fact, evidence suggests that standard IVF yields higher implantation and clinical pregnancy rates.<sup>5,583</sup>

When there is no ejaculate (aspermia) or only rare or no sperm (azoospermia) in the ejaculate, a variety of methods can be used to retrieve sperm for fertilization. Donor sperm also can be used, by design or as a contingency should efforts to retrieve sperm on the day of oocyte retrieval fail. Men with ejaculatory failure have either no ejaculate or retrograde ejaculation. Ejaculatory failure may result from neurologic dysfunction or injury to the sympathetic outflow tracts that control emission and ejaculation (spinal cord injury, diabetes mellitus, multiple sclerosis, retroperitoneal surgery) or can be psychogenic in origin. Azoospermia may relate to ductal obstruction (obstructive azoospermia) or result from Sertoli cell-only syndrome, maturation arrest, or hypospermatogenesis (nonobstructive azoospermia). The diagnostic evaluation for aspermic and azoospermic men is described in detail in [Chapter 26](#).

## Sperm Retrieval Techniques

In the past, men with nonobstructive azoospermia were considered sterile and untreatable by any means other than the use of donor sperm. However, testis biopsy specimens in such men often demonstrate sperm,<sup>585</sup> suggesting low-level production of sperm that do not survive epididymal transit to reach the ejaculate.<sup>586</sup> **Whereas conventional wisdom was that sperm must traverse the male reproductive tract to acquire the ability to fertilize an oocyte, success with ICSI using epididymal or testicular sperm has demonstrated otherwise.** Even grossly immature sperm (round spermatid nuclear injection; ROSNI) have been used to achieve fertilization, albeit with limited success.<sup>587</sup>

**It is important to emphasize again that genetic evaluation and counseling are indicated for men with severe seminal abnormalities before their sperm are used for ICSI.** Men with congenital bilateral absence of the vas deferens (CBAVD) or less severe forms of vasal aplasia, and their female partners, should be screened for cystic fibrosis gene mutations before any attempts at pregnancy via ART to determine the risk for transmitting cystic fibrosis or CBAVD to offspring.<sup>588,589,590</sup> Men with nonobstructive azoospermia or severe oligospermia (<5 million/mL) should be offered karyotyping and screening for Y chromosome microdeletions.<sup>590</sup>

## Sperm Recovery in Men with Retrograde Ejaculation

Men with documented retrograde ejaculation may be treated with sympathomimetics directed at control of the internal sphincter (imipramine 25 mg twice daily or 50 mg at bedtime, pseudoephedrine 60 mg, ephedrine 25–50 mg four times daily, phenylpropanolamine 50–75 mg twice daily). When medical treatment proves unsuccessful, sperm can be recovered directly from the bladder after masturbation; best results are achieved when urine pH and osmolality (300–380 mOsm/L) are carefully controlled by alkalinizing the urine (sodium bicarbonate 650 mg four times daily, beginning 1–2 days before collection) and controlling fluid intake.<sup>591,592</sup> Alternatively, the bladder can be filled with buffered medium immediately before ejaculation.

## Vibratory Stimulation and Electroejaculation

In men with psychogenic ejaculatory failure or spinal cord injuries below the T6 level, vibratory stimulation often can succeed in producing an ejaculate. Rectal probe electrical stimulation (electroejaculation) is recommended for men who fail vibratory stimulation and those with previous retroperitoneal surgery.<sup>593,594</sup> Induced ejaculations may be retrograde and further require the procedures described above. Because

electroejaculates frequently exhibit asthenospermia and teratospermia, ICSI is often necessary.

## **Epididymal Sperm Aspiration**

Sperm can be obtained by MESA at the time of vasoepididymostomy or as an isolated procedure in men with CBAVD or uncorrectable obstructions. The technique involves incision of an isolated dilated tubule, gradually moving more proximally, if necessary, until sperm are obtained.<sup>595,596</sup> Sperm are collected into a micropipette by capillary action with gentle compression of the testis and epididymis and flushed into a container with a small volume of IVF culture medium. Recovered sperm are cryopreserved in multiple aliquots for use in IVF cycles, if required.<sup>597</sup>

Percutaneous epididymal sperm aspiration (PESA) using a fine needle also has been used successfully to obtain sperm and achieve pregnancy,<sup>598,599</sup> but the technique is less reliable, the small quantities of sperm obtained are sometimes inadequate to allow cryopreservation, and the pregnancy rates achieved generally have been lower than with the open technique.

## **Testicular Sperm Extraction and Aspiration**

In men with nonobstructive azoospermia and those in whom epididymal sperm aspiration techniques fail or do not apply, sperm can be retrieved using any of three other techniques. Open microsurgical TESE yields the greatest number of sperm with potential for cryopreservation. Percutaneous core biopsy or aspiration of the testis has also been described but is most applicable in men with normal spermatogenesis and obstructive azoospermia.<sup>600,601</sup>

Using the preferred open microsurgical technique, sperm can be retrieved from the majority of men, even those with nonobstructive azoospermia. Magnification minimizes the risk of injury to the testicular blood supply, increases the probability of retrieving a blood-free biopsy specimen, and allows identification of larger caliber tubules that are more likely to yield sperm.<sup>602,603</sup> Normal pregnancies have been achieved even in those with congenital or acquired testicular failure,<sup>604</sup> postchemotherapy azoospermia,<sup>605</sup> and Klinefelter syndrome.<sup>606</sup>

In men with nonobstructive azoospermia, TESE is best performed on the day of or day before oocyte retrieval, when possible, and no earlier than approximately 6 months after any previous biopsy or TESE procedure, for several reasons. First, up to one-third of men with apparent nonobstructive azoospermia may exhibit sperm in their ejaculate on the day of planned retrieval and will not require TESE.<sup>607</sup> Second, sperm retrieved from men with nonobstructive azoospermia may not be motile or viable after

cryopreservation and thawing; ICSI using immotile sperm may yield worse results than when performed with fresh motile sperm.<sup>608</sup> Finally, the likelihood of successful retrieval of viable sperm for ICSI is significantly reduced when TESE is performed soon after a testis biopsy or previous TESE.<sup>608</sup> Matched donor sperm should be offered and available as backup, because TESE yields viable sperm in only about half of men with nonobstructive azoospermia.<sup>602,609,610</sup> When TESE cannot be performed near the time of oocyte retrieval, elective TESE can be performed and the recovered sperm cryopreserved; the risk of having no viable sperm after thaw is real but relatively low, and donor sperm can be used if needed.<sup>611,612,613</sup>

# Intracytoplasmic Sperm Injection

Assisted fertilization techniques were developed to circumvent the need for sperm to penetrate the zona pellucida. A variety of methods have been described, but the success of ICSI has rendered all others obsolete.<sup>614,615</sup> Earlier methods, including zona “drilling” (using a micropipette and acidified Tyrode solution or laser),<sup>616,617</sup> partial zona dissection (opening the zona with a microneedle),<sup>618</sup> and subzonal insertion or insemination (injection of sperm beneath the zona in the perivitelline space),<sup>619</sup> still required sperm to interact with the oolemma and did not prevent polyspermic fertilization, but ICSI solved those problems.<sup>620</sup>

In the ICSI procedure, a single selected sperm is first immobilized by compressing the sperm tail with an injection pipette (inner diameter 5–7  $\mu\text{m}$ ), then drawn into the pipette. The oocyte is stabilized with a holding pipette at the 9 o’clock position, usually with the polar body at the 6 or 12 o’clock position, and entered at the 3 o’clock position. The injection pipette pierces the zona and oolemma and the sperm is injected directly into the ooplasm. ICSI does not require sperm to undergo the acrosome reaction or to fuse with the oocyte membrane as occurs with natural fertilization. Instead, the mechanical disruption of the ooplasm and sperm membranes, facilitated by the sperm immobilization procedure and the gentle aspiration and reinjection of oocyte cytoplasm, triggers oocyte activation.<sup>621,622,623,624,625</sup> **In most cases, ICSI achieves fertilization rates comparable to those observed with conventional IVF in the absence of male factors (50–70%).**

ICSI can damage the meiotic spindle even if the area adjacent to the first polar body is avoided, because the second meiotic spindle varies in position and is not always located immediately beneath the first polar body.<sup>626,627</sup> A polarizing optical system that images the meiotic spindle can help to reduce the risk of spindle damage.<sup>628</sup>

The principal indication for ICSI is male factor infertility. Threshold semen parameters vary among centers but typically include severe oligospermia (<5 million sperm/mL), asthenospermia (<5% progressive motility), or teratospermia (<4% normal forms by strict criteria). ICSI also is indicated when using surgically retrieved sperm (because the number of mature sperm is relatively limited) or treatment includes PGD (because conventional insemination may result in extra sperm attached to the zona, which may contaminate the sample for diagnosis by polymerase chain reaction) and for couples with previous failed or poor fertilization with conventional IVF. Other circumstances where low fertilization efficiency or fertilization failure is anticipated may be viewed as an indication for ICSI. To guard against the potential consequences of an undiagnosed sperm function abnormality, some centers perform ICSI on at least a portion of the oocytes retrieved from women with unexplained infertility.<sup>119,629,630</sup> ICSI

also may yield higher fertilization rates for oocytes matured in vitro<sup>631,632,633</sup> and in cryopreserved oocytes,<sup>634,635</sup> which often exhibit a hardened zona (resistance to digestion by proteases).<sup>636,637,638,639</sup>

# EMBRYO CULTURE

---

Much attention has focused on culture media formulations. However, other components of the culture system are equally important, including the carbon dioxide (4–7%) and oxygen(5–20%) concentration, incubation volume (10–50  $\mu$ L), embryo group size (1–4), and the type of protein supplement (human serum albumin, recombinant albumin, synthetic serum substitute).<sup>640,641,642</sup>

Although the first human birth after IVF resulted from transfer of a blastocyst,<sup>2</sup> most transfers in the following years have involved earlier cleavage-stage embryos (day 2 or 3 after fertilization), primarily due to the lack of culture media that could reliably sustain embryos during the compaction (morula) and blastocyst stages of development. However, the identification of key regulators and a greater understanding of the changing physiologic requirements of growing embryos have fostered the development of “sequential” media, which vary in composition with the stage of embryo development.<sup>643</sup> **Whereas precompaction embryos prefer pyruvate as a nutrient and nonessential amino acids (found in higher concentrations in the oviduct), postcompaction embryos favor glucose and essential amino acids (found in higher concentrations in the uterus).**<sup>644,645</sup> Later on, “single-step” culture media containing nutrients, which embryos will need at different stages of development until post fertilization day 5/6, were introduced and provided similar clinical outcome with sequential media.<sup>646,647,648,649,650</sup> Single-step media without the need to replenish the medium on the 3rd day of culture allowed uninterrupted blastocyst culture in time-lapse monitoring systems. Commercially available media now provide the opportunity for any program to incorporate extended culture into its practice. In 2015, 59% of all embryo transfers in the United States were blastocyst transfers.<sup>5</sup>

Extended culture and blastocyst transfer offer several potential advantages over the transfer of cleavage-stage embryos:

- Better assessment of true viability, after activation of the embryonic genome, which occurs at 4- to 8-cell stage in human embryos
- Better synchronization between the stage of embryonic development and the endometrial environment
- The opportunity to perform PGT, when it is indicated
- Higher implantation rates, allowing transfer of fewer embryos, decreasing the risk for multiple pregnancy

**Extended culture is a more reliable test of viability and developmental potential because few embryonic genes are transcribed before the 8-cell stage and early**

measures of quality relate almost exclusively to the quality of the oocyte.<sup>651,652,653,654</sup> Postcompaction embryos also possess a transporting epithelium and can therefore better regulate their intracellular physiology and adapt to their environment.<sup>655,656,657</sup> Although pronuclear and cleavage-stage embryos can adapt to relatively hostile environments, survive, and successfully implant, those demands generate stresses that may compromise viability.<sup>645,658</sup> Extended culture may also help minimize adverse effects of an abnormal hormonal milieu on uterine receptivity and contractility, in the aftermath of ovarian stimulation.<sup>659,660,661,662</sup>

The strongest argument in favor of extended culture is that the implantation rate for blastocysts (30–60%) is significantly higher than for cleavage-stage embryos (12–20%).<sup>663,664,665,666,667,668,669</sup> Almost certainly, the higher implantation rate of blastocysts merely reflects better selection of the most viable embryos, as there is no evidence that extended culture improves the intrinsic quality of embryos.<sup>668</sup>

Not all have embraced the trend to wider use of extended culture, which also has at least two potential disadvantages:

- Embryos of lesser quality that may implant if transferred on day 3 may fail to reach the blastocyst stage in vitro, increasing the risk that there may be no embryos for transfer.
- Whereas higher blastocyst implantation rates permit transfer of fewer embryos, multiple pregnancy rates after transfer of two blastocysts are the same or higher than those observed after transfer of larger numbers of cleavage-stage embryos.

The results of a 2016 systematic review of 27 randomized trials comparing blastocyst and cleavage-stage embryo transfers illustrate both the principal advantage and disadvantage of extended culture, with a higher live birth rate per couple after blastocysts transfer (39% vs. 30.2%; OR = 1.48, CI = 1.20–1.82) and a higher rate of failure to transfer any embryos (OR = 2.50, 95% CI = 1.76–3.55).<sup>668</sup> The difference was independent of number of embryos transferred, prognosis, or day of randomization.

Indeed, the principal disadvantage of extended culture and blastocyst transfer is the higher risk for cancelled transfer. Although “omic” technologies (genomic, transcriptomic, proteomic, or metabolomic profiling) hold promise for helping to identify developmentally competent embryos, none has proven ready for application in clinical practice.<sup>670,671</sup> Evidence suggests that clinical measures (age, parity, AFC)<sup>672,673</sup> and laboratory parameters (fertilization method, number of blastomeres, and the degree of fragmentation observed on day 3)<sup>666,674,675,676</sup> can predict potential for blast formation, but the ability to generate blastocysts in vitro varies widely among individuals<sup>677</sup> and prediction models are not accurate enough to replace extended

culture for identification of embryos that will develop into blastocysts. More recently, time-lapse imaging systems (TLS), which capture images of embryos at predetermined intervals, for example, every 5–15 minutes, while the embryos are still in the culture environment, have been introduced.<sup>678</sup> In these systems, the images are digitally compiled to create a time-lapse sequence of embryo development. This allows assessment of the dynamic morphology of embryos without removing them from the incubator. Morphokinetic parameters, including the timing of cell divisions, intervals between cell cycles, and other development factors, for example, dynamic pronuclei patterns, presence of multinucleation and fragmentation, and blastomere symmetry, which may not be always observed or calculated with standard morphologic assessment at wider time intervals, are used to identify the embryo(s) that will develop to a blastocyst or will have the highest implantation potential. Several commercial or individualized algorithms, utilizing a variety of developmental milestones have been developed and provide a degree of accuracy in predicting blastocyst development as early as 48–72 hours of culture.<sup>679,680,681,682</sup> However, TLS algorithms are not yet precise replacements for extended culture. It is unclear if the monitoring or simply the undisturbed extended culture is helpful. Moreover, TLS algorithms do not reliably predict embryo euploidy or live birth.<sup>678,683,684</sup> Therefore, despite the availability of TLS, risk of cancelled transfer associated with extended culture is quite real (OR = 2.50, CI = 1.76–3.55).

**It is widely accepted that, in good prognosis elective single blastocyst transfer significantly reduces the incidence of twins without reducing the overall pregnancy rate.**<sup>685,686</sup> A study in donor oocyte recipients found that single blastocyst transfer yields a somewhat lower overall pregnancy rate, compared to transfer of two blastocysts, but reduces the twin rate dramatically.<sup>686</sup> Likewise, the U.S. National ART Data for 2015 show that women with good prognosis, that is, younger than age 35 with surplus embryos to cryopreserve, had live birth rates of 50% and 58.3% with single and double blastocyst transfers,<sup>5</sup> while multiple pregnancy rates were 2.2% versus 46%, respectively. It is disappointing that blastocyst transfer has not yet delivered on its promise to reduce the incidence of multiple pregnancy, primarily because few are willing to transfer only a single blastocyst.<sup>687,688,689</sup> In 2015, even though a lower percentage of blastocyst transfers involved three or more embryos (7% vs. 29%), the percentage of multiple-infant live births were higher with blastocyst transfer (24% vs. 21%).<sup>5</sup>

Most,<sup>690,691</sup> but not all studies,<sup>692</sup> have observed a two- to fivefold increase in the incidence of monozygotic twinning after blastocyst transfer. The cause is unknown, but culture-induced changes in the zona pellucida or embryo hatching have been implicated.<sup>693,694,695</sup> Most, but not all,<sup>696</sup> also have observed that blastocyst transfer

shifts the sex ratio, favoring males, compared to that observed in children conceived naturally,<sup>697</sup> or resulting from cleavage-stage embryo transfer.<sup>664,691,698,699,700</sup> The phenomenon may reflect the more rapid development of male embryos,<sup>701,702</sup> and the tendency to select the most advanced embryos for transfer.

A 2018 meta-analysis found the risk of preterm birth after fresh blastocyst transfer to be higher than after cleavage-stage transfer (RR = 1.15, CI = 1.05–1.25).<sup>703</sup> Women who received fresh blastocyst embryo transfers also have a higher risk of very preterm birth (RR = 1.16, CI = 1.02–1.31). However, there was no difference between the groups following FETs. Likewise, while blastocyst transfer resulted in fewer small for gestational age deliveries than cleavage-stage transfer in fresh cycles, rates were similar between the groups in frozen cycles. More large for gestational age (LGA) deliveries were observed after blastocyst compared with cleavage-stage transfer in frozen cycles (RR = 1.18, CI = 1.09–1.27), and there was no difference between the two groups in fresh cycles.<sup>703</sup> A number of reports have raised concern that longer duration of embryo culture may predispose to a higher risk of epigenetic (imprinting) alterations,<sup>704,705,706,707,708</sup> although subsequent studies examining the question have been reassuring.<sup>709,710</sup> Evidence from animal studies showing that developmental programming during the preimplantation interval can be influenced by manipulations in vitro<sup>711,712</sup> suggests that efforts to define and standardize culture conditions are justified and that careful long-term studies of children resulting from blastocyst transfer are warranted.

# Assisted Hatching

“Hatching” of the blastocyst from the zona pellucida is a natural process in which the embryo expands and emerges before implantation. Under culture conditions, the embryo erupts, leaving behind an empty zona, but in vivo, the mammalian zona normally dissolves. Evidence suggests that hatching in vivo results from embryo-uterine interactions with the embryo secreting an activator of zona lysins in the uterine fluid.<sup>713</sup> Zona thickness and relative resistance to enzyme digestion correlate with embryo quality and implantation potential.<sup>714,715,716,717</sup>

“Assisted hatching” describes a variety of techniques for artificially thinning or opening the zona. The procedure is intended primarily to improve implantation potential. Assisted hatching also offers the opportunity to remove cytoplasmic fragments from the perivitelline space,<sup>664</sup> but evidence indicates that removing fragments has no impact on implantation, clinical pregnancy, or live birth rates.<sup>718</sup> A wide assortment of methods has been used for assisted hatching, including zona drilling with acidified Tyrode solution,<sup>719,720,721,722</sup> partial zona dissection with a glass microneedle,<sup>723,724</sup> laser photoablation,<sup>725,726,727</sup> enzymatic thinning,<sup>728,729</sup> and the use of a piezo-micromanipulator.<sup>730</sup>

The idea that assisted hatching might improve implantation and pregnancy rates arose from observations that embryos subjected to zona drilling during early experience with assisted fertilization exhibited increased implantation efficiency.<sup>731</sup> Results of subsequent clinical trials varied widely with some suggesting that assisted hatching improved results in selected individuals having a relatively poor prognosis (advanced maternal age, previous failed IVF cycle, poor embryo morphology, thickened zona),<sup>719,722,724,725,726,727,730</sup> and others observing no demonstrable benefits, particularly when hatching was more broadly applied.<sup>720,721,723,732</sup> A 2012 systematic review and meta-analysis of combined data from 31 randomized trials involving 5,728 women found that assisted hatching increased clinical pregnancy rates (OR = 1.13, 95% CI = 1.01–1.27); however, the difference barely reached statistical significance.<sup>733,734</sup> The data on live birth is limited and does not suggest an improvement with assisted hatching (nine trials, OR = 1.03, CI = 0.85–1.26). While assisted hatching was associated with increased multiple pregnancy rates (14 trials, OR = 1.38, CI = 1.11–1.70), it had no impact on miscarriage rates (14 trials, OR = 1.03, CI = 0.69–1.54).<sup>733</sup> More recent studies and reviews yield conflicting results, even in subgroups of patients.

The varying results of clinical trials employing different techniques do not allow confident conclusions regarding the value of assisted hatching. **On balance, the weight of available evidence suggests that assisted hatching may have benefit for selected**

**individuals, especially those undergoing transfer with thawed blastocysts. However, routine or universal hatching is not warranted, particularly because the procedure also has potential risks. Hatching may cause damage to embryos and may increase the risk of multiple pregnancy and monozygotic twinning.**<sup>735,736,737,738,739,740,741,742</sup>

**Regarding the techniques utilized, thinning of the zona pellucida seems to have limited benefit and a higher degree of manipulation such as zona removal can provide better results.**<sup>735,738</sup> **Laser-assisted hatching is consistently reported to perform better than other methods.**

# Preimplantation Genetic Testing

Preimplantation genetic testing broadly describes procedures involving the removal of one or more nuclei of polar bodies from oocytes or cells (blastomeres, trophectoderm) from embryos to test for mutations or evaluate their chromosomal complement.<sup>131</sup> PGT for monogenic disorders (PGT-M, also called preimplantation genetic diagnosis [PGD]) describes testing for a known genetic abnormality carried by one or both parents to determine whether it has been transmitted to the oocyte or embryo. PGT for aneuploidy (PGT-A, also called PGS) describes testing for oocyte or embryo aneuploidy when the parents are known or presumed to be normal.<sup>131</sup>

## Techniques Used for Preimplantation Genetic Testing

The primary challenge in PGT is the small sample size, which varies between 1 and 10 cells depending on the type of biopsy. The past four decades witnessed extensive research that resulted in rapid introduction of technologies to improve diagnostic efficiency of PGT. Below is an introduction of the currently most relevant approaches. It is very likely that alternative technologies will be developed and have similar or better diagnostic accuracy in the near future.

### Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) was introduced in ART in 1990. FISH utilizes probes labeled with colored fluorochromes that bind to specific DNA sequences unique to each chromosome. FISH can detect a large excess or missing piece of chromosomal material. After polar body or embryo biopsy, the cells are fixed on glass, the cytoplasm is dispersed, and the fluorescent probes are applied and allowed to hybridize with complimentary DNA sequences on targeted chromosomes. The different colored fluorescent signals can be observed with microscopy using filters of the appropriate wavelength. The copy number for each chromosomal segment of interest is determined by the number of fluorescent signals detected. When FISH is utilized for a monogenic disease or translocation, only the chromosomal region carrying the affected gene or chromosomal segments are targeted with the fluorescent-labeled complimentary DNA probe. When the purpose is aneuploidy screening, FISH allows assessment of a maximum of 12 chromosomes. In addition to testing for a limited number of chromosomes, and only small sections of those chromosomes, hybridization failure, signal overlap, and splitting are other technical limitations of FISH for aneuploidy testing. Introduction of novel techniques that allow simultaneous assessment of all chromosomes almost in their entirety, having potential to assess monogenic disease/translocations together with aneuploidy, and failure to demonstrate a clinical benefit of PGT-M with FISH has led to abandoning the technology in favor of newer

methods described below.

## **Array Comparative Genomic Hybridization**

In array comparative genomic hybridization (aCGH), DNA from the biopsied cells is amplified, labeled, and hybridized on a DNA microarray together with a differently labeled control DNA. The array is then scanned, and intensity of both hybridization signals are measured and plotted. Differences between the signals from the test and control DNA allow identification of quantitative deviations, that is, extra or missing DNA sequences, in the test DNA. While aCGH can detect aneuploidy and unbalanced translocations, balanced translocations, and inversions go undetected since there is no extra or missing chromosomal content, despite being mislocated. Likewise, aCGH cannot detect polyploidy since test DNA segments all still contribute proportionately equally to hybridization process.

## **Single Nucleotide Polymorphism Array**

Humans are diploid organisms as they have two **alleles** at each genetic locus, with one **allele** inherited from each parent. Single nucleotide polymorphisms (SNPs) are defined as loci with alleles that differ at a single base, with the rarer allele having a frequency of at least 1% in a random set of individuals in a population.

Following the amplification of test DNA sample, analysis of the ratio of the intensity of both alleles at heterozygous loci allows detection of duplications in, and deletions from whole chromosomes in small regions. SNP arrays also allow determination of parental origin of abnormalities, and detection of uniparental disomy. However, these require genotyping the parents. Allowing detection of parental origin and high resolution renders SNP array useful for PGT for monogenic disease and unbalanced translocation. SNP array also allows PGT for aneuploidy by assessing copy number of all 24 chromosomes.

## **Quantitative PCR**

Quantitative PCR (qPCR) can be used for diagnosis of monogenic disorders using primers targeting the mutation of interest. When applied for aneuploidy, qPCR involves amplification of at least two sequences from each arm of each chromosome by using high-order multiplex PCR. Then each product is rapidly quantified by qPCR, and the amounts of products are compared to each other to calculate total genomic content. An advantage of qPCR is running multiplex PCR directly on the test DNA, avoiding whole genome amplification.

## **Next-Generation Sequencing**

Next-generation sequencing (NGS) is high-throughput sequencing and is the term used to describe a number of different sequencing technologies. Briefly, the test DNA is amplified and cleaved into short fragments, which are ligated to generic adaptors and annealed to a slide. The slide is flooded with fluorescent-labeled nucleotides and DNA polymerase, and depending on the particular technology, snapshots are taken (Illumina and Roche 454) or pH changes are monitored (Ion Torrent Proton/PGM sequencing) after addition of each base. The process is rapidly repeated many times and bioinformatics is utilized to construct the sequences with the optical information collected. Hundreds of thousands of fragments are sequenced simultaneously, until the desired sequencing depth, that is, the number of sequence reads for each given position in the genome, is reached. The generated sequence data from all chromosomes are compared with the reference genome and counted. Since the number of sequences from a particular chromosome should be proportional to the copy number of that chromosome, aneuploidy will result in greater or lower numbers of reads. NGS allows detection of whole chromosome aneuploidy, segmental chromosome imbalances, and single-gene disease.

## **Timing of Biopsy for Preimplantation Genetic Testing**

Preimplantation genetic testing can be performed on polar bodies removed from oocytes before and after fertilization (also called preconception diagnosis)<sup>743</sup> or on blastomeres (obtained from cleavage-stage embryos) or on trophoctoderm biopsies (removed from blastocysts). The equipment and techniques required for embryo biopsy are the same as for ICSI and related procedures (assisted hatching). After creating an opening in the zona pellucida using a laser or acid Tyrode solution, the polar body, blastomere(s), or trophoctoderm biopsy is extracted for genetic analysis.

Preconception diagnosis is cumbersome and often requires sequential removal of both the first and second polar bodies to decrease misdiagnoses.<sup>744</sup> Indeed, a recent study involving the biopsy of the first and second polar bodies for aneuploidy analysis in women of advanced maternal age (mean age 40.0) revealed an approximately equal proportion of errors in both meiotic divisions. Interestingly, in about half of cases where there had been an error in meiosis I, this error was balanced in meiosis II.<sup>745</sup> Therefore, in the zygote, there were more aneuploidies resulting from errors in meiosis II than meiosis I. Even if both polar bodies are analyzed, mitotic errors in the embryo and any resulting from paternal inheritance cannot be detected. Moreover, when polar body analysis is inconclusive, embryo biopsy must be performed. The cumulative trauma likely exceeds that of a single cleavage-stage embryo or trophoctoderm biopsy.

To detect abnormalities in cleavage-stage embryos, one or two nucleated cells are removed, typically on the 3rd day after fertilization (the 6–8 cell stage), before

compaction when the blastomeres become more tightly adherent.<sup>746</sup> After biopsy, the embryo can be placed in extended culture to develop to the blastocyst stage, or cryopreserved until the results of genetic analysis can be completed. A potential advantage of blastomere biopsy is its compatibility with fresh embryo transfer on day 5 to day 6 of embryo development, if the test results become available within 2 days of biopsy.<sup>747</sup> Extracting two blastomeres is more traumatic for embryo development and should be avoided, if possible.<sup>748</sup> A randomized controlled study showed that even single blastomere biopsy by an experienced operator in a high-volume laboratory harms implantation potential of embryos, leading to a decrease in sustained implantation rates (50% implantation rate in unbiopsied vs. 30% in biopsied sibling embryos in the same cycle).<sup>749</sup>

The risk of mosaicism, that is, the existence of different blastomeres with a different genetic constitution, is another drawback of blastomere biopsy. Mosaicism can lead to false-positive or false-negative results, when the biopsied blastomere is not representative of the embryo.<sup>747,750</sup>

A human blastocyst is 0.1–0.2 mm in size and has approximately 200 cells; typically, 5–10 trophoctoderm cells are removed during the biopsy. The above mentioned randomized trial demonstrated that the developmental potential of embryos undergoing trophoctoderm biopsy at the blastocyst stage was equivalent to the nonbiopsied control siblings.<sup>749,751,752,753</sup> Later sampling leaves little time for analysis before the embryo must be transferred or frozen. Yet, currently trophoctoderm biopsy is preferred over blastocyst biopsy. Although biopsied embryos might be more sensitive to the rigors of freezing and thawing, technical modifications in cryopreservation techniques have largely overcome the limitation.<sup>750,754,755</sup> A 2017 RCT compared clinical outcome following fresh or vitrified warmed transfer of euploid blastocysts and reported similar implantation (67% vs. 75%, respectively) and live birth rates (59% vs. 77%, respectively).<sup>756</sup> **Overall trophoctoderm biopsy is currently the most reliable and least traumatic option for preimplantation genetic testing.**

## Preimplantation Genetic Testing for Monogenic Disorders

Preimplantation genetic testing for monogenic disorders (PGT-M) also called PGD is indicated for couples at risk for transmitting a specific genetic abnormality to their offspring. The risk of transmission is 50% for carriers of autosomal dominant disorders (e.g., Marfan syndrome), 25% for carriers of autosomal recessive disorders (e.g., cystic fibrosis), and 25% (half of male embryos) for female carriers of X-linked disorders (e.g., hemophilia A). PGT-M also can be used to detect genetic mutations that predispose to a disease (early-onset Alzheimer disease,<sup>757</sup> familial adenomatous

polyposis coli,<sup>758</sup> p53 tumor suppressor gene mutations<sup>759</sup>), to detect an unbalanced chromosomal translocation in the embryos of a couple harboring a balanced translocation, and for human leukocyte antigen (HLA) matching of embryos to an existing child of the same parents (bone marrow transplantation).<sup>760</sup>

PCR is the method of choice for PGT-M, since customized PCR can detect particular mutations or changes in the DNA sequence. Yet, new technologies can be utilized for diagnosis of some diseases. Parental SNP genotypes and Mendelian genetic analysis can be used to generate a karyomap for each chromosome or chromosome segment inherited by each embryo.<sup>761</sup> Although karyomapping is commercially available and theoretically applicable to all monogenic disease without the need for prior optimization of the assay for the disease concerned, relatively higher cost and the requirement for genetic information from an affected individual or embryos as reference limits the use of SNP for PGT-M.<sup>762</sup> Array CGH is incapable of detecting single-gene mutations and can only be used to detect copy number variations. Recently, targeted NGS was shown to reliably detect cystic fibrosis, Walker-Warburg syndrome, familial dysautonomia, X-linked hypophosphatemic rickets, and neurofibromatosis 1.<sup>763</sup> The potential for simultaneously screening for both monogenic disease and aneuploidy is noteworthy. In one study, approximately 50% of PGT-M unaffected embryos were aneuploid.<sup>764</sup> Accordingly, when the clinical outcomes of PGT-M/PGT-A versus PGT-M alone were compared, implantation rates were 75% versus 53%, live birth rates were 59.4% versus 37.5%, and miscarriage rates were 20% versus 40%, respectively. Therefore, although patients performing PGT-M/PGT-A may ultimately have fewer embryos for transfer, these embryos will potentially have a higher reproductive potential.<sup>132</sup>

Currently, aCGH, SNP microarray, or NGS with trophoctoderm biopsy are used for PGT in balanced reciprocal and Robertsonian translocations. For couples harboring a balanced chromosomal translocation, whether PGT decreases the risk of miscarriage is debated. A 2018 systematic review of studies reporting reproductive outcomes in couples with recurrent pregnancy loss due to structural chromosomal rearrangements, live birth rates after natural conception ranged between 25% and 71% among couples with a history of RPL and translocations as opposed to 26.7% and 87% after IVF-PGT.<sup>765</sup> The miscarriage rate ranged between 25% and 55.6% after natural conception as opposed to 5.3% and 39% after IVF-PGT.<sup>765</sup> In two comparative studies including a total of 50 couples, the live birth rates were 66.6% and 67.6% in the IVF-PGD groups compared with 55.8% and 65.4% in the natural conception groups. Time to live birth varied greatly being 12.4 and 23.3 months in the IVF-PGT groups compared with 11.4 and 17.5 months in the natural conception groups.<sup>766,767</sup> It should be noted that studies included in this review utilized suboptimal techniques of cleavage-stage biopsy and

FISH for PGT, and whether trophectoderm biopsy and comprehensive chromosomal screening (CCS) yields the same result should be seen. Regardless, most couples with balanced translocations ultimately will achieve a successful pregnancy without IVF and PGT.<sup>765,768,769,770</sup>

**PGT-M offers couples who carry serious genetic disorders the opportunity to have a healthy child without the practical and ethical problems associated with terminating an affected pregnancy after traditional prenatal diagnosis (chorionic villus sampling, amniocentesis). However, careful counseling is required and must include the following:**

- The possibility of diagnostic error or inconclusive results
- The possibility that the chance for success may be reduced, compared to that expected when PGT-M is not performed, due to embryo trauma and the smaller number of embryos available after abnormal embryos are excluded
- The need for conventional prenatal diagnosis to confirm the accuracy of PGT-M

## **Preimplantation Genetic Testing for Aneuploidy**

Aneuploidy is common in human embryos, most resulting from meiotic errors in the oocyte, which increase in prevalence with advancing age. Although aneuploidy is more common in morphologically abnormal embryos, even embryos with normal morphology and developmental progress may be aneuploid.<sup>771,767</sup> As a diagnostic test, PGT-A is not expected to improve total reproductive potential of an egg retrieval cycle, that is, cumulative pregnancy rate after exhaustion of all available embryos, fresh and frozen from a single cycle. However, embryo biopsy, aneuploidy screening, and transfer of proven euploid embryos would be expected to improve implantation efficiency and to reduce the incidence of futile embryo transfers and possibly miscarriage in pregnancies resulting from IVF. Older women with relatively higher rate of embryo aneuploidy and good prognosis patients with several embryos available to choose from for embryo transfer are the most obvious potential candidates for PGT-A. Others include women with a history of recurrent pregnancy loss, those with repeated IVF failure despite transfer of morphologically normal embryos, and couples with severe male factor infertility.

Initial PGT-A utilized blastomere biopsy and FISH allowing the examination of a limited number of chromosomes. As such, all but one RCT of this initial approach failed to demonstrate a benefit.<sup>773,774,775,776</sup> Furthermore, two of these RCTs reported decreased live birth rates with PGT-A with blastomere biopsy and FISH.<sup>775,776</sup> As a result of these well-designed studies, the American Society for Reproductive Medicine (ASRM) and the European Society for Human Reproduction and Embryology released a

statement advising against the use of PGT-A with FISH.

Since then, alternative techniques have become available (discussed above) for CCS, and new RCTs provided high-quality evidence regarding IVF pregnancy outcomes in select populations with PGT-A.<sup>132</sup> A RCT assessing the effectiveness of PGT-A utilized first and second polar body biopsy with aCGH in 396 women aged 36–40 years.<sup>777</sup> Fifty of the 205 (24%) participants in the chromosome screening group had a live birth with intervention within 1 year, compared to 45 of the 191 in the group without intervention (24%) (difference = 0.83%, 95% CI = –7.60 to 9.18%). In the CCS group, significantly fewer participants underwent an embryo transfer (relative risk [RR] = 0.81, 95% CI = 0.74–0.89) and fewer had a miscarriage (RR = 0.48, 95% CI = 0.26–0.90).<sup>777</sup> The rate of embryo development was similar between the two groups (53% vs. 50% morphologically transferable) suggesting that the polar body biopsy procedure did not have a detrimental effect; however, the analysis was inconclusive for 8% of oocytes assessed by aCGH.<sup>777</sup> Due to the diagnostic limitations previously discussed, as well as the findings of this study, a polar body-based CCS approach is not likely to be widely utilized in the near future.

Another multinational study randomized women with advanced maternal age (38–41 years old), prior to cycle start to routine blastocyst transfer versus a PGT-A group that had a biopsy of a single blastomere on day 3 with fresh blastocyst transfer on day 5 after the retrieval.<sup>774</sup> The live birth rates were significantly higher in the PGT-A group when analyzed per embryo transfer (52.9% vs. 24.2%,  $p < 0.0002$ ) and per started cycle (36% vs. 21.9%,  $p < 0.031$ ). Moreover, the miscarriage rate was significantly lower in the PGT-A group (2.7% vs. 39%,  $p = 0.0007$ ). When the outcomes for FET cycles performed during the 6 months after the completion of the study were added, cumulative live birth rates were similar (37% vs. 33.3% in PGT-A and controls, respectively). However, the mean number of ETs needed per live birth was lower in the PGT-A group compared with the control group (1.8 vs. 3.7), as was the time to pregnancy (7.7 vs. 14.9 weeks).<sup>774</sup> The use of blastomere biopsy could be regarded as a factor limiting the generalizability of the results of this study.

Three other RCTs involved women with better prognosis, that is, younger than 35 years or having at least two blastocysts amenable to biopsy. The RCT including 112 women younger than 35 years, with tubal or male factor infertility, and without any prior failed cycles utilized trophoctoderm biopsy on day 5, aCGH, and fresh transfer on day 6.<sup>778</sup> Blastocyst for transfer in the control group were selected by traditional morphologic assessment, and also transferred on day 6. Array CGH group achieved significantly higher ongoing pregnancy rates (69.1% vs. 41.7%,  $p = 0.009$ ), while miscarriage rate was similar between PGT-A and control groups (2.6% vs. 9.1%, in PGT-A and controls, respectively,  $p > 0.05$ ). Another RCT included 175 women

younger than 42 years old who had at least two expanded blastocyst on day 5 or 6, compared clinical outcome of elective single euploid blastocyst transfer with transfer of two morphologically selected blastocysts.<sup>779</sup> Trophectoderm biopsy and qPCR were used for PGT-A. Ongoing pregnancy rate beyond 20 weeks were similar in the two groups (60.7% vs. 65.1%), with significantly lower multiple pregnancy rate in the PGT-A group (0% vs. 53.4%,  $p < 0.05$ ). The risks of preterm delivery, low birth weight, and neonatal intensive care admission were also lower with PGT-A.<sup>780</sup> Another RCT randomized 155 women with two or more blastocysts on day 5 to trophectoderm biopsy with qPCR-based CCS on day 5 and transfer on day 6 or morphologic grading and embryo transfer on day 5.<sup>781</sup> Patients in the control group had significantly more embryos transferred than the PGT-A group (2.0 vs. 1.86,  $p < 0.001$ ), which was due to 10 patients in the study group having only one euploid embryo for transfer while all patients in the control group underwent double embryo transfer. Clinical implantation rates were significantly higher in the PGT-A group (79.8% vs. 63.2%, in PGT-A and controls, respectively,  $p = 0.002$ ). Delivery rate per cycle was also significantly higher in the PGT-A group (84.7% vs. 67.5%,  $p = 0.01$ ). Based on the reported data, the calculated spontaneous abortion rates were 8.9% and 21.1%, in PGT-A and control groups, respectively. These three RCTs suggest elective single euploid blastocyst transfer selected by PGT-A with trophectoderm biopsy, and comprehensive chromosome screening with 24 chromosomes results in higher implantation, pregnancy, and delivery rates following the first embryo transfer of an egg retrieval cycle in women with good ovarian reserve.

A 2017 trial randomized 323 women aged 25–34 years, 170 women aged 35–37 years, and 95 women aged 38–40 years to PGT-A or morphologic blastocyst assessment at 34 clinics in 4 countries. Women between 25 and 40 years of age, with less than 3 prior ART failures and less than 2 prior miscarriages, and who are not a known carrier of a single-gene disorder or chromosomal abnormality were recruited. Decreased ovarian reserve, oligospermia, azoospermia, use of donor oocytes or gestational carrier, and undergoing PGT outside the study context were exclusion criteria. Trophectoderm biopsy and NGS were utilized for PGT-A. In both arms, blastocyst-stage embryos underwent vitrification for single-embryo transfer in a later cycle. In women younger than 35, 20-week ongoing pregnancy rates were not different between PGT-A and control groups (53% vs. 49%), while there was a significant improvement in women 35–40 years old (51% vs. 37%,  $p = 0.035$ ). Miscarriage rates ranged between 8% and 11% in age brackets and were not significantly different between the PGT-A and control groups.<sup>782</sup> Overall, this RCT failed to replicate the favorable results achieved with the above mentioned RCTs in women with good prognosis while it showed a benefit in women over 35 years old.

A recurring theme in PGT-A is mosaicism and the complexity of determining the

reproductive potential of human embryos diagnosed as mosaic. In one study, chromosomal mosaicism was diagnosed by aCGH in 181 of 3,802 blastocysts (4.8%).<sup>783</sup> Eighteen women who did not have any euploid embryos underwent single-embryo transfer of mosaic embryos, eight pregnancies ensued, of which six resulted in the birth of a singleton infant at term. All pregnancies that went to term were confirmed, by means of sampling of the chorionic villi, to have a normal karyotype. The findings of this study suggest that embryos diagnosed as mosaic can develop into healthy euploid newborns.<sup>783</sup> These findings should be kept in mind when counseling women who undergo IVF resulting in mosaic embryos but no euploid embryos.

**Techniques applied for PGT-A are rapidly evolving and many of the key techniques used in published RCTs are no longer in use; qPCR and aCGH have been replaced by NGS-based analysis for comprehensive chromosome screening, fresh transfers have been replaced by thaw transfers of cryopreserved embryos. NGS is also being reassessed regarding the best way to amplify the genome and how to achieve the necessary depth of sequencing in a most cost-efficient way. The next decade will uncover whether these developments will further improve diagnostic accuracy of PGT-A and help determine the appropriate applications. While some express concern about the diagnostic accuracy, many view this approach for embryonic selection as an avenue to reduced time to live birth and increased live birth rate per transfer, at least in selected populations.**

# EMBRYO TRANSFER

---

Although embryos have been transferred successfully at any stage of early development, from zygote to blastocyst, transfer is most commonly performed 5 days after oocyte retrieval, while some programs continue performing day 3 transfers, at least for certain subsets of patients. The relative advantages and disadvantages of extended culture to the blastocyst stage are discussed above. Systems for grading the quality of embryos vary among programs, but the morphologic features on which grading is based are similar and depend on morphology and cleavage rate.

The essential features of embryo transfer have not changed significantly since the procedure was first described in 1984.<sup>784</sup> Although the impact of transfer technique on results is difficult to study, most clinicians believe it is as important as embryo quality.<sup>785</sup> The success of the procedure is clinician dependent.<sup>786,787,788,789</sup> Yet, a 2017 survey showed that all clinicians were allowed to perform embryo transfer, regardless of their skill level, without a standardized technique.<sup>790</sup> This has led the Practice Committee of the American Society of Reproductive Medicine (ASRM) to prepare a guideline and a standard embryo transfer protocol template.<sup>786,791</sup> Further, the ASRM has developed embryo transfer simulators that can be used for training and standardization.

Embryo transfer is typically a pain-free procedure. Thus, neither anesthesia nor analgesics are required routinely. Despite some theoretical advantages, evidence for an effect of massage, relaxation techniques, acupuncture, transcutaneous electrical acupoint stimulation, and Chinese medicine is limited and does not suggest an unequivocal benefit from these adjuvant interventions. Likewise, routine use of broad-spectrum antibiotics seems unnecessary.

A trial transfer before the cycle begins can identify women with cervical stenosis or an acutely angled cervicouterine junction that can make transfer technically difficult to perform.<sup>792</sup> Several studies have suggested that, when required, cervical dilation is best performed before the cycle begins;<sup>793,794,795,796</sup> shorter intervals of time between dilation and transfer may be insufficient to allow the endometrium to recover from the trauma or bacterial contamination and are associated with significantly lower pregnancy rates. Dilation with laminaria in advance of the treatment cycle also can be effective.<sup>797</sup> The notes from a prior mock or real embryo transfer, when available, should be reviewed before embryo transfer to prepare for an anticipated difficult transfer and to facilitate the procedure.

Embryo transfer under transabdominal ultrasonography offers a number of advantages over a blind technique. **Ultrasonography facilitates the insertion of soft**

**catheters, confirms correct positioning, and avoids inadvertent trauma to the fundal endometrium.**<sup>798,799</sup> Urine in the bladder also may help to straighten the plane of the cervicouterine junction.<sup>800,801</sup> Uterine position and orientation often change in the interval between the mock transfer and the actual transfer, primarily due to the ovarian enlargement.<sup>269</sup> Two recent systematic reviews, both including 21 RCTs, reported significantly higher live birth rate after guided transfers<sup>802,803</sup>; the probability of a live birth was increased almost 1.5-folds with ultrasound guidance.

The use of sterile latex-free gloves is preferred as per common practice and standard expected occupational safety and health administration requirements. Two-thirds of physicians report using surgical masks during embryo transfer.<sup>791</sup>

An embryo transfer has a number of potential pitfalls. An appropriate size speculum should be used to expose the cervix easily, and any remnants of vaginal progesterone and secretions are gently cleaned with sterile saline or embryo transfer media. Mucus within the cervical canal may plug the catheter tip, resulting in retained embryos or improper placement.<sup>793,804,805</sup> Cervical mucus also can be a source of bacterial contamination of the endometrial cavity, adversely affecting results.<sup>805,806</sup> Any obvious or excess cervical mucus is best removed before transfer.<sup>807,808,809</sup> However, cervical trauma should be avoided and excessive lavage is not shown to be helpful.<sup>798</sup>

Transfer catheters vary widely in design. Current catheters are comprised of an outer sheath and an inner catheter, the latter carrying the embryos. Definitions of “soft” and “firm” catheters vary in the literature. It is reasonable to categorize all catheters with a soft inner catheter as a soft catheter, since the aim is to dislodge the embryos without endometrial trauma.<sup>786</sup> Stiff catheters and those with a rigid outer sheath are easier to insert but more traumatic than soft catheters, which can better follow the contours of the endocervix and endometrium.<sup>810</sup> Controlled trials consistently show better clinical outcome with soft catheters, with 1.4-fold (CI = 1.2–1.6) higher pregnancy rates.<sup>786</sup> However, no soft catheter performs significantly better than another soft catheter, and commercially available soft catheters are regarded to perform similarly.<sup>786,811</sup> If a soft catheter with a firm outer sheath is used, pushing the tip of the outer sheath beyond internal ostium can cause endometrial trauma and lower pregnancy rates.<sup>812</sup> When transfer proves difficult, a malleable stylet can be used to introduce the outer sheath of a soft catheter just beyond the internal cervical os, then replaced by the soft inner catheter containing the embryos (“afterloading”). Transmyometrial embryo transfer under ultrasound guidance has been described<sup>813,814</sup> but yields lower pregnancy rates,<sup>815</sup> probably relating to uterine contractions,<sup>816</sup> and rarely should be necessary.

The tip of the embryo transfer catheter is placed at the upper or middle area of the

endometrial cavity before dislodging the embryos.<sup>817,818,819,820,821,822</sup> Transfers higher in the fundus may increase the risk of ectopic pregnancy,<sup>823,824</sup> and low transfers may result in cervical implantations.<sup>825</sup>

Larger volumes of transfer media (>20–50 µL) or air above the column of media may increase the risk that embryos may be expelled from the uterus or propelled into the fallopian tube.<sup>826,827</sup> The concentration of protein and the viscosity of transfer medium do not appear to affect results.<sup>828,829</sup> Whether adherence compounds containing hyaluronic acid in embryo transfer media improve clinical pregnancy rates is controversial.<sup>830,831,832,833,834,835</sup> Syringes that may be used with a transfer catheter also vary in design and performance characteristics. Even though quantitative analysis of injection speed is difficult, fast injection close to the fundus has been associated with increased ectopic pregnancy rates.<sup>786,836,837,838,839</sup> While the presence of mucus on the catheter tip is not associated with decreased pregnancy and live birth rates, results are mixed regarding the effect of the presence of blood.<sup>786,793,804,840,841,842,843,844,845,846,847,848,849</sup> Yet, it is prudent to avoid cervical and/or endometrial trauma during embryo transfer.

Embryos adhering to the outside of the catheter after transfer can be relocated or removed inadvertently when the catheter is withdrawn.<sup>798,826</sup> Microscopic examination of the catheter immediately after transfer identifies retained embryos requiring a second transfer procedure; immediate retransfer of retained embryos does not seem to affect implantation, pregnancy, or abortion rates.<sup>786,793,826,840,845,846,847,848,849,850,851,852,853,854,855,856</sup>

There is good quality evidence to recommend against bed rest after embryo transfer.<sup>786,857,858</sup> Indeed, a 2016 meta-analysis suggests possible harm.<sup>859</sup> Thus, patients can resume normal daily activities; physical activity and diet have no demonstrable effect on outcomes. Mild intermittent cramping and bloating are normal symptoms, but moderate or severe pain requires evaluation to exclude infection, ovarian torsion, OHSS, and other causes of abdominal pain.

In summary, the goal of embryo transfer is to deliver embryos to the uterus in an accurate and atraumatic fashion. **A preliminary trial transfer can identify women who may benefit from cervical dilation before treatment begins, and transfers in small volumes using soft catheters guided by ultrasonography produce the best results.**<sup>786</sup>

# Embryo Transfer Guidelines

The goal of IVF is to maximize pregnancy rates while, at the same time, minimizing multiple gestations, high-order multiple gestations in particular. The likelihood of success increases with the number of embryos transferred, to a point, beyond which only the risk of multiple pregnancy increases.<sup>860,861,862</sup> Multiple pregnancy does not only increase the risk of preterm birth and associated neonatal and infant morbidity and mortality but is also associated with maternal morbidity.<sup>863</sup> Moreover, preterm deliveries that result from ART-associated multiple pregnancies add a substantial burden to overall U.S. health care expenditure annually.<sup>864</sup> Financial concerns affect couples' preferences for number of embryos to be transferred, and public reimbursement plans accompanied by strict regulations for number of embryos to be transferred seem to increase not only ART utilization rates but also the uptake of single-embryo transfers.<sup>865,866,867,868</sup> Strict regulations on the number of embryos transferred, as defined by law in some countries, reduce the number of multiple pregnancies and all but eliminate high-order multiple gestations<sup>860</sup>; however, they do not allow treatment to be individualized, considering unique patient characteristics and circumstances (age, the number and quality of embryos, the opportunity for cryopreservation, and the outcome of any previous cycles), or to be adjusted according to new clinical data.<sup>869,870,871</sup> Registry data from the United States strongly suggest that regulations ignoring the unique circumstances of individual women inevitably reduce the chance of pregnancy.<sup>861</sup>

In essence, elective single-embryo transfer could be considered for almost all women, since cumulative live birth rate per egg retrieval cycle would be maintained following consecutive FETs with current success achieved in embryo cryopreservation. Indeed, clinics that perform higher rates of elective single-embryo transfer in women aged less than 38 years have decreased rates of multiple gestation, with no significant impact on cumulative live birth rates.<sup>872</sup> The data generated by individual programs can guide the decision regarding the optimal number of embryos to transfer in women of varying age and clinical characteristics. In their absence, the Society for Assisted Reproductive Technology (SART) and the ASRM have offered guidelines. First published in 1998,<sup>873</sup> the guidelines have been revised several times, based on new clinical data reflecting steady advances in ART indicating that fewer embryos can be transferred without adversely affecting the likelihood for success.<sup>874,875</sup> The guidelines issued in 2017 categorize patients as those with a favorable prognosis and those without.<sup>876</sup> The following characteristics have been associated with a favorable prognosis: (1) expectation of one or more high-quality embryos available for cryopreservation, (2) euploid embryos, and (3) previous live birth after an IVF cycle. Additional favorable criteria for FET cycles include the availability of vitrified, high-

quality, day 5, or day 6 blastocysts for transfer.<sup>876</sup> Recommended number of embryos to be transferred is based on the age of the woman, presence or absence of favorable characteristics, and stage of embryos, that is, cleavage or blastocyst. The recommendations are noted in the section that follows.

## Recommendations

### Patients with a favorable prognosis:

- In patients of any age, transfer of a known euploid embryo has the most favorable prognosis and should be limited to one.
- Patients under the age of 35 should be encouraged to receive a single-embryo transfer, regardless of the embryo stage.
- For patients between 35 and 37 years of age, strong consideration should be made for a single-embryo transfer.
- For patients between 38 and 40 years of age, no more than three cleavage-stage embryos or two blastocysts should be transferred. In cases where euploid embryos are available, a single blastocyst embryo transfer should be the norm.
- Patients 41–42 years of age should plan to receive no more than four cleavage-stage embryos or three blastocysts. In cases where euploid embryos are available, a single blastocyst transfer should be the norm.

### Other scenarios:

- In all age groups, patients who do not meet the criteria for a favorable prognosis may have an additional embryo transferred according to individual circumstances (Table 28.2). The patient must be counseled regarding the additional risk of twin or higher-order multiple pregnancy.
- If otherwise favorable patients fail to conceive after multiple cycles with high-quality embryo(s) transferred, physicians and patients may consider proceeding with an additional embryo to be transferred.
- Patients with a coexisting medical condition for which a multiple pregnancy may increase the risk of significant morbidity should not have more than one embryo transferred.
- In the rare cases where the number of embryos or blastocysts transferred exceeds recommended limits, both the counseling and the justification must be documented in the patient's permanent medical record.
- In women  $\geq 43$  years of age, there are insufficient data to recommend a limit on the number of embryos to transfer when the patient uses her own oocytes. Caution should be exercised as the risk associated with multiple pregnancy increases

dramatically with advancing maternal age.

**TABLE 28.2 Recommendations for the Limit to the Number of Embryos to Transfer**

Prognosis	Age in years			
	<35	35–37	38–40	41–42
Cleavage-stage embryos <sup>a</sup>				
Euploid	1	1	1	1
Other favorable <sup>b</sup>	1	1	≤3	≤4
All others	≤2	≤3	≤4	≤5
Blastocysts <sup>a</sup>				
Euploid	1	1	1	1
Other favorable <sup>b</sup>	1	1	≤2	≤3
All others	≤2	≤2	≤3	≤3

<sup>a</sup>See text for more complete explanations.

<sup>b</sup>Other favorable = Any ONE of these criteria: fresh cycle, expectation of 1 or more high-quality embryos available for cryopreservation or previous live birth after an IVF cycle; FET cycle, availability of vitrified day 5 or day 6 blastocysts, euploid embryos, first FET cycle, or previous live birth after an IVF cycle.

Please note: Justification for transferring additional embryos beyond recommended limits should be clearly documented in the patient's medical record.

In donor oocyte cycles, the age of the donor should be used to determine the appropriate number of embryos to transfer. For example, when the donor is less than 35 years of age and other favorable criteria exist, single-embryo transfer should be planned.

In frozen embryo transfer cycles, favorable characteristics should be based on the age of the woman when the embryos were frozen and include the presence of high-quality vitrified embryos, euploid embryos, first FET cycle, or previous live birth after an IVF cycle. Embryo transfer numbers should not exceed the recommended limit on the number of fresh embryos transferred for each age group.

Overall, the weight of available evidence indicates that an optimal balance between pregnancy rates and the risk of multiple pregnancy can be achieved with a flexible embryo transfer policy based on maternal age, embryo quality, and the availability of surplus high-quality embryos (see [Table 28.3](#)).

**TABLE 28.3 Live Births per Transfer and Percentages of Multiple-Infant Births for Women Under Age 35 with Surplus Embryos Suitable for Cryopreservation, by Number of Embryos Transferred<sup>5</sup>**

Embryos Transferred	Live Births per Transfer	Singletons	Twins	Triplets +
1	49.5%	97.9%	2.1%	<0.1%
2	56.2%	56.3%	42.7%	1%
3	50.9%	62.4%	28.2%	9.4%
4+	44.4%	100%	0%	0%

# LUTEAL PHASE SUPPORT

---

Controlled ovarian hyperstimulation with exogenous gonadotropins generally yields multiple corpora lutea that might well be expected to sustain supraphysiologic serum concentrations of estradiol and progesterone during the luteal phase of IVF cycles. Cotreatment with GnRH analogs for prevention of premature LH surge and luteinization effectively suppresses endogenous LH secretion, as intended. Unfortunately, even though agonist and antagonist treatment end abruptly on the day of hCG administration, residual suppression of endogenous LH does not. **Abnormally low levels of LH during the luteal phase may be insufficient to stimulate and maintain the level of luteal function required to promote timely endometrial maturation in preparation for implantation or to support an early pregnancy once established.** Endogenous LH secretion can remain suppressed for as long as 10 days after treatment with a GnRH agonist ends and luteal function is frequently inadequate in amount or duration.<sup>877</sup> Although antagonists have a much shorter duration of action, they often have the same consequence. Integrated estradiol and progesterone levels are abnormally low, and luteal phase duration is grossly short in GnRH antagonist treatment cycles, particularly when a GnRH agonist rather than hCG is used to stimulate the final stages of oocyte maturation.<sup>878</sup> Because there is no way to predict who may or may not require luteal support in any given cycle, some form of treatment must be provided for all.

Progesterone supplementation generally begins on the day of oocyte retrieval or at the time of embryo transfer.<sup>879,880,881</sup> Numerous clinical trials have compared clinical, ongoing, or delivered pregnancy rates or spontaneous abortion rates between groups receiving treatment with different luteal phase support regimens, with varying results. Progesterone has been administered orally (300–800 mg daily); vaginally as a bioadhesive 8% gel (90 mg daily), cream, or tablet (100–600 mg daily); and by intramuscular (25–50 mg daily) or subcutaneous (25 mg daily) injection; supplemental doses of hCG generally have been administered every 3 days (1,500–2,500 IU). There is no evidence that any one treatment regimen is superior, although results achieved with oral progesterone have been inconsistent. However, dydrogesteron (30 mg daily), a retroprogesteron, which has higher oral bioavailability than micronized progesterone, has been shown to be as effective as vaginal progesterone gel in a 2016 meta-analysis and a 2017 RCT.<sup>882,883</sup> Even though stopping luteal phase support after a positive pregnancy test does not seem to be associated with lower live birth rates,<sup>884,885,886</sup> 72% of ART clinics continue luteal support until 8–10 gestational weeks worldwide.<sup>887</sup> Supplemental natural progesterone is not associated with any increased risks of birth defects.<sup>880</sup> Although supplemental estradiol also is commonly administered, there is no evidence that it improves outcomes, compared to those achieved with progesterone

supplementation alone. [884,888,889](#)

# EMBRYO CRYOPRESERVATION

---

The first pregnancy resulting from transfer of a cryopreserved human embryo was reported in 1983.<sup>890</sup> In the years since, advances in cryobiology have made embryo cryopreservation an integral part of modern ART. Success with FET cycles significantly increases the overall cumulative pregnancy rate per retrieval. In addition, elective cryopreservation of all embryos may be an effective management strategy, to prevent OHSS in women with an excessive ovarian response to stimulation and to avoid decreased live birth rates with fresh transfer in this scenario.<sup>406,410,411,412,891,892</sup>

The cryopreservation process has two distinct stages, freezing and thawing. The objective of freezing is to avoid ice crystallization of intracellular water, which can result in cellular damage. Freezing protocols vary with the stage of embryo development, which affects cellular permeability. There are two basic methods for embryo cryopreservation, the “slow-freeze” technique and “vitrification.” In both, cellular water is gradually replaced by cryoprotectants (dimethyl sulfoxide, propanediol glycerol) via osmosis by passage through increasing concentrations of the cryopreservative. In the slow-freeze method, embryos are sealed in ampules or vials, cooled to temperatures between  $-30^{\circ}\text{C}$  and  $-110^{\circ}\text{C}$  in a programmed two-step process, and then stored in liquid nitrogen. The first phase of the freezing process is rapid to prevent ice crystal formation (more likely to occur with gradual cooling), and the second phase more gradual. In the vitrification method, embryos are flash frozen by immersion into liquid nitrogen, creating a solid glass-like state.<sup>893,894</sup> After thawing, the process is reversed, gradually passing the embryo through decreasing concentrations of the cryoprotectant, followed by an interval of culture before transfer.

Embryos can be frozen at any stage, from zygote to blastocyst, and remain viable for at least several years, perhaps indefinitely.<sup>895</sup> Numerous studies have compared embryo thaw survival, implantation, and pregnancy rates among embryos frozen at different stages of development. In general, postthaw survival rates after slow freezing range between 50% and 90% and are higher for zygotes than for cleavage-stage embryos and blastocysts.<sup>896,897,898,899,900,901</sup> Implantation rates (5–15%) and pregnancy rates (10–30%) after transfer of slow-frozen-thawed zygotes, cleavage-stage embryos, and blastocysts have varied among studies, but not dramatically. In contrast to slow freezing, vitrification allows rapid cooling of the cells and the extracellular milieu into a glass-like state without ice crystal formation. This is achieved by high initial concentrations of cryoprotectants, low volumes and ultrarapid cooling-warming rates. Vitrification is associated with consistently high survival rates (90–100%) and yields higher implantation and pregnancy rates.<sup>893,894,902,903</sup>

**Despite of the fact that the highest quality embryos are generally selected for**

**fresh transfer, the overall success rates for vitrified embryo transfer cycles are approximately still the same as those observed in fresh transfer cycles.** Results achieved with embryos derived from conventional IVF and ICSI are comparable. Embryos that resume cleavage and survive longer in culture are more likely to result in pregnancy, and cryopreserved sibling embryos derived from successful cycles yield higher success rates than those derived from unsuccessful cycles, probably reflecting overall better embryo quality.

Frozen-thawed embryos can be transferred in a monitored natural cycle in women with normal ovulatory function. Alternatively, transfer can occur in an artificial cycle in which endometrial development is carefully controlled by programmed sequential treatment with exogenous estrogen (oral micronized estradiol 4–6 mg daily or transdermal estradiol 0.2–0.4 mg) beginning with or shortly before the onset of menses, followed by progesterone (50–100 mg daily intramuscularly or 8% vaginal gel administered twice daily).<sup>904,905</sup> Preliminary down-regulation with a GnRH agonist also can be used, as is typical in donor oocyte recipients.<sup>303,906,907,908</sup> A 2017 systematic review including 18 randomized trials comparing different endometrial preparation regimens found no evidence that one method of endometrial preparation was superior to others.<sup>909</sup> In both natural (days after ovulation) and artificial cycles (days of progesterone treatment), the time of transfer is synchronized with the stage of embryo development, as in donor oocyte recipients (discussed below). Based on two retrospective studies, the interval between egg retrieval and FET does not seem to affect clinical outcome, and it is not required to wait for at least one menstrual cycle for the transfer of cryopreserved embryos.<sup>910,911</sup>

# OUTCOMES OF IVF

---

IVF outcomes have improved steadily throughout the years since its introduction into clinical practice. Early on, IVF offered only a modest chance for success and was reserved appropriately for couples who had no option or had failed all other available forms of treatment. As technology and outcomes improved, IVF became a realistic and attractive option for an increasing number of couples. The advent of ICSI revolutionized the treatment of severe male factor infertility and greatly contributed to the growth of ART. Now, ART often is the first and best option for a large proportion of infertile couples.

IVF success rates may be expressed in several ways, using different numerators and denominators. The two most common numerators are pregnancy and live birth, the latter being the most relevant measure. **Approximately 16% of pregnancies result in miscarriage, induced abortion (1.0%), stillbirth (0.7%), or an ectopic pregnancy (0.5%).**<sup>5</sup> Pregnancy or live birth rates may be calculated as a percentage of cycle starts, retrievals, or transfers. Overall, approximately 11% of cycles are discontinued before retrieval, due to an inadequate (82.3%) or excessive response (4.2%) to stimulation, a concurrent medical illness (0.9%), or a patient's own personal reasons (12.5%).<sup>5</sup>

For the year 2015, the U.S. registry recorded a total of 231,936 cycles of ART nationwide. Among these, 91,090 (39.3%) were IVF cycles involving fresh, nondonor oocytes (69% with ICSI), with 29.3% resulting in a pregnancy. The live birth rates were 23.9% per cycle, 26.9% per retrieval, and 36.7% per transfer. Another 69,882 (30.1%) were frozen nondonor embryo transfer cycles, yielding a live birth rate of 44.3% per transfer. Results vary considerably by age. In almost all age groups, success rates were higher for women with a previous live birth and those in their first ART cycle than for nulliparous women and those with a previous failed ART cycle.<sup>5</sup>

# Multiple Gestation

Following the introduction of ART into medical practice, there has been a substantial increase in multiple gestations. In 1998, 2 per 1,000 live births were triplet and higher-order multiple births, representing a more than 6.7-fold increase since 1971. Fertility treatments were responsible for more than 80% of these triplet and higher-order births, and half of these were the result of IVF treatment.<sup>912</sup> While the proportion of high-order multiple deliveries has significantly declined since 1998 due to a trend toward reduction in embryo transfer order, twin rates remain high. In 2015, 22.7% and 16.8% of all births in the United States resulting from fresh and FETs, respectively, were multiples, a rate 5–7 times higher than the 3% multiple-infant birth rate in the general population; 22.1% of live births after fresh nondonor embryo transfers were twins and 0.6% were triplets or more.<sup>5</sup> The higher maternal and neonatal risks associated with multiple pregnancies, their greater financial and social costs, and the many different factors that contribute to the high incidence of multiple births are reviewed in detail in [Chapter 27](#). Consequently, discussion here is limited to issues specifically relating to multiple gestations that result from ART.

**Success rates increase with the number of embryos transferred, to a point, beyond which only the multiple pregnancy rate further increases.**<sup>860,861</sup> The number of embryos corresponding to that threshold generally defines the maximum number of embryos that should be transferred. As reflected in the 2017 revised SART/ASRM embryo transfer guidelines outlined above, that number increases as age increases. Based on data from the 2015 national summary of ART results,<sup>5</sup> when one embryo is transferred, 97.9% of resulting births are singletons. When two embryos are transferred, 65.7% are singletons, 33.6% are twins, and 0.6% are high-order multiple births (triplets or more). When three embryos are transferred, 75% of births are singletons, 22% are twins, and 3% are triplets or more; the distribution of singleton, twin, and high-order multiple births does not change further with transfer of four or more embryos. Importantly, the percentage of transfers resulting in the live birth of a term singleton baby at normal weight decreases linearly with the number of embryos transferred; it is 30.3% after the transfer of a single embryo, 22.4% after two, 15.3% after three, and 10.7% after four embryos based on the 2015 records.<sup>5</sup>

Female age and the number of embryos generated and available for transfer are almost, if not just as important for predicting success as the number of embryos transferred.<sup>885,886,913</sup> Younger women tend to have both higher success rates and higher multiple-infant birth rates. Data from the 2015 U.S. national ART summary illustrate the point ([Table 28.3](#)).

Some have argued that extended culture to the blastocyst stage facilitates selection

of the highest quality embryos having the greatest implantation and developmental potential and thereby reduces both the number of embryos needed to maximize success rates and the risk for multiple birth. In 2015, 58.9% of all transfers occurred on day 5 or 6 after fertilization (blastocysts). For all age groups, the live birth per transfer rate for blastocysts was higher than for cleavage-stage embryos; the absolute differences ranged from 2.7% to 15.4% and were greatest for women under age 35 (50.3% vs. 34.9%) and smallest for those over age 44 (3.2% vs. 0.5%).<sup>5</sup> However, despite a higher percentage of single-embryo transfers (38.6% vs. 20.1%), and a lower percentage of  $\geq 3$  embryo transfers (6.9% vs. 28.7%) on day 5 versus day 3, the proportion of double (2) embryo transfers was quite similar (54.6% vs. 51.2%) between day 5 and day 3. Consequently, 23.7% of live births resulting from day 5 transfers were multiples (23.1% twins, 0.6% triplets and more), compared to 20.8% of day 3 transfers (20.0% twins, 0.8% triplets and more).<sup>5</sup> When two blastocysts are transferred, the incidence of high-order multiple gestation is markedly reduced but not altogether eliminated, because the incidence of monozygotic twinning may be increased after blastocyst transfer,<sup>914</sup> and the incidence of twins is no lower than that associated with transfer of greater numbers of cleavage-stage embryos.<sup>687,689</sup>

As previously discussed, the SART/ASRM guidelines on the number of embryos transferred have been revised several times since first issued in 1998, in efforts to reduce the incidence of multiple pregnancy, high-order multiple pregnancy in particular. The average numbers of embryos transferred in the United States began decreasing in 1997, with the steepest decline observed between 1998 and 1999 after the first guidelines were issued. Whereas the number of pregnancies and live births per cycle has increased steadily, the percentage of high-order multiple pregnancies has decreased, with the steepest decline (20.8%) again occurring between 1998 and 1999.<sup>915</sup> Unfortunately, the percentage of twin pregnancies has remained at a relatively high level.

# Offspring of IVF

Studies of the offspring resulting from IVF have raised concerns that the children may be at increased risk for prematurity, low birth weight, birth defects, genetic and epigenetic abnormalities, vascular and metabolic abnormalities, delayed neurologic development, and cancer.

## Preterm Birth and Low Birth Weight

As previously discussed, ART is associated with increased incidence of multiple pregnancy, which, in turn, is associated with increased incidence of preterm birth and low birth weight. Therefore, to better assess the impact of ART itself on these parameters, one should compare the outcomes of singleton pregnancies. In a 2012 systematic review including 28,000 ART compared with non-ART singletons, the relative risks for preterm delivery less than 37 weeks and less than 32 weeks were 1.54 (95% CI = 1.47–1.62) and 1.68 (95% CI = 1.48–1.91), respectively. The findings for low birth weight (LBW, <2,500 g) and very low birth weight (VLBW, <1,500 g) were also increased with odds ratios of 1.65 (95% CI = 1.56–1.75) and 1.93 (95% CI = 1.72–2.17), respectively. The risk for small for gestational age (SGA) was also increased by 40% in ART babies (OR = 1.39, 95% CI = 1.27–1.52).<sup>916</sup> The risks of preterm delivery and low birth weight are declining over time.<sup>916,917,918,919,920,921</sup> An analysis of data from more than 92,000 ART infants born in Denmark, Finland, Norway, and Sweden confirmed both the increased risk and the improvement in the perinatal outcomes of singleton ART children.<sup>922</sup> The adjusted odds ratios in singletons for preterm birth (PB) less than 37 weeks, PB less than 32 weeks, LBW less than 2,500 g, VLBW less than 1,500 g, and finally SGA were found to be 2.47, 3.80, 2.94, 4.77, and 1.83, respectively, in the analysis for 1988–1992, whereas the odds ratios for the 2003–2007 period were considerably lower at 1.50, 2.06, 1.49, 2.11, and 1.13, respectively. The preterm birth and LBW risks were similar in ART and spontaneously conceived twins, and the risks did not change significantly over time.<sup>922</sup>

ART singleton pregnancies were also associated with a higher risk of antepartum hemorrhage (OR = 2.49, 95% CI = 2.30–2.69), hypertensive disorders of pregnancy (OR = 1.49, 95% CI = 1.39–1.59), gestational diabetes (OR = 1.48, 95% CI = 1.33–1.66), preterm rupture of membranes (OR = 1.16, 95% CI = 1.07–1.26), caesarean section (OR = 1.56, 95% CI = 1.51–1.60), and induction of labor (OR = 1.18, 95% CI = 1.10–1.28) compared to spontaneously conceived singletons.<sup>909</sup> Increased rate of pregnancy complications such as antepartum hemorrhage, placenta previa, and hypertensive disorders of pregnancy, along with more precautionous antenatal care of ART pregnancies, may be at least partly responsible for the higher rate of preterm birth.

The risk of stillbirth between 22nd and 28th gestational weeks is increased by twofolds (95% CI = 1.55–2.78) for ART singletons compared to those spontaneously conceived.<sup>923</sup> However, the risk of stillbirth seems similar after the 28th gestational week. The ART twins have a lower risk of stillbirth compared to spontaneously conceived twins; however, when only dizygotic twins are considered, the risk seems similar in the two groups. The risk of early neonatal and infant deaths for ART singletons and twins seems similar with spontaneously conceived singletons and twins.<sup>923</sup>

Parental characteristics in couples with infertility may contribute to the poorer perinatal outcome. In a 2013 meta-analysis of 14 studies comparing the perinatal outcomes of pregnancies conceived without treatment after a long time to pregnancy interval with pregnancies conceived within 12 months of attempting pregnancy, they found that the risks of preterm delivery (adjusted OR = 1.31, 95% CI = 1.21–1.42), LBW (adjusted OR = 1.34, 95% CI = 1.21–1.48), and SGA (adjusted OR = 1.17, 95% CI = 1.03–1.33) were increased in women with a long time to pregnancy interval.<sup>924</sup> A study comparing the perinatal outcomes of women treated with ART, women with subfertility but spontaneous pregnancies, and fertile women in a total of 334,628 births and fetal deaths in Massachusetts revealed that the risks for both preterm birth and low birth weight were significantly higher for the ART group (adjusted ORs and CIs: OR = 1.23, 95% CI = 1.08–1.41, and OR = 1.26, 95% CI = 1.08–1.47, respectively) compared with the subfertile group and risks in both the ART and the subfertile groups were higher than those among the fertile group (adjusted ORs and CIs: OR = 1.53, 95% CI = 1.40–1.67 and OR = 1.51, 95% CI = 1.37–1.67 for the ART group, and OR = 1.24, 95% CI = 1.12–1.38 and OR = 1.20, 95% CI = 1.06–1.36 for the subfertile group, respectively).<sup>925</sup> There were no significant differences between the three groups for SGA in this study. These results indicate that subfertility itself may be partly responsible for the poorer perinatal outcome.

Some of the increased risk may be attributable to the endometrial environment. The stimulation associated with ART may impair implantation. The risk of preterm birth was found to be similar between singletons from FET and spontaneous conceptions, whereas the risk was lower compared to ART singletons from fresh embryo transfers (adjusted OR = 0.85, 95% CI = 0.76–0.94; frozen vs. fresh embryo transfer).<sup>926</sup> Furthermore, the risk of preterm birth in singletons with a ‘vanishing co-twin’ was significantly increased compared to a single gestation (adjusted OR = 1.73, 95% CI 1.54–1.94).<sup>919</sup> Concerning number of embryos transferred, meta-analysis of three studies revealed that the risk of preterm birth was similar for singletons from single embryo transfer and those from double embryo transfer (adjusted OR = 0.83, 95% CI 0.64–1.06,  $p = 0.21$ ),<sup>926</sup> while another study utilizing publicly available data from 5 states found that singletons born

following single embryo transfer had equivalent obstetric outcomes to non-ART singletons; however, the singletons following double embryo transfer were more likely to be preterm <37 weeks and <32 weeks, and have LBW or VLBW.<sup>929</sup>

In a population-based retrospective registry study comparing neonatal and maternal outcome after 4,819 blastocyst transfers with 25,747 cleavage-stage transfers and 1,196,394 spontaneous conceptions, perinatal mortality and the risk of placental complications were significantly higher in the blastocyst transfer compared to the cleavage-stage transfer group (adjusted OR = 1.61, 95% CI = 1.14–2.29, for perinatal mortality, and adjusted OR = 2.08, 95% CI = 1.70–2.55 and adjusted OR = 1.62, 95% CI = 1.15–2.29 for placenta previa and placental abruption, respectively).<sup>927</sup> The risks for placenta previa and placental abruption were also significantly increased in the blastocyst transfer group compared to spontaneous conceptions (adjusted OR = 6.38, 95% CI = 5.31–7.66 and adjusted OR = 2.31, 95% CI = 1.70–3.13, respectively).

## Large-for-Gestational Age Babies

Singletons conceived after FET have an increased risk of being LGA, and having macrosomia, defined as a birth weight greater than 4,500 g.<sup>928,929,930</sup> A Nordic study compared the perinatal outcomes of 6,647 singletons conceived after FET with 42,242 singletons conceived after fresh embryo transfer and 288,542 spontaneously conceived singletons found significantly increased risks of both LGA and macrosomia in the FET group. The adjusted ORs for LGA and macrosomia were 1.45 (95% CI = 1.27–1.64) and 1.58 (95% CI = 1.39–1.80), respectively, compared to the fresh embryo transfer group and 1.29 (95% CI = 1.15–1.45) and 1.29 (95% CI = 1.15–1.45), respectively, compared to spontaneously conceived children.<sup>930</sup> Similarly, a meta-analysis of three national registry-based cohort studies revealed significantly higher risk of LGA and macrosomia in both FET versus fresh singletons and FET versus natural conceptions.<sup>929</sup> In another analysis that aimed to distinguish the intrinsic maternal factors from those related to the freezing and thawing processes, the prevalence of LGA was compared in consecutive sibling pairs, where one sibling was born after FET and the other after fresh embryo transfer. The first sibling group consisted of 550 singletons with the first sibling born after fresh embryo transfer and the second one after FET, whereas the second sibling group consisted of 116 singletons with the first sibling born after FET and the second sibling after fresh embryo transfer. In the cohort with the first child born after fresh embryo transfer, the risk of LGA in the FET sibling was significantly higher with an adjusted OR of 3.45 (95% CI = 1.33–8.33). In the latter cohort with the first sibling born after FET, the risk of LGA was also increased albeit lower than the first cohort. The risk remained increased after adjustment for parity and birth order in the complete sibling cohort, indicating the contribution of the freezing and thawing

procedures per se.<sup>929</sup> With increasing reliance on cryopreserved embryo transfers and improving laboratory conditions, large prospective studies are awaited to determine the impact of embryo cryopreservation on birth weight.

## Congenital Anomalies

The risk of birth defects in ART babies has been the subject of many studies albeit with several shortcomings. These limitations include different definitions of major malformations, time and extent of evaluation for birth defects and the duration of follow-up, inclusion of pregnancies terminated for fetal malformations and stillbirths, use of inappropriate control groups (e.g., spontaneous conceptions in normal vs. subfertile couples), and diversity of ART techniques (IVF vs. ICSI, fresh vs. FET, cleavage vs. blastocyst transfer, hatching, etc.) used.<sup>931,932</sup>

Several meta-analyses revealed a 30–40% increase in relative risk of birth defects in singleton and multiple ART pregnancies combined, compared to spontaneous conceptions.<sup>916,920,931,933,934,935,936</sup> A 2012 systematic review including 46 studies with 124,468 children conceived by ART compared to spontaneously conceived children showed a significantly increased risk of birth defects (RR = 1.37, 95% CI = 1.26–1.48) in the former. When IVF and ICSI pregnancies were compared separately to spontaneous conceptions, the RR of birth defects was higher for ICSI children than IVF children (1.58 vs. 1.30, respectively); however, the difference between the two groups was not statistically significant ( $p = 0.11$ ). Furthermore, analysis of 24 studies that compared 46,890 IVF babies with 27,754 ICSI babies revealed no significant difference in risk of birth defects (RR = 1.05, 95% CI = 0.91–1.20).<sup>936</sup> A 2013 meta-analysis confirmed the former and the risk ratio for birth defects was found to be 1.32 (95% CI = 1.24–1.42) in 92,671 ART children. The risk was further increased (RR = 1.42, 95% CI = 1.29–1.56) when studies evaluating only major malformations were analyzed. Additionally, the RR for singleton ART pregnancies was 1.36 (95% CI = 1.30–1.43) whereas analysis of studies in ART twin pregnancies adjusted for distribution of zygosity revealed a pooled risk of 1.26 (95% CI = 0.99–1.60) compared to non-ART twins.<sup>934</sup> Similar to the results of the 2012 study, there was no significant difference in the pooled risk estimates in ICSI versus non-ART children (RR = 1.37) compared to IVF versus non-ART children (RR = 1.36).<sup>934</sup>

In a recent and large registry-based study comparing the prevalence of birth defects among 64,861 live born infants conceived using ART with 4,553,215 non-ART infants including singleton and multiple pregnancies, the adjusted RR for nonchromosomal birth defects was 1.28 (95% CI = 1.15–1.42).<sup>937</sup> Furthermore, tracheoesophageal fistula/esophageal atresia (aRR = 1.93, 95% CI = 1.40–2.67), rectal and large intestinal atresia/stenosis (aRR = 2.03, 95% CI = 1.51–2.74), and reduction deformity of the

lower limbs (aRR = 2.18, 95% CI = 1.39–3.43) were significantly increased with ART use. Similarly, regarding singleton live born infants only, the adjusted RR for nonchromosomal birth defects was found to be 1.39 (95% CI = 1.21–1.59), and the risks for tracheoesophageal fistula/esophageal atresia (aRR = 1.90, 95% CI = 1.23–2.94) and rectal and large intestinal atresia/stenosis (aRR = 1.88, 95% CI = 1.26–2.82) were significantly higher for ART versus non-ART infants. **Both earlier and more recent meta-analyses suggest a 30–40% relative increased risk of birth defects in ART children, from a baseline of 2–3% to 2.7–4%.**<sup>934,938,939</sup>

However, similar to the data on obstetric risk, it is unclear if it is the actual exposure to ovarian hyperstimulation/embryo culture or the underlying infertility that is the primary driver of this effect. A large registry-based observational Australian study of approximately 310,000 deliveries compared the risk of birth defects in spontaneous conceptions, ART infants, spontaneous pregnancies in women who had a previous birth with ART, and spontaneous pregnancies in women with infertility. Mothers in the assisted conception group were older and were more likely to be nulliparous, white, and of higher socioeconomic status. After multivariate adjustment, the increased risk for birth defects in the IVF/ICSI combined group (adjusted OR = 1.24, 95% CI = 1.09–1.41) and the ICSI group (adjusted OR = 1.57, 95% CI = 1.30–1.90) remained significant, whereas the increased risk for the IVF group (adjusted OR = 1.07, 95% CI = 0.90–1.26) was no longer significant. Regarding risks of other types of assisted conception compared to spontaneous conceptions, gamete intrafallopian transfer, intrauterine insemination, and the use of clomiphene citrate at home were associated with significantly increased risk of birth defects, whereas clinically supervised ovulation induction, low-dose hormonal stimulation, timed intercourse, and donor insemination were not. Furthermore, adjusted risk of birth defects showed a 25% relative increase in spontaneously conceived children of women who have had a previous ART pregnancy (adjusted OR = 1.25, 95% CI = 1.01–1.56). Borderline increased risk of birth defects was also observed in spontaneously conceived children of women with a history of infertility (OR = 1.29, 95% CI = 0.99–1.68).<sup>940</sup> Another study comparing the prevalence of birth defects in the Danish national birth registry between fertile couples (time to pregnancy  $\leq$ 12 months) and those who conceived spontaneously after 12 months addressed the effect of subfertility per se.<sup>941</sup> The risk for malformations was increased in the latter group (OR = 1.20, 95% CI = 1.07–1.35), and the overall prevalence of congenital malformations increased with increasing time to pregnancy. A meta-analysis calculated that subfertility was responsible for about 40% of the increased risk of birth defects associated with ART and reported an adjusted overall odds ratio of 1.01 (95% CI = 0.82–1.23), indicating no significant increased risk associated with ART.<sup>942</sup>

## Chromosomal, Genetic, and Epigenetic Abnormalities

Limited evidence suggests that the prevalence of chromosomal abnormalities in children conceived with ART is not different from that in children conceived naturally. Nonetheless, concerns persist that the use of sperm from infertile men, and ICSI itself, might increase the risk for conceiving a child with a chromosomal or genetic defect, because infertile men (and women) are more likely than fertile men (and women) to have a genetic abnormality that may contribute to their infertility and that their children may inherit.

Genomic imprinting describes the process that limits expression of the imprinted gene from one parental allele (maternal or paternal). For a number of genes involved in early embryonic growth and placental and neurologic development, transcription is normally restricted to one allele. Usually, the maternal allele is active in imprinted genes involved in fetal development, and the paternal allele is active in genes involved in placental growth. Imprinting disorders can arise via several mechanisms, including mutations in an imprinted gene, uniparental disomy (both copies of a gene coming from one parent), and changes in DNA methylation. There is reason for concern that elements of ART might predispose to imprinting disorders; imprints are established during meiosis and at the time of each meiotic division in the oocyte (the first occurring at ovulation and the second at fertilization), and they are exposed to treatments and manipulations during ART. Any excess risk for imprinting disorders that might relate to ART is difficult to detect because the disorders are quite rare (1 in 12,000 births). Nonetheless, three of the nine known disorders have been linked to ART, including Beckwith-Wiedemann syndrome,<sup>705,706,707,943,944,945</sup> Angelman syndrome,<sup>704,946,947</sup> and maternal hypomethylation syndrome.<sup>712</sup> Although earlier studies suggested an increased incidence of Beckwith-Wiedemann syndrome in ART children, later cohort studies did not confirm an increased risk of imprinting disorders.<sup>709,948,949</sup> In addition, the relative risks of these syndromes were the same in subfertile women with or without ART, and thus, the increased prevalence of imprinting disorders, if any, has been attributed to subfertility rather than ART procedures themselves.<sup>950</sup> It is very challenging to estimate the impact of ART on these rare imprinting disorders, and large prospective cohort studies are needed.

## Vascular and Metabolic Abnormalities

There are a number of cohort studies suggesting that cardiovascular and general metabolic health may be mildly compromised in children conceived via ART. A comparison of 233 ART singletons with 233 spontaneously conceived children from subfertile parents, after matching for age and gender, showed that ART children had significantly more peripheral adipose tissue.<sup>951</sup> Height, weight, body mass index (BMI),

bone mineral content, bone mineral density, central fat measures, and pubertal stage were similar in both groups. Another study on the same cohort showed that ART children had significantly higher systolic and diastolic blood pressures than controls (systolic  $109 \pm 11$  vs.  $105 \pm 10$  mm Hg,  $p < 0.001$ ; diastolic  $61 \pm 7$  vs.  $59 \pm 7$  mm Hg,  $p < 0.001$ , respectively).<sup>952</sup> While fasting insulin concentrations and BMI were comparable, fasting glucose levels were significantly higher in the IVF group ( $5.0 \pm 0.4$  vs.  $4.8 \pm 0.4$  mmol/L  $p = 0.005$ ).

Another study compared 106 ART with 68 spontaneously conceived children and found that the former had significantly higher blood pressures.<sup>953</sup> BMI, fasting glucose-to-insulin ratio, high-density lipoprotein (HDL), low-density lipoprotein (LDL), uric acid, apolipoprotein-A1, apolipoprotein-B, lipoprotein(a), leptin, adiponectin, high-sensitivity C-reactive protein (hsCRP), and high-sensitivity interleukin-6 (hs IL-6) were similar in both groups; only triglyceride levels were significantly increased in the IVF group compared to controls ( $59.5 \pm 25.1$  vs.  $52.4 \pm 23.3$  mg/dL, respectively  $p = 0.031$ ). When SGA and LGA born children were analyzed separately, IVF children still had significantly higher blood pressures; however, the difference in triglyceride levels was no longer significant. A previous study of 69 ART and 71 spontaneously conceived children reported an improved lipid profile including higher HDL levels ( $1.67 \pm 0.04$  mmol/L vs.  $1.53 \pm 0.04$  mmol/L,  $p = 0.02$ ) and lower triglyceride levels ( $0.65 \pm 0.04$  mmol/L vs.  $0.78 \pm 0.04$  mmol/L,  $p = 0.02$ ) in IVF children.<sup>954</sup>

Systemic and pulmonary vascular functions of 65 ART and 57 spontaneously conceived children were compared, and BMI, systolic and diastolic blood pressures, glucose and insulin levels, HOMA, LDL, HDL, and triglyceride levels were similar.<sup>955</sup> However, there were concerns raised over endothelial cell function and risk for atherosclerosis; flow-mediated dilation of the brachial artery was approximately 25% less ( $p < 0.0001$ ), pulse wave velocity was significantly faster ( $p < 0.001$ ), and carotid intima-media thickness was significantly greater in ART children ( $p < 0.0001$ ). Similarly, when the subjects were taken to a higher altitude and pulmonary artery pressure was measured by Doppler echocardiography, ART children had 30% higher systolic pulmonary artery pressure ( $p < 0.0001$ ).

While metabolic effects of ART are not well established, some studies indicate that ART may have an unfavorable effect on the vascular system. However, the differences observed are inconsistent between studies, quite small for each parameter, and of unknown biologic significance. The long-term consequences, if there are any, of these initial findings are to be determined in subsequent studies.

## **Behavioral and Cognitive Aspects**

Multiple studies have examined whether children conceived via IVF were at greater

risk of psychomotor delay, altered socialization, or emotional problems. A 2009 study compared behavioral and socioemotional functions of 139 children born after IVF with 143 children conceived spontaneously by subfertile couples.<sup>956,957</sup> The results were corrected for parity, birth weight, prematurity, gestational age, and mother's educational level. ART children had significantly fewer externalization problems, thought and attention problems, and aggressive behavior. A 2011 study using the same cohort showed that ART children scored comparably in total problem scale, internalizing, anxious/depressed behavior, somatic complaints, social problems, thought problems, attention problems, aggressive behavior, and rule-breaking behavior with spontaneously conceived children.<sup>957</sup> Moreover, there were no differences in externalization and withdrawn/depressed behavior between the two groups. These findings suggest that ART does not seem to cause any behavioral effects in adolescents. A 2001 study compared socioemotional functions of 38 spontaneously conceived children, 49 adopted children, and 34 ART children with a mean age of 11, using interviews and a number of standardized questionnaires that were filled by children, their parents, and teachers.<sup>958</sup> Likewise, ART children were found to have similar social and emotional functions when compared with the other groups. **Overall, ART children seem to have normal social and emotional functions, at least in early life.**

A study comparing information processing, attention, and visual-motor function in children conceived spontaneously and by ART reported similar general cognitive ability, information processing, and attention (speed, accuracy and sustainability of attention, capacity of mental shifting, memory) in both groups.<sup>959</sup> While ART group scored significantly lower in motor speed and motor coordination, the results were still within the normal range. Similar intelligence quotient (IQ), visual-motor coordination, visual memory, and verbal comprehension abilities are reported in 51 IVF children and 51 control children.<sup>960</sup> Cognitive development of 86 ICSI, 83 IVF, and 85 natural conceptions reported a crude difference in IQ was 3.9 (95% CI = -0.7 and 8.4) between ICSI and IVF children and 6.8 (95% CI = 2.0 and 11.6) between ICSI and natural conception children. The above notwithstanding, mean IQ was within the normal range in all groups.<sup>961</sup>

**Assessing neurocognitive outcomes for ART has methodologic challenges such as lack of blinding, being underpowered, using nonstandardized assessment tools, low participation rates, and selection bias.<sup>962</sup> Still, available evidence suggests cognitive and motor functions are not affected by method of conception.**

## Cancer

Another concern about ART is its possible association with childhood cancers. Many

studies have been conducted to determine whether offspring born following ART treatment have an increased risk of developing various cancers.

A 2013 meta-analysis of 25 studies showed an increased risk (RR 1.42, 95% CI = 0.96–1.8).<sup>963</sup> Only 2 of the 25 studies in the meta-analysis included untreated subfertile controls; neither of these studies identified a link between ART and cancer risk. In the same year, a large British study included 106,103 ART children born from 83,967 pregnancies between 1992 and 2008 and identified 108 children diagnosed with cancer. Expected number of cancer cases was 109.7 for the same cohort, resulting in a standardized incidence ratio of 0.98 (95% CI = 0.81 and 1.19) for the study group.<sup>964</sup> A more recent large population study in 2014 included ART babies born between 1982 and 2007 in Sweden, Denmark, Finland, and Norway.<sup>965</sup> A total of 91,796 ART children were compared with 358,419 spontaneously conceived children. After adjusting for country, maternal age, parity, gender, gestational age, birth defects, and chromosomal defects, hazard ratio for cancer in ART children was not significant: 1.08 (95% CI = 0.91–1.27). While 2 in 1,000 children were diagnosed with cancer in the ART group, this rate was 1.8 in 1,000 spontaneously conceived children. Risks for two cancer types were significantly increased in ART children, central nervous system tumors (adjusted HR = 1.44, 95% CI = 1.01–2.05), and malignant epithelial neoplasms (adjusted HR = 2.03, 95% CI = 1.06–3.89). However, the authors underline that this contributes very little to the absolute risk for these cancers, and overall patients can be reassured about safety of ART procedures. **In conclusion, although some studies inconsistently show increased risk for certain cancer types, ART children do not seem to be at significant risk for childhood cancers.**

## Key Points

- Concerns about the health and welfare of children born after ART are reasonable and understandable.
- The available data indicate that ART is associated with an increased risk of multiple gestation, congenital anomalies, preterm delivery, low birth weight, and the complications associated with these outcomes.
- The concerns are justified but are not cause for undue alarm. Children born from ART are generally healthy.

# OOCYTE DONATION

---

Until approximately 25 years ago, women with ovarian failure were understandably considered irreversibly sterile, but advances in ART have changed that view. Oocyte donation now offers women with premature ovarian insufficiency, premature reproductive aging, and surgical removal of the ovaries and even women beyond their normal reproductive years a very realistic chance for pregnancy.

A successful pregnancy established in one woman (the recipient) using oocytes from another (the donor) was first reported in 1983. The original technique involved intracervical artificial insemination of a normal volunteer with sperm from the male partner of an infertile woman, uterine lavage during the preimplantation interval, and transfer of the recovered embryo to the uterus of the infertile female partner who received a programmed regimen of hormone replacement designed to synchronize endometrial and embryo development.<sup>966</sup> Numerous ethical and technical problems prevented wide application. That same year saw the first report of a pregnancy established by ovum donation, IVF, and transfer to a cycling recipient.<sup>967</sup> Within another year, the first successful pregnancy resulting from oocyte donation and IVF in a woman with ovarian failure was reported.<sup>968</sup> The U.S. national ART registry recorded 21,182 oocyte donation cycles in 2015.<sup>5</sup>

Oocyte donation is now commonly achieved by IVF using oocytes retrieved from healthy young donors after controlled ovarian hyperstimulation and the sperm of the recipient's partner, with the resulting embryos then transferred to the uterus of the recipient.<sup>969</sup> Success with donor oocytes also has been achieved using tubal transfer techniques. Although straightforward in concept, the requirements for successful ovum donation IVF are many and complicated. The unique and key features of a donor oocyte IVF cycle relate to the need for embryo/endometrial synchronization and exogenous hormonal support of early pregnancy until the luteal-placental shift. Other important issues relate to donor recruitment, selection, and screening.

# Indications

There are a number of accepted indications for ovum donation IVF—ovarian failure, genetically transmitted disease, declining or absent ovarian function, advanced reproductive age, and persistent poor oocyte quality in IVF cycles.<sup>970</sup> Women with ovarian failure from any cause (X chromosome abnormalities; idiopathic gonadal dysgenesis or premature oocyte depletion; previous surgery, irradiation, or chemotherapy; autoimmune disease) are candidates. Also included are women who carry specific heritable disorders not amenable to PGD or who reject PGD and women with a DOR due to age or other causes who have a poor prognosis for successful IVF using their own oocytes. Oocyte donation is also an option for male same-sex couples who choose parenthood through assisted reproduction.

# Donor Oocyte Recipients

With a few exceptions, the pretreatment evaluation and screening of couples seeking oocyte donation are virtually identical to that recommended before conventional IVF. Psychological counseling is an important element of the evaluation and helps to identify couples with unresolved concerns or fears and to ensure that both partners are fully committed to the effort.

Women with Turner syndrome may be considered candidates for ovum donation and deserve specific mention. **Evidence indicates that pregnancy may pose unique and serious risks for women with Turner syndrome, who often have cardiovascular malformations involving the aortic root.** Like women with Marfan syndrome, women with Turner syndrome are at increased risk for aortic dissection during pregnancy, presumably relating to the increased cardiovascular demands. **The maternal risk of death from rupture or dissection of the aorta in pregnancy may be 2% or higher.**<sup>971</sup> Women with Turner syndrome expressing interest in oocyte donation should be carefully evaluated, to include echocardiography or magnetic resonance imaging, with any significant abnormality best regarded as a contraindication to oocyte donation. In general, even women with normal evaluations should be discouraged, because aortic dissection still may occur. Those who choose to proceed require careful observation and frequent reevaluation during pregnancy.<sup>972</sup>

## Controlled Endometrial Development

In spontaneous cycles, endometrial proliferation and secretory maturation are driven by sex steroid production associated with follicular growth, ovulation, and luteal function; development of the endometrium and the embryo is naturally synchronized. In ovum donation cycles, that same careful synchronization must be orchestrated. The “window of endometrial receptivity,” the interval during which implantation normally occurs, is relatively narrow and spans approximately 3 days, perhaps as much as 5 days.<sup>973,974</sup> The opening and duration of the implantation window are controlled primarily by the duration of progesterone exposure. The length of the preceding proliferative phase is extremely flexible and can vary widely,<sup>973</sup> as occurs naturally in oligo-ovulatory women.

To synchronize endometrial development with the embryos to be transferred, recipients with functioning ovaries are first down-regulated with a long-acting GnRH agonist, treatment that women with ovarian failure obviously do not require. In either case, a programmed regimen of sequential estrogen and progesterone replacement is used to simulate the natural cycle and to promote normal endometrial growth and maturation, the same way as in FET cycles (discussed above). A wide variety of

treatment regimens have been used successfully to achieve controlled endometrial development and maturation.

Estrogen can be administered orally (micronized estradiol 4–6 mg daily) or transdermally (estradiol 0.2–0.4 mg daily). Both routes of administration are effective and neither has proven superior, despite the widely varying serum estradiol levels that can result.<sup>124,975,976,977,978</sup> Oral and transdermal estrogen treatment regimens are designed to achieve serum levels that approximate those observed in the late follicular phase in natural cycles (200–400 pg/mL); equivalent doses of vaginal estrogen achieve markedly higher serum and tissue concentrations.<sup>979</sup> The duration of estrogen therapy is quite flexible and can range from as short as 7 days to as long as 3 weeks or more.<sup>976</sup> Progesterone can be administered intramuscularly, in doses designed to achieve serum concentrations approximating 20 ng/mL (50–100 mg daily),<sup>980,981</sup> and/or vaginally, in the form of suppositories, tablets, or gel (180–600 mg daily). Intramuscular administration yields substantially higher serum concentrations, but endometrial tissue levels are highest after vaginal treatment.<sup>975</sup>

The methods and extent of monitoring vary widely among programs. Many use transvaginal ultrasonographic measurements of endometrial thickness, aiming to achieve a thickness greater than a minimum of 6–7 mm.<sup>362,386,982,983</sup>

To maximize the probability for successful implantation, embryo transfer must be carefully timed. To achieve the same coordination of embryo and endometrial development that occurs in natural conception cycles, progesterone treatment in the recipient should begin on the day the donor undergoes retrieval.<sup>881</sup> Day 2 embryos (2 days after retrieval and fertilization) are transferred on the 3rd day of progesterone therapy, day 3 embryos on the 4th day, and day 5 embryos on the 6th day.<sup>124</sup> Although the effective “transfer window” is wider than a single day, synchronous transfer provides a margin of safety and compensates for any minor variations in the speed of endometrial maturation. Flexibility in the duration of preliminary estrogen treatment in the recipient facilitates convenient scheduling. In general, estrogen therapy begins at 2 days before the time that stimulation begins in the donor, allowing ample time to achieve the desired degree of endometrial proliferation before the donor’s retrieval (**Figure 28.7**).

**FIGURE 28.7**

## Luteal Phase and Early Pregnancy Support

In naturally conceived early pregnancies, the rapidly rising levels of hCG first “rescue” and then stimulate the corpus luteum to maintain the high levels of estrogen and progesterone secretion necessary to ensure endometrial stability in support of early embryonic growth and development until the emerging placenta achieves the capacity to assume that responsibility. The donor oocyte recipient has no corpus luteum. Consequently, exogenous luteal support must be provided for the requisite interval. Normally, the luteal-placental transition is completed between 7 and 9 weeks of gestation (menstrual dates) or between 4 and 6 weeks after a blastocyst transfer.<sup>984</sup>

**Exogenous estrogen and progesterone treatment therefore must continue until at least 7 weeks, and many recommend treatment until approximately 10 weeks of gestation, for added safety.** Some prefer to monitor serum estradiol and progesterone concentrations during the early weeks of pregnancy, decreasing the dose of exogenous hormone treatment by half after observing a sharp rise in levels and discontinuing treatment after an additional week if concentrations continue to rise normally.

# Oocyte Donors

The limited availability of suitable oocyte donors is the greatest obstacle in maintaining an active donor oocyte program. Donors may be a known relative or acquaintance of the recipient,<sup>985</sup> but most are anonymous, young healthy volunteers recruited from the local population. In most metropolitan areas in the United States, oocyte donors are compensated for their time, inconvenience, and assumption of risk. Outside of the United States, such compensation is discouraged and, in some countries, is illegal.

The ASRM has provided detailed guidelines for the appropriate screening of candidate oocyte donors.<sup>970</sup> In brief summary, all donors should be between 21 and 34 years of age, have a thorough medical history and physical examination to exclude those at high risk for sexually transmitted infections or genetically transmissible disease, and undergo standard preconception testing. In accordance with U.S. federal law, candidate donors also must be thoroughly screened for sexually transmitted infections, including syphilis, hepatitis B (surface antigen and core antibody), hepatitis C (antibody), and HIV-1/HIV-2, using tests performed in a laboratory approved by the U.S. Food and Drug Administration (FDA) for donor screening. Screening also includes tests for gonorrhea and chlamydia, and all tests must be performed within the 30 days immediately preceding oocyte retrieval. False-positive results exclude anonymous donors and repeated testing is not permitted. Other exclusion criteria can be found in the ASRM Practice Committee Recommendations for gamete and embryo donation.<sup>970</sup> Written documentation of donor eligibility is also required. The donor should undergo appropriate genetic evaluation based on history, in accordance with ethnic background and current guidelines. Cystic fibrosis testing should be performed on all donors. Consideration should be given to fragile X and spinal muscular atrophy testing on donors, but is not required. Similarly, some programs test egg donors using expanded carrier screening for a large number of recessive disorders, although it is not required. Psychological evaluation by a qualified mental health professional is strongly recommended.<sup>970</sup>

Vitrification has greatly improved the efficiency of oocyte cryopreservation, and since 2013, the use of vitrified/warmed oocytes for fertility preservation is no longer considered experimental.<sup>127</sup> Fertilization and pregnancy rates are similar to IVF/ICSI with fresh oocytes when vitrified/warmed oocytes are used for young women. No increase in chromosomal abnormalities, birth defects, and developmental deficits has been reported in offspring born from cryopreserved oocytes when compared to pregnancies from conventional IVF/ICSI and the general population.<sup>127</sup> Egg banking simplified oocyte donation dramatically, by eliminating the need to synchronize donors and recipients, and has the added benefit of serving to decrease the number of unused

frozen embryos resulting from conventional oocyte donation cycles.

# Outcomes of Oocyte Donation

Experience with ovum donation has provided important insights into the mechanisms involved in the age-related decline in female fertility. The oocyte donation model effectively dissociates oocyte and uterine age. Success rates with conventional IVF decline steadily as age increases, most noticeably after age 35, and viable pregnancies are infrequent beyond age 42. **In contrast, the live birth rate in oocyte donation cycles varies little across all age groups.** These data demonstrate that the declining developmental potential of aging oocytes is the limiting factor.

Data from the 2015 U.S. national ART summary indicate that among 7,331 fresh donor oocyte cycles across all age groups, 55.6% of transfers resulted in a live birth, with an average of 1.6 embryos transferred. Among 12,151 transfers of frozen embryos derived from donor oocytes, 35.4% resulted in a live birth, with an average of 1.5 embryos transferred.<sup>5</sup>

Because most recipients are over age 35, their pregnancies may be considered high-risk pregnancies. Multiple pregnancies are common and are associated with well-known and specific risks. In 2015, 28.3% of pregnancies and 27.7% of live births resulting from oocyte donation were multiples.<sup>5</sup>

A 2017 systematic review and meta-analysis showed an increased risk of preterm delivery in oocyte donation pregnancies compared to nondonor oocyte pregnancies (OR = 1.45, 95% CI = 1.20–1.77). Similarly, the risk of low birth weight was higher after transfer of fresh embryos derived from donated oocytes compared to nondonor oocyte pregnancies (OR = 1.34, 95% CI = 1.12–1.60).<sup>986</sup>

Two 2016 systematic reviews showed approximately threefold increased risk of preeclampsia in oocyte donation pregnancies compared with other methods of ART or natural conception. The risk of gestational hypertension was also increased significantly in oocyte donation pregnancies in comparison with other methods of ART or natural conception. The risks for preeclampsia and gestational hypertension were similarly increased in singleton and multiple gestations from donor oocytes.<sup>987,988</sup>

# Gestational Surrogacy

Gestational surrogacy offers women without a functional uterus the opportunity to have genetic offspring. The techniques involved are no different than those applied in other forms of ART, but the ethical, legal, and psychosocial issues involved are complex.

Gestational surrogacy involves transfer of embryos to the uterus of a woman willing to carry a pregnancy on behalf of an infertile couple. **Surrogacy is an option for couples wherein the female partner has no uterus (congenital, hysterectomy), an irreparably damaged uterus (congenital malformation, severe intrauterine adhesions), or a medical condition for which pregnancy may pose a life-threatening risk. Surrogacy is also an option for male same-sex couples who choose parenthood through assisted reproduction.** The host carrier may be a relative, a friend, or someone with no attachment to the couple who may or may not be compensated for her service. Regardless what the circumstances are, candidates for surrogacy should have previously given birth and undergo thorough psychological evaluation. The legal status of gestational surrogacy varies widely among different states, and even where it has recognition, a formal legal contract is required to formalize agreements between the infertile couple and the surrogate.

# GAMETE AND ZYGOTE INTRAFALLOPIAN TRANSFER

---

Gamete intrafallopian transfer and ZIFT are alternatives to IVF in which oocytes and sperm (GIFT) or zygotes (ZIFT) are transferred to the fallopian tubes via laparoscopy instead of into the uterus. Once commonly performed because they offered significantly higher success rates than IVF to women with normal tubal anatomy, both procedures are now extremely rare.

Combined data from the United States and Canada indicate that as of 1995, the delivery rates per retrieval for GIFT (27.0%) and ZIFT cycles (27.9%) were still higher than for IVF (22.5%).<sup>856</sup> Over subsequent years, IVF success rates steadily improved and surpassed those achieved with GIFT and ZIFT. Accordingly, the procedures now have few indications that can justify the greater costs and risks associated with surgical transfers. In 2015, the U.S. national ART registry reported that ZIFT and GIFT accounted for less than 1% of all ART procedures.<sup>5</sup>

In the GIFT procedure, stimulation and oocyte retrieval proceed as in a conventional IVF cycle. Very soon thereafter, laparoscopy is performed, and oocytes and sperm are drawn into a specially designed catheter (separated by air) and deposited into the fallopian tubes at a level approximately 4 cm proximal to the fimbria. The techniques involved in ZIFT are the same as for GIFT, except that conventional IVF is first performed in the laboratory and zygotes are transferred on the following day. Today, GIFT and ZIFT are reserved entirely for women in whom a uterine transfer cannot be accomplished for technical reasons. Whereas fertilization is documented in ZIFT, in GIFT, it is not. With GIFT, fertilization occurs in vivo rather than in vitro. For that reason, GIFT may be the only option for couples with personal, moral, ethical, or religious objections to conventional IVF. Predictably, the risk of ectopic pregnancy is higher for GIFT and ZIFT than for conventional IVF; the risk of multiple pregnancies is comparable.

# Fertility Preservation

Women requiring gonadotoxic treatment can now choose from one or more fertility preservation options. Similar options are available for women who desire to postpone childbearing due to personal reasons. Egg and embryo freezing are no longer considered experimental and are routinely employed worldwide with good outcomes. The evolving field of ovarian tissue cryopreservation is still considered experimental but appears to be promising with more than 100 babies born using this approach.<sup>1,2,3,4,5</sup> In males, fertility preservation is largely limited to sperm cryopreservation in adults as there are currently no established methods to generate mature sperm from cryopreserved testicular tissues obtained from prepubertal boys. We will therefore focus on fertility preservation in females.

# Malignant Diseases

Annual worldwide new cancer cases are projected to increase by more than 50% in the next two decades (14–21 million from 2012 through 2030), while the overall cancer death rates continue to decline, with a 13% drop in the United States from 2004 through 2013 ([www.cancer.gov](http://www.cancer.gov)). Not surprisingly, the number of cancer survivors continues to increase and has reached nearly 14.5 million in 2014 in the United States, where it is expected to rise to 19 million by 2024. About 9% of new cancer cases are diagnosed during the reproductive age, and, as of January 2016, there are 8 million female cancer survivors in the United States, of which 5% are 15–40 years of age.

Approximately 82,000 prepubertal girls are diagnosed with cancer each year worldwide, of which 5,000 are in the United States.<sup>6</sup> This group's overall 5-year survival that was 82% in 2014 is steadily increasing due to early diagnosis and treatment.<sup>6</sup> The most common cancers in children (0–14 years old) in the United States are leukemia (31%), central nervous system malignancies (21%), and lymphoma (10%).<sup>7</sup> Nowadays, lymphoma and leukemia (in young women) as well as breast cancer (in relatively older women but who are still in their reproductive age) can be cured or enter long remission following an aggressive chemotherapy with or without radiotherapy. These cancers in particular and others (such as sarcomas and pelvic cancers) make up the majority of cancer-related indications for fertility preservation interventions, preferably prior to the administration of the gonadotoxic chemo-radiotherapy. Gonadotoxicity is an adverse effect of chemotherapy (especially alkylating agents) and pelvic radiotherapy. These directly affect the oocytes and granulosa cells and therefore may lead to a complete irreversible ovarian failure (i.e., iatrogenic menopause). Although chemo- or radiotoxicity is type and dose dependent, the extent of ovarian damage and whether it is reversible or not can only be estimated rather than accurately calculated. To date, there is a lack of consensus on what specific doses of chemotherapy or radiotherapy lead to premature ovarian insufficiency (POI).<sup>1</sup>

# Nonmalignant Conditions

There are multiple benign conditions that may lead to decreased ovarian reserve and POI (e.g., Turner syndrome, fragile X permutation, family history of POI).<sup>8,9</sup> Alternatively, there are benign conditions that necessitate systemic chemotherapy treatment with its gonadotoxic adverse effects potentially leading to POI<sup>10</sup> (e.g., high-grade systemic lupus erythematosus or bone marrow ablation followed by allogeneic transplantation for benign bone marrow disorders such as aplastic anemia, sickle cell disease, and thalassemia). Additionally, nonmalignant conditions such as severe endometriosis have a profound effect on fertility potential owing to disease's natural progression and spread and the surgical interventions for the removal of endometriomas.<sup>11</sup> The resection of bilateral benign ovarian tumors such as teratomas is another example of a surgical intervention that may decrease ovarian reserve. Recurrent ovarian torsion may also be an independent risk factor for POI.

# Fertility Decline Associated with Advanced Age

Age is the most significant threat to female fertility, as oocyte quality declines with age. Today, more and more women are postponing childbearing due to personal reasons such as graduate education, career choices, lack of a partner, or financial considerations.<sup>12</sup> Consequently, the age at which women attempt their first pregnancy is steadily increasing.<sup>10</sup> In the United States, the average age at first pregnancy has increased from 22.5 in 1970 to 25.0 in 2006 and 26.3 in 2014.<sup>13</sup> Furthermore, in many instances, the first pregnancy attempt takes place after the age of 35 when fertility potential may have decreased significantly. In the United States, in 2014, 21.1% of mothers had their first birth at the age of 30–34 years. More strikingly, the same year, 9.1% had their first birth at the age of 35 or later; this was an almost 10-fold increase from 1970 when only 1 out of 100 women would delay their first birth to age 35 or later.<sup>13</sup>

# CRYOPRESERVATION OF EMBRYOS AND OOCYTES

---

Embryo and mature oocyte cryopreservation are the only established effective fertility preservation approaches currently available.

The first report of human pregnancy following embryo cryopreservation<sup>14</sup> occurred only 5 years after the first in vitro fertilization (IVF) live birth,<sup>15</sup> and embryo cryopreservation has now been successfully employed for over than 30 years. Today, the transfer of vitrified (superior to slow freezing) thawed embryos is as effective as the transfer of fresh ones, without a decline in live birth rates.<sup>12</sup>

The making of embryos requires sperm from a male partner or a donor. This approach is therefore not ideal for women who would like to preserve their fertility but currently do not have a male partner and do not wish to use donor sperm. Oocyte cryopreservation, on the other hand, provides reproductive autonomy to women who wish to preserve their fertility.

Following the first report of a pregnancy achieved with cryopreserved oocytes by Chen in 1986,<sup>16</sup> progress in the field of oocyte cryopreservation has been challenging. Mature (MII) oocytes are among the largest cells in the human body and contain the delicate meiotic spindle. As oocyte cytoplasm contains a high proportion of water in comparison to other cells, damage due to ice crystal formation was an initial hurdle to oocyte viability after frozen storage. Protocols that include dehydration of oocytes before and/or during the cooling procedure reduced ice crystal formation and led to improved clinical outcomes. Cryopreservation of mature oocytes has also been shown to cause hardening of the zona pellucida, resulting in adverse effects upon fertilization.<sup>17</sup> Significant improvement in the fertilization of cryopreserved oocytes was achieved with the use of intracytoplasmic sperm injection (ICSI),<sup>18,19</sup> possibly due to the circumvention of the effects of zona hardening.

Research in the field of oocyte cryopreservation has been in part fueled by legal limitations imposed on embryo cryopreservation in a number of countries. As an example, Italian law had restrictions regarding the cryopreservation of excess embryos but allowed egg freezing.<sup>20</sup> The vitrification technique (already described in the 1990s) of oocytes as an alternative to slow freezing reduced damage to internal structures and led to improved success rates (**Figure 29.1**).<sup>21,22,23,24</sup> Embryo<sup>12</sup> and oocyte<sup>25</sup> cryopreservation (preferably by vitrification) have now become efficient treatment modalities for women with infertility.<sup>26</sup> Additionally, in a similar fashion to embryo cryopreservation, the live birth rate from cryopreserved versus fresh oocytes is now

considered comparable.<sup>27</sup> Indeed, oocyte vitrification yields remarkable cumulative live birth rates of 60.5% among healthy women who are 35 years old or younger.<sup>28</sup> Women with cancer, however, are expected to have a lower live birth rate likely due to lower oocyte quality caused by the disease.<sup>29</sup> It is also important to note that prepubertal ovaries may not respond to medical stimulation and therefore will not yield mature oocytes available for freezing or fertilization. Therefore, in prepubertal girls, the only available fertility preservation option is ovarian tissue freezing, which is described in detail below (Table 29.1).<sup>30,31</sup>

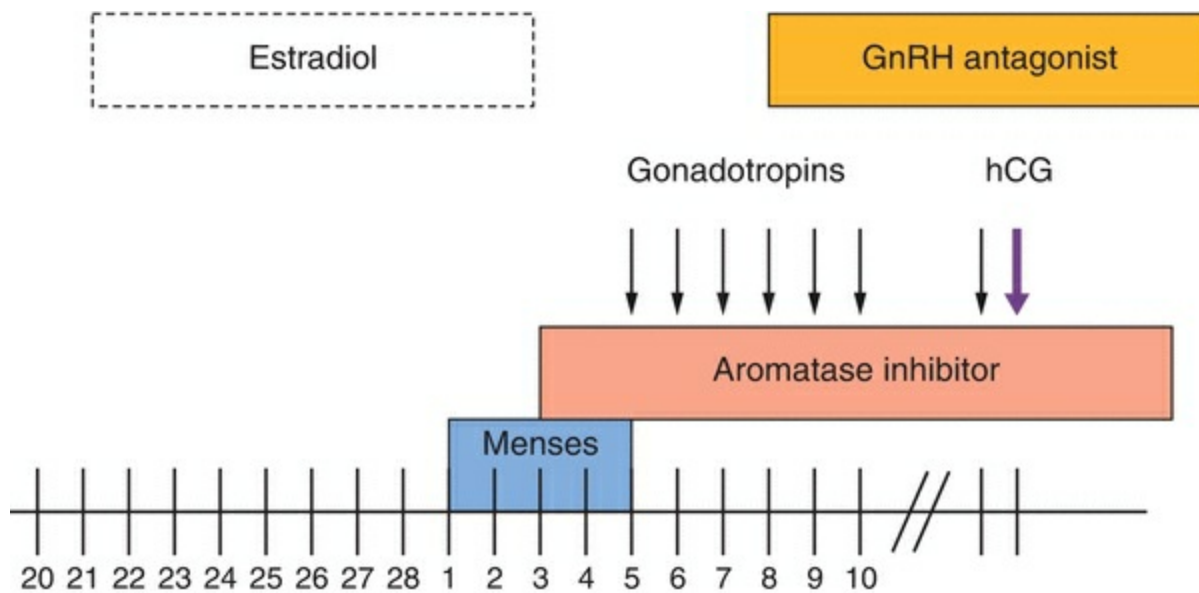

**FIGURE 29.1**

**TABLE 29.1 Advantages and Disadvantages of Embryo, Oocyte, and Ovarian Tissue Cryopreservation**

	Embryo Cryopreservation	Oocyte Cryopreservation	Ovarian Tissue Cryopreservation
Sperm is required	+	-	-
Shared ownership	+	-	-
Delays chemotherapy	+	+	-
Can be used in prepuberty	-	-	+
Effect on endocrine function (at the time of procedure)	-	-	-
Requires ovarian stimulation	+	+	-
Considered experimental	-	-	+
Live births reported	+	+	+
Resumption of endocrine function potential	-	-	+ <sup>a</sup>
Requires surgery	-	-	+
Risk of reseeding cancer	-	-	+

<sup>a</sup>Ovarian tissue harvesting, cryopreservation, and autotransplantation are the only way allowing regaining of endocrine function following gonado-ablative chemo- and/or radiotherapy.

When planning embryo or egg cryopreservation, several factors should be taken into consideration: (1) Age. The younger the woman is at the time of oocyte retrieval and egg/embryo freezing, the higher the live birth rate.<sup>12,28,32</sup> Therefore, women should be encouraged to engage in fertility preservation at a young age, if possible, especially for cases of elective fertility postponement. Another consideration related to age is that prepubertal ovaries are not responsive to gonadotropins due to the absence of ovarian receptors to gonadotropins. Prepubertal cancer patients therefore cannot benefit from fertility preservation techniques that require ovarian stimulation. (2) Delay in cancer treatment. Oocyte and embryo cryopreservation require controlled ovarian hyperstimulation, delaying the administration of chemotherapy by a minimum of 10–12 days. This delay should be acceptable to the oncology team and not jeopardize cancer treatment outcome. Importantly, the delay might be much longer, depending on where the patient is in her menstrual cycle, if a new cycle is awaited for stimulation. However, random-start approaches to ovarian hyperstimulation are equally effective, and such delays are not necessary.<sup>33</sup> (3) Hormone sensitivity of malignancies. Low estradiol levels during ovarian stimulation are considered safer in the setting of malignancies sensitive to estrogens. The ovarian stimulation protocol should therefore be tailored to the steroid hormone sensitivity of the cancer. For example, in the case of estrogen receptor–positive breast cancer, controlled ovarian hyperstimulation with agents that block estrogen production given in conjugation with gonadotropins result in low peak estradiol levels.<sup>34</sup> One option is to start stimulation with an aromatase inhibitor on the second or third day of the menstrual cycle followed by addition of daily follicle-stimulating hormone (FSH) (**Figure 29.2**). The aromatase inhibitor is continued until the day of ovulation trigger and even later if serum estrogen levels are more than 250 pg/mL. using a combination of aromatase inhibitor and FSH for ovarian stimulation seems to yield a comparable number of mature oocytes with only a modest increase in serum estradiol.<sup>35</sup>

**FIGURE 29.2**

# OVARIAN TISSUE CRYOPRESERVATION

---

Ovarian tissue cryopreservation is a unique approach to fertility preservation as it is the only option that is suitable for prepubertal girls. In addition, ovarian tissue extraction does not require prior ovarian stimulation, allowing cancer treatments to begin immediately.

Ovarian tissue cryopreservation and transplantation have been studied in animals for more than 60 years.<sup>36</sup> The first human ovarian transplantation with cryopreserved ovarian tissue was performed in 1999 by Kutluk Oktay.<sup>37</sup> In 2004, the first live human birth from frozen ovarian tissue was reported.<sup>38</sup> Studies in pre- and postpubertal women indicate that autotransplantation of frozen-thawed ovarian tissue is useful for the restoration of endocrine function before and after puberty.<sup>39,40,41</sup> Furthermore, ovarian endocrine activity can be restored in more than 95% of cases.<sup>1</sup>

Although promising, at the time of writing this chapter, this approach was still considered experimental. Given the experimental state of frozen-thawed ovarian tissue transplantation, a significant portion of the literature reporting live births has been provided via case reports.<sup>37,42,43,44</sup> To date, at least 130 live births have been reported globally following the transplantation of cryopreserved ovarian tissue with pregnancies achieved in 1/4 to 1/3 of cases.<sup>45,46,47,48,49</sup>

Live births following cryopreservation of prepubertal ovarian tissue have not yet been described. However, in 2015, Demeestere et al.<sup>44</sup> reported the first live birth following autotransplantation of ovarian tissue extracted before the onset of menarche (during puberty).

# Whole Ovary Cryopreservation

The ovarian cortex harbors the eggs. In most centers worldwide, ovarian cortical tissue is extracted rather than the whole ovary. However, tissue ischemia with loss of follicles remains a common problem after ovarian tissue autotransplantation. Whole ovary autotransplantation may overcome this problem by the reanastomosis of the transplanted vascular pedicle.<sup>5</sup> The disadvantages include possible reseeding of malignancy, technical difficulties with vascular reanastomosis, and greater risk for cryoinjury during the freezing process of a relatively large tissue volume. Additionally, whole ovary freezing may be challenging in humans given the difficulty with adequate diffusion of cryoprotective agents.<sup>5</sup>

Martinez-Madrid et al.<sup>50</sup> succeeded in slow freezing a whole ovary with its vascular pedicle and demonstrated 75% survival of follicles after thawing. In 2008, Silber et al.<sup>51</sup> demonstrated a successful pregnancy in monozygotic twins after fresh whole ovary transplantation. Although healthy offspring have been demonstrated after frozen-thawed whole ovary transplantation in sheep, to date, no human live births have been reported.

# Ovarian Tissue Freezing Techniques and Transplantation Locations

Independent of the freezing technique, cryoinjury may occur during cooling and warming, thereby compromising cell or tissue viability.<sup>52,53</sup> Cryopreservation of ovarian tissue can be performed using one of two established techniques: slow freezing or rapid freezing (vitrification). The slow-freezing method has already resulted in dozens of live births worldwide, whereas vitrified tissue has only led to a few reported live births to date.<sup>2,54,55,56</sup> However, the clinical outcomes of tissue vitrification are not inferior to those of the conventional slow-freezing technique.<sup>57</sup> Therefore, owing to its overall simplicity, the vitrification method might become more popular in clinical practice, as happened for vitrification of oocytes.

The “physiologic” transplantation of frozen-thawed ovarian cortical fragments is orthotopic transplantation, into the remaining ovary, the ovarian fossa, or the broad ligament. Orthotopic transplantation provides the ability to achieve a natural pregnancy without the requirement for IVF. In 2000, Oktay and colleagues<sup>58</sup> reported the first laparoscopic orthotopic transplantation with ovarian tissue placed into the pelvic peritoneum. Subsequently, the first pregnancies resulting in live births after frozen-thawed orthotopic transplantation of ovarian tissue were reported by Donnez et al.<sup>38</sup> and Meirow et al.<sup>59</sup> in 2004 and 2005, respectively. Donnez and colleagues grafted ovarian tissue fragments onto preexisting ovarian tissue.<sup>38</sup> The findings by Donnez and colleagues were promising; however, questions later arose regarding whether the fertilized oocyte had ovulated from the grafted tissue versus the preexisting ovarian tissue.<sup>60</sup> Nonetheless, there are several case reports of live births after transplantation preceded by bilateral oophorectomy, confirming that following orthotopic transplantation, frozen-thawed ovarian cortical ovarian tissue may regain its endocrine function as well as its fertility potential.

Heterotopic transplantation (into the subcutaneous space of the forearm, subcutaneous tissue of the abdomen, anterior wall of the abdomen, just beneath the peritoneum, or in the rectus muscle) is advantageous in cases of severe pelvic adhesions, distorted pelvic anatomy, and poor pelvic vasculature due to previous irradiation. Heterotopic transplantation can be done by a less invasive surgical approach, which does not require general anesthesia thereby creating a more patient-friendly and cost-effective option.<sup>61</sup> However, heterotopic transplantation may produce lower quality oocytes and embryos when compared to the orthotopic approach.<sup>61</sup> These results are likely linked to the less favorable conditions of heterotopic sites in regard to temperature, pressure, reduced paracrine factors, and suboptimal blood supply. To date,

a small number of spontaneous live births after heterotopic transplantation of frozen-thawed ovarian tissue have been reported.<sup>62,63</sup> Importantly, while restoration of ovarian function has been reported for both approaches, live births in women with prior bilateral oophorectomy has only been documented from orthotopic transplantations<sup>64,65</sup> until the report by Stern et al. in 2013, where frozen-thawed ovarian tissue was transplanted to the anterior abdominal wall. Subsequent ovarian stimulation and transabdominal ultrasound-guided oocyte retrieval from the grafts resulted in two oocytes that were fertilized by ICSI. Two embryos were transferred and resulted in a twin pregnancy.<sup>66,67</sup> This report provides evidence that cryopreservation preserves follicular development, and that standard ovarian function and pregnancy can occur from a “heterotopic” transplantation site.

## **In Vitro Follicle Maturation**

An alternative to orthotopic or heterotopic transplantation of frozen-thawed ovarian cortical fragments would be to mature follicles in vitro, especially primordial follicles, which constitute the largest pool of follicles stored in the ovary. This approach would also allow the patient avoid potential reseeding of cancer cells that might have metastasized to the ovarian tissue. However, in vitro maturation (IVM) of immature follicles has proven to be extremely challenging.

More than two decades ago, John Eppig reported a two-step culture protocol that allowed the production of oocytes competent enough to undergo maturation, fertilization, and development to live offspring from primordial follicles of newborn mice.<sup>68</sup> The first step was organ culture of intact newborn ovaries, and the second step was isolation and culture of oocyte-granulosa cell complexes isolated from preantral follicles that developed in the organ-cultured ovaries. Unfortunately, the frequency of successful preimplantation development was very low, and only one live offspring (0.5% of embryos transferred) was produced. Thus, the conditions for oocyte development were not optimal, and the significance of the single birth was questioned. Eppig then conducted studies on factors affecting the development of mouse oocytes in vitro<sup>69,70</sup> and developed a revised two-step protocol that achieved improved developmental competence of oocytes grown in vitro from primordial follicles producing 59 living offspring from in vitro grown oocytes,<sup>71</sup> although the efficiency remained low. Importantly, to address the low efficiency, Eppig used newborn mice, taking advantage of the large wave of folliculogenesis that occurs in mice soon after birth (and prior to sexual maturation). The physiology of this first cohort of follicles is less well defined, and the extent of the findings’ applicability to mature animals remains to be determined.

Most recently, Evelyn Telfer in Edinburgh reported that she was able to develop

mature oocytes from human ovarian cortical strips using a four-step approach.<sup>72</sup> It is noteworthy that it is difficult to establish whether the mature human oocytes generated by Telfer were from primordial follicles or later stages. Moreover, the developmental potential of these eggs remains to be tested. In sum, patients should be informed that an efficient method of generating mature oocytes in vitro from cryopreserved ovarian cortical tissue does not yet exist.

# Combination of Ovarian Tissue Cryopreservation with Other Assisted Reproductive Technologies

Preservation of fertility has proven to be very successful using the established techniques of oocyte and embryo vitrification. This begs the question: would combination of ovarian tissue freezing with assisted reproductive technologies further improve fertility? Is it possible to achieve better fertility preservation outcomes following ovarian tissue cryopreservation by harnessing the efficiency of assisted reproductive technologies?

With the integration of the yet experimental *in vitro* activation (IVA) following ovarian tissue freezing, Kawamura et al.<sup>54,55</sup> have recently shown that women with primary ovarian insufficiency (POI) can have live births following the activation of immature follicles from ovarian tissue formerly considered menopausal. The IVA protocol includes mechanical fragmentation of ovarian tissue to disrupt Hippo signaling and the incubation of ovarian tissue with AKT-stimulating drugs, both of which stimulate the growth of resting follicles.<sup>73,74,75</sup> This approach could potentially be combined with ovarian tissue cryopreservation to activate the resting follicles from vitrified menopausal ovarian tissue *in vitro*, to reach maturity *in vivo*, resulting in sufficient endocrine function, and to produce live births. However, while the idea is promising, uncertainty remains regarding potential negative effects of the drugs involved on oocyte quality. In addition, in interpreting successful live births following IVA in patients with POI, one must also consider the 5% spontaneous pregnancy rate in women with confirmed POI.<sup>76</sup>

The IVM of human oocytes can accompany procedures that involve ovarian tissue cryopreservation. In 2014, Prasath and colleagues<sup>77</sup> reported the first live birth from an immature oocyte that was aspirated *ex vivo* from an extracted ovarian tissue, matured and fertilized *in vitro*. This patient had undergone bilateral oophorectomy for ovarian cancer. Both of her ovaries were found to have cancer cells, and, therefore, ovarian tissue autotransplantation would not be an acceptable option using current technology.

In order to maximize their fertility potential, cancer patients with malignancies insensitive to gonadotropins or estrogen may undergo short ovarian stimulation and egg retrieval before the extraction of ovarian tissue for cryopreservation and the initiation of chemotherapy. Hourvitz and colleagues<sup>78</sup> reviewed the records in their institution and concluded that oocyte aspiration just prior to ovarian tissue cryobanking yielded more oocytes, with a better maturation rate than oocytes retrieved from *ex vivo* ovarian tissue. The combination of ovarian tissue stimulation, egg retrieval, and tissue

cryopreservation has the ability to optimize the endocrine function and fertility potential.

The recent advancements in the field of reproductive technology raise the question: what combination of procedures/techniques might offer the best chance of success for our patients? Certainly, there are a number of promising ideas and more research is needed.

# Menopause and Premature Ovarian Failure in the Era of Tissue Cryopreservation

Even a “radical procedure,” such as unilateral oophorectomy, only marginally affects fertility and the onset of menopause. In a large study, Lass et al.<sup>79</sup> compared IVF treatment outcomes between women who had unilateral oophorectomy and women who had both of their ovaries. Although the oophorectomy group required more ampoules of human menopausal gonadotropin, a longer induction period, and produced fewer oocytes, there was no difference between the pregnancy rates (per oocyte retrieved) between the groups. More recent studies found that women with one ovary entered menopause about a year earlier than women with two ovaries.<sup>80,81</sup> Anderson et al.<sup>82</sup> summarized the current data on menopause and concluded that “...normal women will experience little if any effect on fertility and age of menopause by having ovarian tissue removed when young.”

What if menopause and its related complications could be physiologically delayed? Although the primary goal of ovarian cryopreservation is fertility preservation, transplantation of frozen-thawed ovarian tissue could serve as a physiologic solution to prevent osteoporosis and other menopause-related disorders. Andersen and Kristensen<sup>82</sup> have presented a thought-provoking commentary addressing this question. As noted before, the authors propose that excision of ovarian tissue will advance menopause marginally, but it will not reduce natural fertility. If the tissue is autotransplanted at perimenopausal period, sufficient circulating concentrations of sex steroids may be maintained for years and may potentially delay postmenopausal symptoms for even decades.

Ovarian tissue, with its enormous resting follicle pool, can be cryopreserved in youth and used for multiple purposes in the future. Assuming that natural ovarian hormone production is not harmful regarding breast cancer risk (a theory that has yet to be tested),<sup>83,84</sup> a potential physiologic approach to postpone menopause is readily available: during the perimenopausal period, in cases where a patient wishes to simply delay menopause but is not interested in conception, a minimally invasive subcutaneous transplantation of ovarian cortical strips could be performed. In order to preserve the endocrine function, once the transplant is depleted of functioning follicles, another cryopreserved ovarian cortical strip (or strips) could be transplanted. This approach could be implemented with today’s technology and theoretically has the potential to obviate menopausal symptoms.

# Potential Complications Resulting from Tissue Transplantation

Posttransplantation ischemia is likely responsible for follicular loss. Revascularization after transplantation may take up to 5 days in humans.<sup>85</sup> Research identifying methods to promote angiogenesis will aid in increasing reproductive potential by decreasing ischemia and follicular loss in the transplanted tissue. A live birth following ovarian tissue transplantation utilizing a human decellularized extracellular tissue matrix as a scaffold has been reported.<sup>86</sup> This kind of scaffold is thought to aid in the grafted tissue revascularization and, therefore, improve its function and survival; however, such an effect remains to be experimentally established.

Reimplantation of malignant cells together with the grafted ovarian tissue remains a serious concern. The concept of an artificial ovary may be useful in cases in which malignant cells are suspected to be in the harvested ovarian tissue. Selective transplantation and maturation of healthy follicles in an artificial ovary or grafting material could reduce or eliminate the possibility of reintroducing malignant cells to a patient who has been cured and wishes to conceive. Such approaches have been successfully applied in the mouse using designer biomaterial grafts and retrievable hydrogels.<sup>87,88</sup>

# MEDICAL MANAGEMENT OF OVARIAN PROTECTION

---

Gonadotropin-releasing hormone (GnRH) agonists have a potential benefit in decreasing ovarian tissue damage while exposed to gonadotoxic chemotherapy agents.<sup>89</sup> While the mechanism of protective action remains unclear, several theories have been proposed: (1) Inhibition of FSH-dependent accelerated follicular demise. In the adult ovary, ovarian reserve is primarily made up of primordial follicles that constitute about 90% of the total follicular pool.<sup>90</sup> These follicles are at resting stage and contain oocytes arrested at the prophase of first meiotic division. Primordial follicles initiate follicle growth through an unknown mechanism, which is FSH independent.<sup>91,92</sup> FSH receptors are not expressed in primordial or primary follicles, but the expression is uniformly present in as early as secondary (preantral) follicles with three to four granulosa layers. It has been hypothesized that the gonadotoxic chemotherapy induces an accelerated rate of follicular demise due to low estrogen and inhibin levels resulting in supraphysiologic FSH secretion.<sup>93</sup> According to this theory, high FSH levels accelerate the rate of preantral follicle recruitment to enter the unidirectional process of maturation, resulting in their further exposure to gonadotoxic effects of chemotherapy, and in an accelerated follicular demise. The administration of GnRH agonists could interrupt this vicious cycle by inducing pituitary desensitization, preventing the increase in FSH concentrations despite low inhibin and estrogen levels.<sup>93</sup> However, as discussed above, primordial follicles constitute the great majority of follicular reserve in adult ovary and do not express FSH receptors. Therefore, the molecular basis for this theory is weak. (2) Decrease in utero-ovarian perfusion. Continuous exposure to a GnRH agonist leads to decreased levels of FSH and LH that result in hypoestrogenic state. Hypoestrogenic state decreases utero-ovarian perfusion,<sup>94,95</sup> which in turn brings to lower total cumulative exposure of the ovaries to the circulating chemotherapeutic agents.<sup>93</sup> (3) GnRH agonist's direct action in the ovary. In addition to its classical releasing action at the pituitary level, GnRH seems to act on extrapituitary sites to regulate various reproductive functions. In the rat ovary, specific high affinity GnRH receptors have been identified in granulosa and theca cells. These binding sites mediate the inhibitory effects of GnRH and its agonists on gonadotropin-stimulated estrogen, progesterin, and androgen biosynthesis. At the granulosa cell level, GnRH treatment decreases aromatase activity as well as the biosynthesis of pregnenolone and progesterone via inhibition of cholesterol side-chain cleavage and 3-beta-hydroxysteroid dehydrogenase enzymes.<sup>96</sup> In addition, in vitro studies suggested that GnRH agonists may decrease chemotherapy-induced granulosa cell damage by interacting directly with GnRH receptors expressed on the granulosa cells' membrane,<sup>97</sup>

while others failed to show an increase in cAMP or activation of ERK or p38 signaling in cultured granulosa cells in response to GnRH or its agonists.<sup>98</sup>

Regardless of these theories, evidence supporting a strong benefit from GnRH agonist use is still lacking, although a mild effect seems to be likely. Recent meta-analyses suggest that GnRH agonists may be effective in protecting ovarian function during chemotherapy in lymphoma<sup>99</sup> and breast cancer<sup>100</sup> patients. Additionally, another meta-analysis shows that GnRH agonists are effective in reducing amenorrhea rates following chemotherapy, and that pregnancy rate was higher in the GnRH agonist arms.<sup>101</sup> On the other hand, a recent randomized trial shows no benefit in preserving endocrine function nor fertility potential<sup>102</sup> as well as other studies providing conflicting data regarding the benefit of GnRH agonists in regard to recovering endocrine function.<sup>103,104</sup> Despite unclear mechanism of protective action and low effectiveness, given the low cost and risk associated with a GnRH agonist cotreatment, its use remains at individual physician's discretion. However, it is important to note that GnRH agonist administration should not be used as a substitute for proven fertility preservation techniques.

# FUTURE PROSPECTS

---

The general field of tissue cryopreservation is evolving and is likely to provide additional achievements in the near future; research in this field is fueled in part by advances in angiogenesis and biomechanics of tissue engineering.

The concept of an artificial ovary may be useful in cases in which malignant cells are suspected to be in the harvested ovarian tissue. Animal studies have shown that isolated follicles and ovarian cells in a biodegradable scaffold can be successfully grafted.<sup>105,106</sup> Selective implantation and maturation of “healthy” follicles in an artificial ovary could reduce or eliminate the possibility of reintroducing malignant cells to a patient who has been cured from cancer and wishes to conceive. An additional approach could be the cryopreservation of follicles. Cryopreservation and in vitro culturing of isolated human primordial follicles is now available.<sup>107</sup> Using a follicular isolation technique, a predetermined number of follicles, sufficient for a desired endocrine function, could be transplanted at a given time. When the levels of sex hormones drop below a desired threshold, the transplantation of additional follicles could be performed. Further development in follicle isolation techniques and artificial ovary substrates may result in a cancer-free source of follicles that could last longer and be safer than pieces of ovarian cortex.

Another important area of interest is the minimization of follicular loss due to posttransplantation ischemia. One approach is the promotion of neovascularization at ovarian transplantation sites, using proangiogenic growth factors.<sup>108,109</sup> Additional approaches could be the inhibition of apoptosis, proliferation of ovarian stromal cells with the administration of Sphingosine-1-Phosphate,<sup>41,110</sup> or even introducing bone marrow stem cells to help stimulate follicle development.<sup>111</sup> While oocyte and embryo cryopreservation are established techniques in fertility preservation, this is still a rapidly evolving field with many new options on the horizon.

## Recurrent Early Pregnancy Loss

Spontaneous abortion or miscarriage is defined as the involuntary termination of pregnancy before 20 weeks of gestation (dated from the last menstrual period) or below a fetal weight of 500 g. Losses after 20 weeks are considered stillbirths or premature births and generally have different causes than losses that occur earlier in gestation.

Historically, recurrent pregnancy loss (RPL) or “habitual abortion” was defined as three or more consecutive spontaneous miscarriages. Popular theory during the 1930s and 1940s held that risk for spontaneous miscarriage increased progressively with each successive loss. Calculations based on that assumption by Malpas and later by Eastman suggested that three consecutive miscarriages demonstrated a predisposition to pregnancy loss that raised the risk for spontaneous miscarriage in the next pregnancy to as high as 73–84%.<sup>1,2</sup> In that era, the “control” for numerous studies evaluating the effectiveness of various treatments for recurrent pregnancy loss (hormones, vitamins, psychotherapy) was theoretical rather than real; the observed incidence of miscarriage in treated women was compared to the predicted or expected incidence rather than to the actual incidence observed in untreated or placebo-treated women. Unfortunately, one of the consequences of such flawed study design was the erroneous conclusion that treatments, including diethylstilbestrol (DES), were effective when in fact they were not. Years later, clinical studies based on empiric observations demonstrated that the risk of miscarriage after three previous losses is actually much lower than predicted (30–45%) and varies with the number of previous live births (none, 40–45%; one or more, about 30%).<sup>3,4,5,6</sup>

There is no specific number of miscarriages or firmly established criterion that justifies evaluation for recurrent pregnancy loss or defines the scope of investigation. Decisions must be individualized and consider the female partner’s age, the timing and circumstances surrounding earlier pregnancy losses, elements of the personal and family medical history, and the couple’s level of anxiety. It is estimated that fewer than 5% of women will experience two consecutive pregnancy losses, and only 1% experience three losses or more.<sup>7</sup> Today, recurrent pregnancy loss is usually defined as three or more pregnancy losses (not necessarily consecutive).<sup>8</sup> Most also consider clinical investigation and treatment appropriate in couples with two consecutive spontaneous miscarriages. It is important to remember that self-reported losses by patients may not be accurate. In one study, only 71% of self-reported clinical pregnancy losses were

consistent with hospital records.<sup>9</sup> Therefore, for purpose of determining whether evaluation for RPL is appropriate, clinical pregnancy should be defined by ultrasound documentation or histopathologic examination. Evaluation is especially indicated when any of the following are also present:

- Embryonic heart activity observed before any earlier pregnancy loss.
- Normal karyotype on products of conception from an earlier loss.
- Female partner age over 35 years.
- Infertility.

The vast majority of all early pregnancy losses result from chromosomal abnormalities arising in the egg, the sperm, or during early embryonic development and are random events. Even repeated miscarriages can occur by chance alone, but at least some affected couples have a predisposing factor. Among all the factors that have been implicated, the only undisputed causes of recurrent pregnancy loss are genetic (balanced chromosomal translocation in either partner, maternal age-related increase in prevalence of aneuploid oocytes), anatomic (congenital and acquired uterine abnormalities), or immunologic (the thrombotic complications of antiphospholipid syndrome). **Alloimmunopathology, inherited thrombophilias (factor V Leiden and others), endocrinopathies (thyroid disorders, diabetes, luteal phase deficiency), infections (genital mycoplasmas), and environmental exposures (smoking, heavy alcohol, or caffeine consumption) have been implicated but are not established causes of recurrent pregnancy loss.** Even after a comprehensive evaluation, recurrent pregnancy loss remains unexplained in well more than half of affected couples ([Table 30.1](#)).

### **TABLE 30.1 The Risk of Recurrent Early Pregnancy Loss in Young Women<sup>4,5,6</sup>**

	Number of Prior Miscarriages	% Risk of Miscarriage in Next Pregnancy
Women who have had at least one live-born infant	0	12%
	1	24%
	2	26%
	3	32%
	4	26%
	6	53%
Women who have not had at least one live-born infant	2 or more	40–45%

**For all couples who have suffered recurrent pregnancy loss, education can provide important perspective; most couples welcome the offer of evaluation to identify any predisposing factor. When a likely cause can be defined, specific counseling and treatment can improve the prognosis for a successful pregnancy. When no specific cause can be found, reassurance and encouragement are no less valuable.**

# EPIDEMIOLOGY OF PREGNANCY LOSS

Early pregnancy loss is a very common event, even more so than most couples realize. Almost all chromosomally abnormal conceptions spontaneously abort, most before 10 weeks' gestation, and over 90% of conceptions having a normal karyotype continue.<sup>10,11</sup> Miscarriage may thus be viewed as a natural selection process for quality control. Learning that miscarriage is common, normal, and inevitable in most cases does not heal the emotional wounds left by earlier losses or eliminate the anxiety that affected couples have when contemplating another attempt at pregnancy,<sup>12,13</sup> but an accurate perspective is nonetheless important and often very helpful.

Overall, approximately 12–15% of clinically recognized pregnancies end in spontaneous miscarriage between 4 and 20 weeks of gestation. However, the true early pregnancy loss rate, including both clinically recognized and unrecognized occult early miscarriages, is 2–4 times greater, depending on age. Careful studies in normally cycling healthy young women attempting pregnancy have shown that human chorionic gonadotropin (hCG) can often be detected transiently in the urine of women who are otherwise quite unaware that they had conceived and miscarried.<sup>14,15,16</sup> No less than 30% of all conceptions abort within the first 12 weeks of gestation, and at least half of all losses go unnoticed. The reproductive loss that occurs even before a first missed menses is substantial.<sup>17</sup> Most recognized pregnancy losses occur before 8 weeks of gestation, and relatively few occur after 12 weeks (**Figure 30.1**).<sup>18</sup>

**FIGURE 30.1**

Numerous studies have documented that the risk of spontaneous miscarriage varies with past obstetrical history.<sup>3,18,19,20</sup> In general, women in their first pregnancy, those whose only other pregnancy was electively terminated, and women whose only or last pregnancy was successful have a relatively low risk of spontaneous miscarriage (4–6%). Conversely, women whose only or last pregnancy ended in loss have a higher risk of miscarriage in their next pregnancy (19–24%).<sup>18</sup> Unless there has been a subsequent successful pregnancy, even a single loss increases risk for another spontaneous miscarriage in the next pregnancy. Taken together, available evidence also suggests that miscarriage risk increases with the number of pregnancy losses, but very gradually.<sup>4,5,6</sup> Overall, the risk is still less than 40% after four previous losses and no higher than about 50% even with six or more; risk may be modestly higher for women with recurrent pregnancy loss and no previous live-born children.

Independent of past obstetrical history, the risk of clinically recognized spontaneous miscarriage increases with age. Risk is relatively low before age 30 (7–15%) and only slightly higher for women aged 30–34 (8–21%) but then rises more sharply for ages 35–39 (17–28%) and women age 40 and older (34–52%).<sup>21,22,23,24,25</sup> Among women with a past history of pregnancy losses, advancing age adds to the risk related to previous losses; the miscarriage risk for women over age 40 (52%) is more than twice that for women under age 30 (25%).<sup>6</sup> If both recognized and occult pregnancy losses are considered, total pregnancy wastage in women over age 40 may reach or exceed 75%.<sup>15,25,26</sup>

**In summary, approximately 12–15% of all clinically recognized pregnancies end in miscarriage, but the true incidence of miscarriage, including unrecognized early pregnancy losses, is 2–4 times higher (30–60%). Miscarriage risk increases with the number of previous pregnancy losses but rarely exceeds 40–50%. Risk for pregnancy loss also rises with increasing maternal age, moderately after age 35 and more rapidly after age 40.**

# Prognostic Value of Transvaginal Ultrasound Observations

Careful serial observations during early pregnancy have indicated that the risk for miscarriage decreases as the duration of pregnancy increases. The risk of pregnancy loss falls progressively after observation of a gestational sac (12%) and a yolk sac (8%) and as embryonic crown-rump length increases (>5 mm, 7%; 6–10 mm, 3%; >10 mm, <1%).<sup>27</sup> The observation of embryonic heart activity (by approximately 6 weeks' gestation) is another important developmental milestone and good prognostic indicator because most ill-fated pregnancies fail before then, but its predictive value varies with the past obstetrical history, clinical context, and age. In both normal and infertile asymptomatic young women, the timely appearance of embryonic heart activity decreases the risk of pregnancy loss from the global risk of 12–15% to between 3% and 5%.<sup>28,29</sup> In women with past histories of recurrent pregnancy loss, the miscarriage rate after detection of embryonic heart activity is still 3–5 times higher (15–25%).<sup>30,31</sup> In women with threatened abortions, demonstrable embryonic heart activity is again a good prognostic indicator overall (15% loss rate), but the incidence of subsequent loss is higher when there are other abnormal sonographic findings (slow- or late-appearing heart activity, size/date discrepancies, subchorionic hematoma).<sup>32,33,34,35</sup> Finally, the prognostic value of embryonic heart activity declines with increasing maternal age; whereas the risk for subsequent loss is low (<5%) in women age 35 and under, it is 2–3 times higher (approximately 10%) in women ages 36–39 and increased another threefold (29%) in women age 40 and over.<sup>36</sup>

# GENETIC FACTORS

---

Most spontaneous miscarriages result from chromosomal abnormalities in the embryo or fetus. Numerous studies in which large numbers of abortuses have been cultured and karyotyped have suggested that approximately 50% of all first-trimester pregnancy losses, 30% of second-trimester abortuses, and 3% of stillbirths are chromosomally abnormal.<sup>23,24,37,38,39</sup> However, these studies have very likely underestimated the prevalence of chromosomal abnormalities among abortuses because the data are biased by unrecognized maternal cell contamination and because normal euploid cells (from the mother or abortus) are less likely to fail culture than abnormal cell lines.<sup>40,41,42</sup> **Analyses using newer techniques not dependent on cell culture (comparative genomic hybridization or microarray) and more recent careful cytogenetic studies of early missed abortions suggest that the true incidence of chromosomal abnormalities in miscarried early pregnancies is closer to 75%.<sup>43,44</sup>**

Over 90% of the chromosomal abnormalities observed among abortuses are numerical (aneuploidy, polyploidy); the remainder are split between structural abnormalities (translocations, inversions) and mosaicism.<sup>44,45</sup> Overall, autosomal trisomies are the most common abnormality (usually involving chromosomes 13–16, 21, or 22), followed by monosomy X (45,X) and polyploidies.<sup>23,44,46,47</sup> Among women with history of recurrent pregnancy loss, chromosomally normal (euploid) abortuses are more common, particularly in those age 35 and under.<sup>47,48,49,50</sup> The distribution of chromosomal abnormalities observed among the abortuses of women with recurrent pregnancy loss is otherwise no different from that seen in the general population when stratified by maternal or gestational age.<sup>47</sup> The high incidence of sporadic miscarriage and random chromosomal abnormalities means that some of the pregnancy losses in women with recurrent miscarriages result from chance. The likelihood of a euploid abortus increases with the number of previous miscarriages and after a previous abortion having a normal karyotype.<sup>26,49</sup>

# Parental Chromosomal Abnormalities

There is a very high frequency of sporadic karyotypic abnormalities in products of conception, while the actual incidence of karyotypic abnormalities in the parents is low. Indeed, the overwhelming majority of chromosomally abnormal conceptions result from the chance union of one normal and one aneuploid gamete or from nondisjunction during early embryonic development. However, in 4–8% of couples with recurrent pregnancy loss, one or the other partner harbors a chromosomal abnormality that markedly increases the probability of a chromosomally unbalanced conceptus.<sup>51,52,53,54,55,56</sup> Balanced translocations (reciprocal, Robertsonian) are the most common abnormalities; sex chromosome mosaicism, chromosome inversions, and other structural abnormalities can also be observed.<sup>57,58</sup>

In a balanced reciprocal translocation, pieces of two different autosomes (one from each of two different pairs) are translocated (exchanged). In a balanced Robertsonian translocation, the centromeres of two acrocentric chromosomes (numbers 13, 14, 15, 21, 22) fuse to form a single chromosome consisting of the long arms of the two affected chromosomes; the short arms (containing little or no essential genetic material) are lost. In both cases, the translocation carrier is genetically balanced and phenotypically normal. Unfortunately, when their oogonia or spermatogonia undergo meiosis to yield haploid oocytes or sperm, a large proportion of the gametes end up genetically unbalanced and abnormal, having either a deficiency or an excess of genetic material. Depending on how the chromosomes segregate during meiosis, the gametes may be chromosomally normal (containing only the normal copy of each of the two affected chromosome pairs), abnormal but balanced (containing the translocated member of each of the two affected chromosome pairs), or abnormal and unbalanced (containing two copies or no copies of an affected chromosome or chromosome segment). When such chromosomally unbalanced gametes combine with a normal gamete from an unaffected partner, the conceptus will have a trisomy and/or a monosomy and will almost always abort; an unbalanced conceptus may occasionally survive, but those that do are at high risk for malformations and mental retardation.<sup>59</sup>

Genetic counseling is very important when a structural genetic factor is identified. The probability of a subsequent genetically normal conceptus and live birth depends on the chromosome(s) involved and the type of rearrangement. In theory, one-fourth of the gametes produced by reciprocal translocation carriers should be normal, one-fourth should be abnormal but balanced, and one-half should be abnormal and unbalanced, yielding a 50% probability of a normal pregnancy (normal or balanced conceptus) and a 50% probability of an abnormal pregnancy (abortion or a viable but anomalous fetus), assuming union with a chromosomally normal gamete from the unaffected partner. Similarly, given the three different ways in which a Robertsonian translocation

chromosome and the normal members of the affected chromosome pairs may align and segregate during meiosis, one-sixth of the gametes produced by carriers should be normal, one-sixth should be abnormal but balanced, and the remaining two-thirds should be abnormal and unbalanced, yielding a 33% probability of a normal pregnancy (normal or balanced conceptus) and a 67% probability of an abnormal pregnancy (abortion or a viable but anomalous fetus), again assuming a union with a chromosomally normal gamete from the unaffected partner. However, when a Robertsonian translocation involves both members of a single pair of chromosomes, the carrier will produce no normal gametes because all will have either two copies or no copy of the affected chromosome.

Some reciprocal translocations are predisposed to specific rather than random segregation patterns and may yield a skewed distribution of normal, balanced, and unbalanced gametes.<sup>60,61,62</sup> The probability of a successful pregnancy and the risk of a chromosomally abnormal but viable fetus vary with the specific chromosomes involved and the size and location of the translocated segments.<sup>45,59</sup> Abnormalities of some chromosomes (chromosome 21) are better tolerated than others and risk of an unbalanced but viable conceptus is higher when the exchanged chromosomal segments are small. By their very nature, reciprocal translocations tend to be rather unique, so there is usually no easy way to accurately predict the probability of specific pregnancy outcomes for an individual affected couple. At best, the karyotype of the affected partner can allow one to predict the most likely segregation patterns for a specific translocation and to estimate the risk of unbalanced offspring. When the male partner is the translocation carrier, the distribution of normal, balanced, and unbalanced sperm and the prognosis for successful conception can be more accurately defined.<sup>62</sup> When the female partner is the carrier or the distribution of gametes is otherwise unknown, the couple's own reproductive history (and that of any other similarly affected family member) is the best gauge. One exception is a specific recurring translocation involving chromosomes 11 and 22, t(11;22)(q23;q11), the most common reciprocal translocation in humans; over 100 unrelated affected families have been reported, and the reproductive performance of carriers has been well defined.<sup>63,64,65</sup>

Chromosomal inversions occur less frequently than translocations and may or may not have reproductive implications, depending on their size and location. Pericentric inversions (those that involve the centromere) often have no clinical consequences; a pericentric inversion of chromosome 9, inv(9)(p11q13), is so common (1–1.5% in the general population) that some consider it a normal variant with no importance.<sup>66,67</sup> However, the crossovers and recombinations that can occur with paracentric inversions (those not located at the centromere) frequently result in an excess of genetic material resulting in abortion or an anomalous fetus.<sup>45</sup>

As might be anticipated, the most common reproductive history in translocation carrier couples includes both a normal child and early pregnancy losses (6–7%); other histories involving only spontaneous miscarriages or combinations of malformed children, stillbirths, and abortions are slightly less common (4–5%).<sup>54</sup> The probability of identifying a balanced chromosomal translocation in a couple with three or more previous pregnancy losses is not significantly higher than in those having had only two. In some couples, family history (recurrent pregnancy loss, stillbirths, or birth defects) suggests the possibility of an occult chromosomal abnormality after only one spontaneous miscarriage. Couples with miscarriages interspersed with normal pregnancies and outcomes should be evaluated in the same fashion as couples with consecutive miscarriages.<sup>68</sup>

Balanced chromosomal translocations can be found in either partner, and both must be karyotyped to exclude the possibility.<sup>54</sup> Any balanced translocation so identified may have arisen *de novo* or have been inherited from one of the carrier's own parents. If the translocation was inherited, any of the carrier's siblings and, in turn, their offspring might also be affected.<sup>69</sup> Any pregnancy in an affected couple becomes a candidate for prenatal diagnostic studies, regardless of the mother's age or previous reproductive history.<sup>68</sup> Consequently, counseling of translocation carrier couples with recurrent pregnancy loss should consider karyotyping the carrier's parents and, where appropriate, other potentially affected individuals in the kindred. For minor children who may be carriers, karyotyping is best postponed until they reach an age where they are able to grant informed consent.

It is likely that some couples with recurrent pregnancy loss may harbor a genetic abnormality that predisposes to a higher risk of miscarriage but cannot be detected using standard cytogenetic techniques. Possibilities include isolated gonadal or germ-line mosaicism (including a trisomic cell line) and single-gene defects.<sup>45</sup> The recent advent of genome-wide high-resolution technologies, such as chromosome microarray analysis and next-generation sequencing (NGS), including whole exome sequencing (WES), has opened new possibilities for discovery of genetic changes that are too small to be detected by traditional chromosome analysis.

# Aging and Gamete Aneuploidy

The mechanisms responsible for the age-related increase in the incidence of miscarriage and the use of ovarian reserve tests in the evaluation of reproductive age and prognosis are discussed in detail in [Chapter 25](#). The genetic factors that contribute to the increase in pregnancy wastage associated with reproductive aging and the utility of ovarian reserve testing in women with recurrent pregnancy loss are only summarized briefly here.

Several lines of evidence suggest that age-related instability or degradation of the cellular mechanisms that govern meiotic spindle formation and function results in an increasing incidence of meiotic segregation errors and a rapid rise in the numbers of aneuploid oocytes during the later reproductive years.<sup>70,71,72,73,74,75,76</sup> Prevalence studies indicate the aneuploidy in oocytes is relatively low before age 35 (<10%) but increases abruptly thereafter, reaching nearly 100% after age 45.<sup>70</sup> These observations offer a logical explanation for the overall age-related increase in the incidence of miscarriage and the higher prevalence of aneuploidy among the abortuses of aging women.<sup>21,22,23,24</sup> Indeed, most trisomies observed among abortuses can be traced to maternal meiotic errors and oocyte aneuploidy.<sup>77</sup>

Some women with otherwise unexplained recurrent pregnancy loss have a diminished ovarian reserve (DOR) that may help to explain their poor reproductive performance.<sup>78,79</sup> The prevalence of abnormal ovarian reserve tests in women with unexplained recurrent pregnancy loss is higher than in women with other defined causes of recurrent pregnancy loss<sup>78</sup> and comparable to that observed in the general population of infertile women.<sup>79</sup> Moreover, there is evidence that infertile women with DOR and also unexplained RPL patients with DOR have a higher percentage of aneuploid blastocysts as compared to infertile women with normal ovarian reserve and unexplained RPL patients with normal ovarian reserve, respectively, although ovarian reserve is generally not considered a marker of oocyte quality.<sup>80,81,82</sup> These observations suggest that women at advanced stages of ovarian follicular depletion are at higher risk for miscarriage. While it is still controversial whether this association between DOR and miscarriage is true regardless of age,<sup>82</sup> it appears to be stronger in patients 35 years of age or older and to increase with maternal age.<sup>83</sup> Some women will suffer premature ovarian follicular depletion because they are born with a smaller than normal ovarian follicular pool and are genetically destined to be among the 10% of women who experience an early menopause.<sup>84,85,86,87,88</sup> Women who have had a trisomic abortus reach menopause at an earlier average age.<sup>89</sup> Other women may have their ovarian follicular pool depleted by disease that destroys ovarian tissue or requires its removal. Either way, the end result is the same—accelerated follicular depletion,

declining fertility, and increasing risk for miscarriage begin at an earlier than normal age. Besides offering information that may help to explain recurrent pregnancy loss, ovarian reserve testing may identify young women at increased risk for fetal aneuploidy in subsequent pregnancies who would otherwise not be considered candidates for prenatal diagnostic studies.<sup>90,91,92,93,94</sup> The incidence of Down syndrome is increased in women with elevated serum levels of follicle-stimulating hormone (FSH), regardless of age and regardless of whether the low ovarian reserve the high FSH reveals came about naturally or resulted from ovarian surgery.<sup>90,92,93,94</sup>

The prevalence of skewed X chromosome inactivation, defined as preferential inactivation (more than 90%) of one of the two X chromosomes in female cells, is increased in women with recurrent pregnancy loss,<sup>95,96,97,98,99</sup> although this finding was not confirmed in two studies.<sup>100,101</sup> This observation has prompted speculation that X-linked mutations lethal to the male cause skewed X chromosome inactivation in female carriers and predispose to abortion of male conceptuses and an increased prevalence of female live births.<sup>97,102</sup> However, investigation of this issue has not confirmed the predicted excess of chromosomally normal male abortuses.<sup>98</sup> Observations of an increased prevalence of trisomic abortuses among women with recurrent pregnancy loss and skewed X chromosome inactivation have suggested the alternative hypothesis that X chromosome mutations or X-autosome translocations result in skewed X chromosome inactivation and a smaller than normal ovarian follicular pool or accelerated follicular depletion that predisposes to oocyte aneuploidy and recurrent pregnancy loss.<sup>98,103</sup>

Ill-fated chromosomally abnormal conceptuses can also result from fertilization of a normal euploid oocyte by an aneuploid sperm. The sperm of men whose partners have a history of unexplained recurrent pregnancy loss exhibit a higher prevalence of abnormal morphology, chromosome aneuploidy, DNA fragmentation, and abnormal tests of sperm function such as hypo-osmotic swelling.<sup>104,105,106,107,108,109,110,111</sup> The incidence of sperm aneuploidy rises with paternal age, if only slightly,<sup>60,112</sup> and the incidence of miscarriage in young women with older male partners is higher than in those whose partners are young.<sup>113</sup> Taken together, these observations suggest that poor semen quality, like a low ovarian reserve in women, can predispose to both infertility and early pregnancy loss, two different points on a continuum of reproductive failure having some causes in common. However, sperm aneuploidy rarely rises above approximately 1–2%. Compared to the influence of oocyte aneuploidy on miscarriage risk, chromosomally abnormal sperm have relatively little importance as a predisposing factor in recurrent pregnancy loss.

# Karyotyping the Abortus

Many view karyotyping the products of conception following miscarriage as an unnecessary and expensive luxury. Others consider it crucially important for differentiating couples who are candidates for thorough evaluation from those who are not. Without karyotyping, women who repeatedly miscarry generally are assumed to be losing normal pregnancies when, in fact, most are not. Some have even advocated karyotyping the first or second abortus, reasoning that women who abort chromosomally normal pregnancies should be screened for treatable causes of pregnancy loss sooner rather than later. Conversely, those who miscarry a chromosomally abnormal pregnancy might be spared unnecessary and costly evaluation and empiric treatments.<sup>11</sup>

Unfortunately, the karyotype of an abortus cannot provide information so definitive; a karyotype may be useful but has limitations and pitfalls that must be carefully considered. Most early failed pregnancies lose viability well before onset of clinical symptoms of miscarriage or other recognition of the inevitable loss; products of such conceptions may therefore fail to grow in culture. Tissue specimens passed spontaneously are more likely to fail culture than those obtained by curettage.<sup>47</sup> Newer array-based assessment or NGS can yield more complete information as these techniques are applied directly without the need for viable tissues and cell culture.

A normal abortus karyotype might be interpreted as suggesting that genetic factors are not likely responsible, focusing attention on evaluation for other possible causes of recurrent pregnancy loss.<sup>11</sup> Unfortunately, a normal 46,XX karyotype can also represent maternal cell contamination of the tissue specimen and preferential growth of the normal maternal cell line in culture, particularly when no specific care has been taken to dissect, isolate, and submit only chorionic villi for cell culture.<sup>40,41,42</sup> Results from an embryoscopic and cytogenetic study of early missed abortions challenge directly the notion that a normal karyotype effectively excludes genetic causes for a failed pregnancy. Whereas 75% of the abortuses were chromosomally abnormal, fully two-thirds of the remaining 25% having a normal karyotype (17% of the total) exhibited gross developmental abnormalities as severe as those observed in aneuploid abortuses.<sup>44</sup> These observations strongly suggest that over 90% of all early missed abortions involving a recognizable embryo result from genetic errors and imply that a substantial proportion of failed early pregnancies result from gross genetic flaws in organizational and morphogenic processes not detectable with conventional cytogenetic techniques or even more modern methods (FISH, comparative genomic hybridization). Arguably, pregnancies that fail before any recognizable embryogenesis (empty sacs or “blighted ova”) are even more likely to result from chromosomal abnormalities, the inference being that well more than 90% of all early pregnancy losses can result from genetic causes.

Genome-wide high-resolution technologies, such as chromosome microarray analysis and NGS, including WES are being increasingly used and are bound to uncover more subtle changes underlying some of the currently unexplained losses. The clinical relevance of such higher-resolution platform was demonstrated in an analysis of 755 samples determined to be normal by conventional karyotyping that were reevaluated by NGS. In this series, clinically relevant copy number variants (CNVs) (described as corresponding to postnatal microdeletion and microduplication syndromes, clinically significant phenotypes with reduced penetrance or >5 Mb) were identified in 1.6% of euploid losses,<sup>114</sup> while rare variants of uncertain clinical significance (VUS) were seen in approximately 1–40% of sporadic and recurrent euploid miscarriages.<sup>115</sup> Although the relevance of such identified genetic changes to RPL etiology remains to be determined by functional studies, it is likely that genetic variants are underlying the etiology of at least some of the cases currently categorized as unexplained RPL.

An abnormal abortus karyotype revealing trisomy, monosomy, or polyploidy explains that specific pregnancy loss and suggests it is likely resulted from chance alone and generally has been considered as evidence that the risk for recurrence is not significantly increased.<sup>26,50</sup> Whereas such findings may suggest that no formal evaluation is therefore needed, one must assume that couples with other specific causes for recurrent pregnancy loss have at least the same random chance for conceiving an aneuploid pregnancy as anyone else; they might be overlooked if evaluation is offered only to those having a chromosomally normal abortus. Moreover, an aneuploid abortus might also reflect the influence of advanced maternal age or an otherwise unsuspected DOR, in which case the risk for recurrence in a subsequent pregnancy clearly is increased.<sup>116</sup>

A karyotype of an abortus that demonstrates an unbalanced chromosomal translocation obviously suggests that a parent may be a balanced carrier of the same translocation, a suspicion easily confirmed by performing karyotypes on both partners in affected couples.

The more expensive methods for genetic screening to detect variants associated with miscarriages, FISH and comparative genomic hybridization discussed below, can be applied to couples having recurrent miscarriages. However, these are expensive tests, and although variants and polymorphisms can be detected, the chances of having a healthy child, despite a higher risk of miscarriage, are still high, perhaps as high as non-carrier couples.<sup>117</sup>

# Preimplantation Genetic Diagnosis and Aneuploidy Screening

Preimplantation genetic testing (PGT) describes a number of techniques for preconceptional genetic evaluation of embryos resulting from in vitro fertilization (IVF). PGT can be used to detect numerical chromosomal abnormalities (aneuploidy). In this case, it is called preimplantation genetic testing for aneuploidy (PGT-A, previously called preimplantation genetic screening [PGS]). The terms PGT for monogenic disorders (PGT-M, previously called preimplantation genetic diagnosis [PGD]), and PGT for structural rearrangements (PGT-SR), are used when PGT is used to detect inherited monogenic disorders (such as cystic fibrosis, hemophilia, Duchenne muscular dystrophy), or translocations and inversions, respectively.<sup>118,119,120,121</sup> The technique uses one or more cells that may be obtained at different stages of development. The chromosomal composition of the oocyte may be inferred from that of the extruded polar bodies.<sup>118</sup> One or two blastomeres may be removed from cleavage stage embryos. Biopsy of the trophectoderm can be performed at the blastocyst stage and has become the most commonly used technique. When performing a blastocyst stage embryo biopsy, a laser or a dilute solution of acid Tyrode solution is used to create a small hole in the zonapellucida after oocyte retrieval and fertilization. This allows the developing trophectoderm (TE) to protrude after blastulation, facilitating the biopsy. On day 5 post fertilization, approximately five-to-ten cells are excised from the TE using a glass needle or laser energy, leaving the embryo largely intact and without loss of inner cell mass. After genetic diagnosis, the embryos can be replaced during the same cycle or (most commonly) cryopreserved and transferred in a subsequent cycle.

Comparative genomic hybridization is a technique in which test DNA (extracted from blastomeres) and normal male reference DNA (extracted from lymphocytes) are first amplified, then labeled with different colored fluorochromes (green/red), and simultaneously hybridized to template metaphase chromosomes from normal male lymphocytes; the green/red fluorescence ratio reflects the relative copy number for each chromosome in test DNA compared to the normal reference DNA.<sup>122</sup> Comparative genomic hybridization allows analysis of all 24 chromosomes (X, Y, 22 autosomes) and detection of abnormalities not recognized by more limited analysis with FISH.<sup>123,124</sup> This technique has been applied to the genetic evaluation of fetal losses; the diagnostic yield is improved compared with conventional karyotyping, which is often handicapped by culture failures or maternal contamination.<sup>125,126</sup>

Next-generation sequencing (NGS) and massively parallel or deep sequencing are related terms that describe a DNA sequencing technology that has revolutionized genomic research. Using NGS, an entire human genome can be sequenced within a

single day. In contrast, the previous Sanger sequencing technology, used to decipher the human genome, required over a decade to deliver the final draft. There are a number of different NGS platforms using different sequencing technologies, a detailed discussion of which is beyond the scope of this book. However, all NGS platforms perform high-throughput and high-resolution sequencing of millions of small fragments of DNA in parallel. Bioinformatics analyses are used to piece together these fragments by mapping the individual reads to the human reference genome. When whole genome amplification is used, each of the three billion bases in the human genome is sequenced, which makes it challenging to provide high depth to deliver accurate data and an insight into unexpected DNA variation. Alternatively, targeted genome amplification approaches allow higher number of copies to be obtained for each site, and potentially higher diagnostic accuracy. NGS has gained in popularity due to its increased sensitivity in identifying unbalanced translocations, segmental aneuploidies, and some triploidies.<sup>127,128</sup> This increased sensitivity appears to be clinically relevant. One study reexamined embryos that were diagnosed as euploid by aCGH and resulted in miscarriage and found based on NGS that 31.6% of these miscarriages were from mosaic embryos and 5.2% were from triploid embryos.<sup>127</sup> Another study showed that PGT-A using NGS significantly improves pregnancy outcomes versus PGT-A using aCGH in frozen embryo transfers.<sup>129</sup> Regardless of which technique is employed, PGT-A generally involves the analysis of 5–10 TE cells at blastocyst stage, assuming that those selected accurately represent the entire embryo. Unfortunately, a number of studies have now demonstrated that mosaicism (presence of two or more cell lines with a different chromosome content) is common in early human embryos cultured in vitro.<sup>130,131,132,133,134</sup> Mosaicism arises from mitotic segregation errors occurring after fertilization via a variety of mechanisms, including anaphase lag, mitotic nondisjunction, inadvertent chromosome demolition, and premature cell division before DNA duplication.<sup>135,136,137,138,139,140,141,142,143</sup> Interestingly, unlike aneuploidy of meiotic origin, the incidence of mosaic chromosomal abnormality does not change with advancing years, with approximately 30% of blastocyst-stage embryos affected across all maternal ages.<sup>134</sup> However, as the embryos of older reproductive age women are more likely to have meiotic errors, the percentage of TE biopsies containing only euploid cells declines as a woman ages, falling from 50% for women younger than 35 to 10% of blastocysts for women over 42.<sup>134</sup> The mitotic errors, leading to mosaicism, coupled with the advancing risk of meiotic aneuploidy has clinical implications for in vitro fertilization (IVF) treatments, especially those using PGT-A, because it effects the likelihood of detecting an entirely euploid embryo for transfer.<sup>134</sup> Although its impact on implantation and the developmental potential of embryos is not fully known, evidence from several studies suggests that mosaicism influences the implantation rate, with mosaic embryos resulting in lower clinical pregnancy and live birth compared to

euploid embryos.<sup>144,145</sup> Further basic and clinical research will help to better understand the biology of mosaicism and which mosaicism thresholds are clinically relevant.

Overall, the results of PGT-A studies indicate that even in women younger than 35 years, only 50% of embryos are normal for all of the chromosomes examined (biopsy specimens revealing only euploid cells).<sup>146,147,148,149</sup> Data derived from numerous studies reveal that older women and women with a history of recurrent pregnancy loss produce more aneuploid embryos than younger women and those with normal reproductive histories.<sup>150,151,152,153,154</sup> Transfer of PGT-A-selected embryos has been suggested as a strategy to improve implantation rates and decrease abortion rates in women at higher risk for pregnancy loss.<sup>134,138,146,155,156</sup> The ultimate impact of PGT-A on the live birth rate in older women and in women with history of recurrent pregnancy loss is still controversial, and high quality evidence is lacking. A cost-effectiveness analysis in patients with unexplained recurrent pregnancy loss concluded that IVF with PGT-A was not a cost-effective strategy for increasing live birth compared to expectant management, with IVF/PGT-A strategy having a live birth rate of 53% and a clinical miscarriage rate of 7% versus expectant management having a live birth rate of 67% and clinical miscarriage rate of 24%.<sup>157</sup> A cost/benefit analysis in older women concluded that IVF alone is the most cost-effective option under the age of 40, but over age 40, IVF alone and IVF with PGT are equal in cost.<sup>158</sup> Whereas it may be reasonable to consider PGT-A for indications of advanced maternal age or recurrent pregnancy loss in couples with other specific indications for IVF, the results achieved with PGT-A so far do not justify IVF with PGT-A for all couples with advanced maternal age or history of recurrent pregnancy loss. For couples with recurrent pregnancy loss in whom one partner carries a balanced chromosomal translocation, IVF with PGT-SR and transfer of only normal and balanced embryos can achieve pregnancy rates comparable to those observed in unselected infertile couples with substantially decreased risk of spontaneous miscarriage, although pregnancy rates are inversely proportional to the proportion of abnormal gametes.<sup>159,160,161,162,163,164</sup> When the male partner carries the balanced translocation, sperm FISH analysis can be used to determine the proportion of chromosomally unbalanced sperm and to predict the probability of conceiving a successful pregnancy.<sup>62</sup> Data suggest that when there are numerous good-quality embryos and less than approximately 65% unbalanced sperm, translocation carrier couples have a reasonable probability of success with IVF and PGT, but otherwise not.<sup>62</sup> Sperm FISH analysis could prove valuable to affected couples weighing the options of IVF with PGT and therapeutic insemination with donor sperm. Unfortunately, there is no way to obtain similar information for female balanced translocation carriers; depending on the nature of the translocation and on the reproductive history, some

women who carry a balanced translocation may prefer to apply their available resources to IVF with donor oocytes rather than attempt IVF with PGT.

## **Summary of Key Facts Relating to Genetic Factors**

Overall, 50–75% of spontaneous miscarriages result from numerical chromosomal abnormalities in the embryo or fetus and occur by chance; trisomies are the most common. In approximately 5% of couples with recurrent pregnancy loss, karyotypes will reveal a balanced chromosomal translocation that markedly increases the risk of miscarriage due to the high prevalence of aneuploidy in the gametes of the affected parent. Reproductive aging in women is associated with an increasing risk of miscarriage, which reflects a rising prevalence of oocyte aneuploidy. Ovarian reserve testing in women with unexplained recurrent pregnancy loss can reveal evidence of premature reproductive aging. Karyotype of an abortus can explain the loss (aneuploidy), provide evidence for a chromosomal translocation in a parent (when an unbalanced translocation is observed), or suggest a nongenetic cause (when normal). However, a normal karyotype does not entirely exclude genetic causes for the miscarriage, and a normal female karyotype (46,XX) can result from maternal cell contamination of cultured tissue specimens. IVF with preimplantation genetic testing and selected transfer of euploid embryos is an established treatment for couples with recurrent pregnancy loss when one partner carries a balanced chromosomal translocation. IVF with preimplantation genetic testing for aneuploidy screening for reasons of advanced maternal age or in couples with unexplained recurrent pregnancy loss can increase implantation rates and decrease miscarriage risk, but have not increased live birth rates. Consequently, the associated costs in couples without other specific indications for IVF cannot be justified. The limitations of preimplantation genetic testing are still being characterized, and the full biologic significance of mosaicism on embryo implantation and pregnancy potential remains to be defined.

# ANATOMIC FACTORS

---

The anatomic uterine abnormalities that can predispose to a higher risk of pregnancy loss include congenital malformations, uterine leiomyomas, and intrauterine adhesions. Each has been considered in detail elsewhere as factors that may also adversely affect fertility ([Chapters 3 and 25](#)); discussion here is limited to their importance and management in women with a history of recurrent pregnancy loss.

The principal methods for evaluation of the uterus include traditional hysterosalpingography (HSG), transvaginal ultrasonography, and sonohysterography. Magnetic resonance imaging (MRI) and endoscopy (hysteroscopy and laparoscopy) are generally reserved when necessary for better defining the nature of anomalies identified or suggested by simpler methods. Each method and its limitations, pitfalls, and relative accuracy have been described at length in the context of the infertility evaluation ([Chapter 25](#)). However, their relative value for the evaluation of infertility and recurrent pregnancy loss are somewhat different. HSG has some advantages over ultrasonographic techniques for the evaluation of uterine factors in infertile women because it also provides information about tubal patency that transvaginal ultrasonography and sonohysterography cannot. However, for the evaluation of recurrent pregnancy loss, transvaginal ultrasonography and sonohysterography offer distinct advantages over HSG; both image the external uterine fundal contour and, therefore, better distinguish septate and bicornuate uteri,<sup>165,166,167</sup> and both are generally easier to perform and better tolerated than HSG. Compared to HSG, sonohysterography has greater sensitivity and specificity for detection of intracavitary mass lesions (submucous myomas, endometrial polyps) and similar efficacy for diagnosis of intrauterine adhesions.<sup>168,169,170,171,172,173</sup> Three-dimensional transvaginal ultrasonography, with and without saline contrast, can provide high-definition images comparable to those generated with MRI.<sup>174,175</sup> As in women with infertility, endoscopic methods can usually be reserved for excision of cavitary mass lesions or intrauterine septa identified by simpler methods.

# Congenital Uterine Malformations

Developmental uterine anomalies have long been associated with pregnancy loss and obstetric complications. The reported prevalence of uterine malformations in women with recurrent pregnancy loss has varied widely with differences in diagnostic methods and criteria.<sup>176,177,178</sup> The best available data suggest that the prevalence of major uterine anomalies (excluding arcuate uteri) in the general population is approximately 2% and about 3 times greater (6–7%) in women with history of recurrent pregnancy loss, supporting the notion that uterine malformations may indeed be the proximate cause for miscarriages in a small proportion of women with recurrent pregnancy loss.<sup>176,179,180,181,182</sup> Pregnancy losses with uterine congenital abnormalities usually occur later in pregnancy in the second trimester; however, the presence of an uterine anomaly after repeated early losses deserves consideration of surgical repair.<sup>183,184</sup> The pathogenesis of pregnancy wastage in women with congenital uterine malformations is uncertain but generally has been attributed to a reduced intrauterine volume, endometrial dysfunction or poor vascular supply.<sup>185</sup>

A unicornuate uterus results from failure of development of one müllerian duct. Pregnancy outcomes in women with unicornuate uteri are generally poor; approximately half of all recognized pregnancies fail.<sup>186</sup> Most unicornuate uteri are associated with a noncommunicating contralateral uterine horn, some of which have a functional cavity and should be removed to reduce risk for ectopic pregnancy, even if not otherwise necessary (pain, mass, endometriosis).<sup>187</sup> Since approximately 40% of unicornuate uteri are associated with an ipsilateral renal agenesis, further evaluation with an intravenous pyelogram or renal sonogram is also indicated.<sup>187</sup> No surgical procedure can enlarge the unicornuate uterus. Anecdotal reports of successful pregnancies after cervical cerclage are numerous, but the efficacy of cerclage in women with unicornuate uteri has not been carefully studied. **Available evidence suggests that most pregnancies in women with unicornuate uteri are best managed expectantly with cervical cerclage reserved for those with previous second-trimester pregnancy losses or evidence of progressive cervical shortening.**<sup>186</sup>

Uterine didelphys results from complete failure of fusion of the müllerian ducts and normal differentiation of each to form a cervix and hemiuterus. The reproductive outcomes of women with uterine didelphys are slightly better than those of women with unicornuate uteri, possibly because of improved collateral blood supply between the two horns. Nevertheless, approximately 40% of pregnancies in women with uterine didelphys end in spontaneous miscarriage.<sup>186</sup> Failure of the entire müllerian duct to fuse can create two distinct cervixes and two upper hemivaginas; the lower portion of the vagina comes from the urogenital sinus and results in a single lower vagina. Failure of

one hemivagina to fuse with the urogenital sinus results in a transverse vaginal septum that may accumulate menstrual blood as a unilateral hematocolpos. In general, the only surgery indicated in women with uterine didelphys is the removal of an obstructing vaginal septum (75% prevalence).<sup>188</sup> **Unification procedures are usually unnecessary and complicated but can rarely benefit some women with numerous miscarriages or preivable births. When surgery is performed, the recommended technique unifies the two fundi and leaves the two cervixes intact.**<sup>189</sup>

A bicornuate uterus results from incomplete fusion of the müllerian ducts at the level of the fundus, creating two separate uterine cavities with a common lower segment and a single cervix; externally, the uterus has a midline cleft with a depth that varies with the severity of the fusion anomaly. Data from collected series of women with bicornuate uteri reveal miscarriage and overall fetal loss rates of approximately 30% and 40%, respectively.<sup>186</sup> Preterm delivery risks decrease as the size of the common lower uterine cavity increases.<sup>190</sup> **Although the benefits of unification procedures have not been systematically evaluated, surgery generally is considered unnecessary and best reserved for those with a well-established history of otherwise unexplained recurrent pregnancy loss or preivable births.**<sup>186</sup> The Strassman abdominal metroplasty is the surgical procedure of choice, and comparisons between pregnancy outcomes before and after unification suggest that surgery can benefit carefully selected women.<sup>191,192</sup> The incidence of cervical incompetence associated with congenital uterine anomalies is reportedly highest for those having a bicornuate uterus, and there is evidence from case series that cervical cerclage can improve fetal survival rates.<sup>193,194</sup>

A septate uterus results from incomplete resorption of the medial septum separating the two otherwise normally fused hemiuteri. Septum resorption normally occurs only after urologic development is completed; the prevalence of urinary tract anomalies, therefore, is not increased in women with septate uteri. The septate uterus is by far the most common uterine developmental anomaly, accounting for 80–90% of all major malformations in both women with recurrent pregnancy loss (3.5% prevalence) and in the general population.<sup>165,180,182,195</sup> It is also the malformation most highly associated with poor pregnancy outcomes.<sup>165,196</sup> Data from numerous case series indicate that the miscarriage rate associated with septate uteri is approximately 65%.<sup>186</sup> Uterine septa associated with recurrent pregnancy loss are not broader or longer than those observed in women with normal reproductive histories. However, the size of the unaffected cavity (bounded by the leading edge of the septum above and the internal cervical os below) is smaller in women with recurrent pregnancy loss,<sup>176</sup> an observation lending credence to the hypothesis that implantation on a poorly vascularized septum predisposes to pregnancy loss.<sup>197,198,199</sup> Although uterine septa are not always associated with a poor

pregnancy outcome, their discovery in women with recurrent pregnancy loss provides an indication for surgical correction. **Hysteroscopic septoplasty is a relatively brief and straightforward outpatient endoscopic procedure associated with low morbidity and dramatically improved postoperative pregnancy outcomes (80% term delivery, 5% preterm delivery, 15% pregnancy loss).**<sup>165,186</sup> Hysteroscopic septoplasty can be performed using microscissors, any of a variety of electrosurgical instruments, or laser, and excellent results can be achieved with all methods.<sup>165</sup> With few exceptions, only incision rather than excision is required because the septum typically retracts, leaving little if any residual. The procedure usually is complete when both tubal ostia can be viewed at the same time. It is useful to remember that an arcuate uterus is generally regarded as a normal variant and that residual septa measuring less than 1 cm in size have no adverse effect on pregnancy outcome.<sup>200</sup>

Nearly 70% of women exposed to DES in utero have a developmental uterine abnormality.<sup>201</sup> The T-shaped uterine cavity is the single most common malformation; others include a hypoplastic uterus, constriction rings, and irregular intrauterine filling defects. Although the use of DES in pregnancy was banned in 1971 because of an observed association with vaginal clear cell adenocarcinoma and most exposed women are now beyond their reproductive years,<sup>202</sup> affected women are still occasionally encountered. In utero DES-exposed women are at increased risk of adverse pregnancy outcomes, including a twofold higher risk of spontaneous miscarriage (approximately 24%) and a dramatic ninefold higher risk of ectopic pregnancy.<sup>203</sup> Structural changes in cervical collagen content may predispose affected women to cervical incompetence, and data from nonrandomized clinical trials suggest cerclage warrants serious consideration in women with history of second-trimester loss or preterm delivery.<sup>204,205</sup>

# Uterine Leiomyomas

There is no substantial evidence implicating uterine myomas as a cause of recurrent pregnancy loss. What evidence does exist derives from case series comparing reproductive outcomes before and after myomectomy.<sup>206,207,208</sup> All of the mechanisms proposed to explain how myomas might predispose to recurrent pregnancy loss relate to the consequences of poor regional blood flow, abnormal vasculature, and inadequate decidual cell response.<sup>209,210,211,212</sup> Numerous studies have examined the effect of uterine fibroids on fertility (Chapters 3 and 25), but none has specifically examined the effect of myomas on pregnancy outcome in **fertile** women. The best available data come from a series of studies designed to examine the effect of uterine myomas on outcomes achieved with IVF in infertile women.<sup>213</sup> On balance, these data suggest that miscarriage and pregnancy outcomes, like pregnancy and implantation rates, are adversely affected by submucous myomas, but not by subserosal myomas under 5–7 cm in size.<sup>214,215,216,217,218</sup> Evidence regarding the impact of intramural myomas on fertility and miscarriage is less substantial but nevertheless points to lower clinical pregnancy rates, implantation rates, and ongoing pregnancy/live birth rates and significantly higher miscarriage rates.<sup>218</sup> Even if intramural fibroids do indeed decrease fertility, evidence is scarce whether their removal will reverse the process and normalize fertility or miscarriage rates or even be beneficial to the patient. Consequently, management recommendations for women with recurrent pregnancy loss and uterine myomas are comparable to those for infertile women with uterine myomas.

In general, when submucous myomas are single and small, the likely benefits of hysteroscopic myomectomy outweigh the few associated risks.<sup>219,220,221,222,223</sup> When submucous myomas are multiple or large, hysteroscopic myomectomy is more technically challenging and has greater risks, including sterility resulting from severe postoperative intrauterine adhesions; however, this may be the best option for the patient; GnRH therapies may reduce fibroids to a manageable size prior to surgical intervention. When submucous myomas extend deeply into the myometrium, treatment options include subtotal hysteroscopic myomectomy and abdominal myomectomy. When myomas have definite but limited impact on the uterine cavity, the decision to delay or to proceed with surgical treatment may vary, depending on age, reproductive history, size and location of myomas, and the complexity of any other treatments required. **When myomas do not encroach on or distort the uterine cavity, surgery is not indicated in the absence of other specific symptoms attributable to myomas that demand treatment in and of themselves.**

# Intrauterine Adhesions (Asherman Syndrome)

Recurrent pregnancy loss is one possible result of intrauterine adhesions, but menstrual disorders (hypomenorrhea, amenorrhea, dysmenorrhea) and infertility are the more common clinical presentations.<sup>224,225</sup> Any insult severe enough to remove or destroy endometrium can cause intrauterine adhesions, and the gravid uterus seems particularly susceptible to injury.<sup>226,227</sup> Considering that pregnancy loss is among the most common indications for uterine curettage, intrauterine adhesions can first result from and then become a contributing cause of recurrent pregnancy loss. Mechanisms by which intrauterine adhesions can cause recurrent pregnancy loss include a decreased functional intrauterine volume and endometrial fibrosis and inflammation that can predispose to placental insufficiency.<sup>192</sup> The pregnancy outcomes of women with intrauterine adhesions are generally poor (40–80% ending in spontaneous miscarriage and approximately 25% in preterm delivery) and much improved after adhesiolysis (50–90% ending in term delivery, 7–23% ending in miscarriage); the prognosis generally correlates with the severity of disease.<sup>225,226,228,229,230,231</sup>

Hysteroscopy provides the means to confirm a diagnosis of intrauterine adhesions suggested by sonohysterography or HSG and is also the method of choice for treatment, being both safer and more effective than blind curettage. The hysteroscopic appearance of adhesions of varying severity, techniques for lysis, operative risks, and adjuvant therapies are described in detail in [Chapter 25](#).

# **Summary of Key Facts Relating to Anatomic Factors**

**Congenital and acquired uterine abnormalities predispose to an increased risk of pregnancy loss and can be identified by sonohysterography or traditional HSG; magnetic resonance imaging or three-dimensional ultrasound may be required to accurately differentiate septate and bicornuate uteri. The septate uterus is the most common müllerian anomaly, the one most closely correlated with pregnancy loss, and the malformation most easily and successfully corrected; hysteroscopic septoplasty is indicated in women with recurrent pregnancy loss and having a septate uterus. Abdominal metroplasty procedures are rarely indicated for women with a uterus didelphys or a bicornuate uterus. Cervical cerclage may help to improve pregnancy outcomes in women with bicornuate uteri and in those with a unicornuate uterus or a uterus didelphys who have a history of previable delivery or exhibit progressive cervical shortening during early pregnancy. The prevalence of urinary tract abnormalities is increased in women having a unicornuate or bicornuate uterus or a uterus didelphys, but not in those having a septate uterus. Uterine leiomyomas are often identified in women with recurrent pregnancy loss, but only submucous myomas and intramural fibroids that clearly encroach upon or displace the uterine cavity are relevant. Intrauterine adhesions are an uncommon but established cause of recurrent miscarriage; pregnancy outcomes are much improved after hysteroscopic lysis.**

# IMMUNOLOGIC FACTORS

---

Both autoimmune and alloimmune mechanisms have been implicated as causes of recurrent pregnancy loss. Autoimmune disorders involve an immune response directed against a specific part of the host or self; those that have been linked to recurrent pregnancy loss include certain classic autoimmune diseases like systemic lupus erythematosus and the antiphospholipid syndrome. Alloimmune disorders involve an abnormal maternal immune response to fetal or placental antigens; possibilities include maternal cytotoxic antibodies, absent maternal blocking antibodies, and disturbances in natural killer (NK) cell function and distribution.

# Autoimmune Disorders

Systemic lupus erythematosus has long been associated with pregnancy loss. Data from a number of case series suggest that the risk for loss is approximately 20%, all excess risk being attributable to losses occurring during the second and third trimester of pregnancy.<sup>232</sup> Early spontaneous miscarriages are no more common in women with systemic lupus than in the general population, but the incidence of later losses (6%) is 2–4 times higher.<sup>233</sup> Almost all fetal deaths that occur in women with systemic lupus are associated with antiphospholipid antibodies; they are the most sensitive indicator of fetal distress or death.<sup>234,235,236</sup> Active disease at conception, onset of systemic lupus erythematosus during pregnancy, and renal disease also increase the risk for pregnancy loss.<sup>233</sup> Careful monitoring and timely interventions can improve pregnancy outcomes.<sup>237,238</sup> Treatment aimed at preventing pregnancy loss in women with systemic lupus and antiphospholipid antibodies is similar to that for women with antiphospholipid syndrome, which is discussed later. In general, women with active systemic lupus erythematosus should be advised to delay conception until remission can be established, those with moderate renal insufficiency must be advised of the increased risk for pregnancy loss, and women with severe renal insufficiency should be encouraged to avoid pregnancy; even successful pregnancies are at increased risk for preeclampsia and preterm delivery.<sup>233</sup>

**Antiphospholipid syndrome** is an autoimmune disorder having specific clinical and laboratory features; diagnosis requires at least one of each.<sup>239,240</sup> The clinical diagnostic criteria include thromboembolic events (arterial, venous, small vessel) and pregnancy loss (three or more consecutive losses at less than 10 weeks' gestation, a fetal death after 10 weeks, premature birth at less than 34 weeks associated with severe preeclampsia or placental insufficiency). There are also three laboratory diagnostic criteria. One is the lupus anticoagulant, revealed by delayed clotting in phospholipid-dependent coagulation tests (activated partial thromboplastin time, kaolin clotting time, dilute Russell's viper venom time), corrected by addition of excess phospholipid but not by platelet-poor plasma.<sup>241</sup> The second is the demonstration of moderate to high levels of anticardiolipin antibodies (IgG or IgM); low levels may be observed in 3–5% of normal individuals and are of uncertain significance.<sup>242</sup> More recently, a high titer of antibodies to  $\beta$ 2-glycoprotein 1 is also considered sufficient to establish the diagnosis.<sup>243</sup> Abnormal laboratory test results must be observed on at least two separate occasions at least 12 weeks apart.

**The international consensus definition for the diagnosis of antiphospholipid syndrome is noted in Table 30.2.<sup>244</sup> The diagnosis requires one of the clinical criteria and one of the laboratory findings.**

## TABLE 30.2 Diagnosis of Antiphospholipid Syndrome

<b>Clinical criteria</b>	<ul style="list-style-type: none"><li>• Vascular thrombosis</li><li>• Pregnancy morbidity:<ul style="list-style-type: none"><li>○ One or more losses after the 10th week of a morphologically normal fetus</li><li>○ One or more premature births of a normal neonate before the 34th week because of preeclampsia or eclampsia or placental insufficiency</li><li>○ Three or more unexplained consecutive early miscarriages</li></ul></li></ul>
<b>Laboratory tests</b>	<ul style="list-style-type: none"><li>• Lupus anticoagulant present on two or more occasions at least 12 weeks apart</li><li>• Anticardiolipin antibody of IgG or IgM isotype in medium to high titer on two or more occasions at least 12 weeks apart</li><li>• Anti-<math>\beta</math>2-glycoprotein 1 antibody of IgG or IgM isotype in 99th percentile titer on two or more occasions at least 12 weeks apart</li></ul>

Derived from Miyakis S, Lockshin MD, Atsumi T, Branch DW, Brey RL, Cervera R, Derksen RH, De Groot PG, Koike T, Meroni PL, Rebar G, Schoenfeld Y, Tincani A, Vlachoyiannopoulos PG, Krilis SA, International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS), *J Thromb Haemost* 4:295, 2006.244

Although the prevalence of antiphospholipid syndrome among all women with recurrent pregnancy loss is quite low (3–5%),<sup>245</sup> the disorder is nonetheless a potentially treatable cause of recurrent pregnancy loss. **Tests for the detection of a lupus anticoagulant and antiphospholipid antibodies specified above are minimally invasive, relatively inexpensive, and, therefore, justified in the evaluation of most if not all women with recurrent pregnancy loss.**<sup>233</sup> Tests to detect other antibodies associated with this syndrome (antiannexin, antiphosphatidylserine, antiphosphatidylethanolamine, antibodies to plasminogen and plasminogen activator, and others) have been advocated in the evaluation of women with recurrent pregnancy loss but provide no important additional information.<sup>233</sup> Assays for antiphospholipid antibodies other than lupus anticoagulant, anticardiolipin, and anti- $\beta$ 2-glycoprotein 1 have not been standardized or extensively studied, their clinical relevance (independent of lupus anticoagulant, anticardiolipin, and anti- $\beta$ 2-glycoprotein 1) has not been established, and many apparently healthy women have low levels of circulating antiphospholipid antibodies.<sup>233,241,242,246</sup>

The evidence implicating antiphospholipid antibodies as a predisposing factor in recurrent pregnancy loss is largely circumstantial but nonetheless fairly compelling. A small but still important number of women with recurrent pregnancy loss have circulating antiphospholipid antibodies.<sup>233</sup> Women with antiphospholipid antibodies identified by screening in early gestation have an increased rate of pregnancy loss.<sup>247,248</sup> They also exhibit an unusually high rate of loss in subsequent pregnancies, even when treated.<sup>249,250,251,252</sup> Additional evidence comes from animal models; passive

immunization with IgG antiphospholipid antibodies from women with antiphospholipid syndrome induces abortion in mice. Antiphospholipid syndrome can be found in association with systemic lupus erythematosus or in women with no other evidence of autoimmune disease.<sup>253,254,255</sup>

In contrast to observations in most series of women with recurrent pregnancy loss, between one-third and three-fourths of pregnancy losses related to antiphospholipid syndrome are fetal deaths (after 10 weeks' gestation).<sup>249,256,257</sup> Frequently, fetal death is preceded by observations of poor fetal growth, oligohydramnios, heart rate abnormalities and preeclampsia or eclampsia, all of which might reflect hypoxemia resulting from placental insufficiency.

Several mechanisms have been proposed to explain the clinical manifestations associated with aPL. Evidence indicates that antiphospholipid antibodies are directed against platelets (promoting adhesion) and the vascular endothelium (where alterations in prostacyclin/thromboxane metabolism cause vasoconstriction),<sup>258,259</sup> both mechanisms predisposing to thrombosis. Circulating antiphospholipid antibodies have also been linked to reduced levels of an antithrombotic phospholipid-binding protein on the surface of trophoblasts and endothelial cells (annexin V).<sup>260,261</sup> Clustering of annexin A5 on phospholipid surface results in displacement of clotting factor Va, creating an anticoagulant shield. Not surprisingly, spiral arteriolar vasculopathy can often be demonstrated or, in severe cases, placental infarctions.<sup>262</sup> The binding of antiphospholipid antibodies to trophoblast cells reduces proliferation and invasion, as well as the release of hCG. In decidual tissue, antiphospholipid antibodies reduce the production of vascular endothelial growth factor (VEGF) and matrix metalloproteinases and the formation of new blood vessels.<sup>263</sup>

Thrombosis in the placental circulation is a plausible mechanism for late pregnancy loss in women with antiphospholipid syndrome, but does not explain losses that occur before 10 weeks' gestation when maternal arterial connections with the intervillous space become established. Recent evidence suggests that another mechanism relating to abnormalities of early trophoblast invasion may be involved, in both early and late pregnancy losses.<sup>264</sup> In normal early pregnancy, extravillous trophoblast invades the decidual vessels, first forming plugs that later dissociate as the trophoblast migrates along the maternal arterial circulation converting the uteroplacental vessels into a low-resistance circuit.<sup>265</sup> Defective trophoblast invasion of the uteroplacental arteries has been well described in association with later pregnancy complications, including preeclampsia and fetal growth restriction. Antiphospholipid antibodies on the surface of the trophoblast or maternal vessel walls may inhibit endovascular trophoblast invasion, preventing formation of plugs that normally serve to limit intervillous blood flow and prevent pressure-induced or oxidative damage to the trophoblast during early placental

development. Alternatively, antiphospholipid antibodies may damage the trophoblast directly. Either way, abnormal endovascular trophoblast invasion could explain early miscarriages in women with antiphospholipid syndrome and, in less severe cases, the development of later pregnancy complications relating to uteroplacental vascular insufficiency.<sup>264</sup> The pathophysiology involves inflammation at the maternal-fetal interface, preventing normal trophoblast development and function.<sup>266</sup> Activation of the complement cascade has attracted much attention in recent years in the context of inflammation and obstetrical antiphospholipid syndrome. Inflammation is now believed to be at the core of the pathogenesis of this syndrome, and tissue injury is speculated to be the result of complement-mediated inflammatory reaction in addition to thrombosis. Findings from animal models of aPL-induced pregnancy loss and increased injury-induced thrombosis argue that complement factor C3 and C5 are essential proximal mediators of tissue injury to the developing fetal-placental unit.<sup>267</sup>

Treatments for antiphospholipid syndrome have included antiplatelet agents (aspirin), anticoagulants (heparin), and immunosuppressive therapies (prednisone, intravenous immunoglobulins). Whereas most studies have found heparin therapy more effective than aspirin and combined treatment with aspirin and heparin superior to treatment with either alone,<sup>248,251,268,270,270</sup> two trials found that heparin did not further improve the outcomes achieved with aspirin.<sup>271,272</sup> A typical combined treatment regimen includes aspirin (75–85 mg/day), beginning with attempts at conception, and unfractionated heparin (UFH) (5,000–10,000 subcutaneous twice daily), beginning at first indication of pregnancy. Live birth rates for women with antiphospholipid syndrome who receive combined treatment with aspirin and UFH during pregnancy (70–80%) are much improved over those observed in women who receive aspirin treatment or no treatment (20–40%).<sup>268,269,273,274,275</sup> However, treatment does not eliminate the high risk for pregnancy complications (preterm labor, premature rupture of membranes, intrauterine growth restriction and fetal demise, preeclampsia, and placental abruption) and poses additional risks for the mother (gastric bleeding, osteopenia).<sup>269,273</sup> Randomized clinical trials have demonstrated that aspirin and heparin treatment of women with two or more consecutive pregnancy losses in the **absence** of evidence for the antiphospholipid syndrome (unexplained recurrent miscarriages) yields no benefit.<sup>276,277</sup>

Low molecular weight heparin (LMWH) offers a number of advantages over UFH. It has an increased antithrombotic ratio (preventing abnormal clotting with fewer bleeding side effects) and is associated with a lower incidence of both thrombocytopenia and osteopenia; the relatively longer half-life of LMWH also permits less frequent dosing and requires less frequent monitoring, both improving compliance.<sup>278</sup> Although experience with LMWH in pregnancy is relatively limited,

interventional trials among women with recurrent pregnancy loss and antiphospholipid syndrome and other acquired thrombophilias suggest it is both safe and effective.<sup>251,279,280,281</sup> When LMWH and aspirin treatment was directly compared with UFH and aspirin treatment, there were no differences in pregnancy outcome.<sup>282,283</sup> Therefore, both UFH with aspirin and LMWH with aspirin treatment can be utilized for women with aPL and RPL. Prednisone may have some efficacy in the treatment of women with recurrent pregnancy loss and antiphospholipid syndrome, but its risks (diabetes, hypertension, preterm delivery) outweigh its benefits.<sup>284,285</sup> Combined treatment with aspirin and heparin is effective and also safer. Intravenous immunoglobulins have also been used to treat women with recurrent pregnancy loss and antiphospholipid syndrome. Overall, there is evidence from randomized clinical trials for a significant increase in live births following intravenous immunoglobulin G (IVIg) in women with secondary recurrent miscarriage, but there is insufficient evidence to support its use in primary recurrent pregnancy loss.<sup>286</sup> The efficacy of IVIg has not been compared directly to heparin/aspirin or LMWH/aspirin.<sup>287,288</sup>

Although an increased prevalence of antithyroid antibodies and antinuclear antibodies has been observed in women with recurrent pregnancy loss, their relevance is uncertain because neither predicts subsequent pregnancy outcome, and there is no logical and proven effective treatment to offer.<sup>233,289,290</sup> Treatment with levothyroxine in thyroid antibody-positive women undergoing assisted reproduction technologies had no impact on outcomes.<sup>291</sup> Of course, if TSH levels are elevated, even in the range of subclinical hypothyroidism, as discussed later in this chapter, treatment is indicated. Tests to detect antinuclear and antithyroid antibodies have no clinical utility in euthyroid women with recurrent pregnancy loss. However, women with thyroid antibodies have a significant risk of becoming hypothyroid as pregnancy progresses and also an increased risk of postpartum thyroiditis.<sup>292</sup>

An uncommon autoimmune condition, celiac disease, may be linked with recurrent miscarriages and may require appropriate antibody testing in its subclinical form.<sup>293</sup> Another unusual cause of recurrent miscarriages is antibody formation related to a rare blood group, P type. Patients with this condition treated with plasmapheresis have achieved successful pregnancies.<sup>294</sup>

## **Summary of Key Facts Relating to Autoimmune Factors**

**Autoimmune diseases like systemic lupus erythematosus and the antiphospholipid syndrome are identifiable and treatable immunologic disorders associated with recurrent pregnancy loss. A variety of mechanisms can explain how antiphospholipid antibodies predispose to placental thrombosis or interfere with**

**normal development of the uteroplacental circulation to cause both early and late pregnancy losses. At the present time, assays for the lupus anticoagulant, anticardiolipin antibodies, and anti- $\beta$ 2-glycoprotein 1 antibodies are the only validated immunologic tests having clinical utility in the evaluation of women with recurrent pregnancy loss. As yet, assays for other antiphospholipid antibodies have no proven value. Combined aspirin and heparin therapy has proven effectiveness and is the preferred treatment for women with recurrent pregnancy loss associated with antiphospholipid syndrome. Aspirin in combination with either UFH or LMWH has similar efficacy in treatment of women with recurrent pregnancy loss associated with antiphospholipid syndrome.**

# Alloimmune Disorders

In theory, normal pregnancy requires maternal immunologic recognition and response to paternally derived antigens on embryonic tissues, and abnormalities in the maternal alloimmune response may predispose to or cause recurrent pregnancy loss. Suggested mechanisms have included maternal production of cytotoxic antibodies, maternal failure to produce blocking antibodies to prevent a maternal cell-mediated immune attack (possibly because mother and father are too antigenically similar), and cytokine dysregulation of immune mechanisms operating at the maternal-fetal interface.

Antipaternal lymphocytotoxic antibodies have been proposed as a cause of recurrent pregnancy loss.<sup>295</sup> However, they are also present in many women with normal pregnancies and are more prevalent in fertile couples than in those with recurrent pregnancy loss.<sup>296,297</sup> These observations have led most to conclude that lymphocytotoxic antibodies reflect the number and duration of pregnancies and have no effect on subsequent pregnancy outcome.<sup>297,298</sup>

In contrast to the cytotoxic antibody theory, the maternal blocking antibody theory of recurrent pregnancy loss holds that maternal failure to recognize and respond to fetal antigens by production of blocking factors (presumably antibodies) leaves the embryo exposed to a lethal cell-mediated immune rejection.<sup>299</sup> A poor maternal response to paternal cells in mixed lymphocyte culture was regarded as evidence for the putative immune deficiency in women with recurrent pregnancy loss.<sup>300</sup> However, blocking antibodies were not always detectable in women with normal pregnancies<sup>300</sup> but frequently were detected in women with recurrent pregnancy loss,<sup>301</sup> and their presence does not accurately predict subsequent pregnancy outcome.<sup>298</sup> Again, these effects are more likely to reflect the results of previous pregnancies than to explain their outcomes.<sup>297,302</sup>

Increased sharing of major histocompatibility complex human leukocyte antigens (HLA) between mother and father was seen as one factor that might hamper maternal recognition of paternally derived fetal antigens and production of presumed essential blocking antibodies.<sup>299</sup> Numerous studies have examined HLA sharing in couples with recurrent pregnancy loss, but results have varied widely.<sup>302</sup> The best evidence that increased HLA sharing might predispose to recurrent pregnancy loss came from a study in the Hutterites, a highly inbred religious sect wherein HLA sharing was associated with increased risk for pregnancy loss, but in outbred populations at low risk for HLA homogeneity, HLA sharing does not predict pregnancy outcome and testing has no clinical utility.<sup>303,304</sup> Indeed, in a subsequent study of the Hutterites, genotyping for HLA loci (the previous study was with serologic measurements) could not detect any

influence of HLA haplotypes on fetal loss.<sup>305</sup>

Human leukocyte antigen-G (HLA-G) blocks killer cell activity by binding to killer cell receptors. Sequencing of the HLA-G gene indicated a variety of differences in women with recurrent pregnancy losses, polymorphisms that could account for lowered levels of HLA-G and an increased risk of miscarriage.<sup>306,307</sup> In time, this type of genetic profiling could delineate specific molecular mechanisms for fetal rejection.

The idea that successful pregnancy requires some type of maternal immune suppression remains attractive. The most recent concept to emerge has implicated dysregulation of local immune functions at the maternal-fetal interface as a cause of recurrent pregnancy loss. Investigations have focused on a unique population of large granular lymphocytes related to NK cells that predominate in the decidua and on the patterns of cytokine secretion by maternal immune cells in response to trophoblast antigens.

The large granular lymphocytes present in the early pregnancy decidua appear to be regulated by both hormone changes and trophoblast invasion.<sup>308,309</sup> Increased numbers of these decidual NK cells have been observed in mouse models of recurrent pregnancy loss, and the abortion rate in mice increases when NK cells are activated and decreases when they are depleted.<sup>310,311</sup> Later studies in mice lacking all lymphocytes, including NK cells, showed distinct histologic changes and lack of spiral arterial modification in implantation sites, suggesting that NK cells are involved in decidual angiogenesis.<sup>312,313</sup> However, despite these features, litters of normal size are born apparently due to a series of maternal and cardiovascular growth adjustments.<sup>314</sup> Thus, NK cell functions in pregnancy are still poorly defined. In women with recurrent pregnancy loss, increased decidual NK cell activity has been observed,<sup>315,316</sup> and increased numbers of peripheral NK cells have been associated with subsequent pregnancy failure.<sup>317,318</sup> However, whether changes in peripheral NK cells mirror those occurring in the decidua and whether changes observed in the decidua are the result or the cause of pregnancy loss remain unclear.<sup>319,320</sup>

Antigen-stimulated immune responses involving T-helper lymphocytes are of two basic varieties that reflect the environment in which the cells mature and differentiate; those exposed to interferon (INF)- $\gamma$  become T-helper lymphocyte-1 cells, and those exposed to interleukin (IL)-4 become T-helper lymphocyte-2 cells.<sup>321,322</sup> T-helper lymphocyte-1 cell responses are associated with inflammation and typically characterized by the release of INF- $\gamma$  and IL-12, IL-2, and tumor necrosis factor (TNF)- $\alpha$ . T-helper lymphocyte-2 cell responses are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6.<sup>323,324</sup> TNF- $\alpha$  can be secreted by both T-helper lymphocyte-1 and T-helper lymphocyte-2 cells but is usually associated with a T-helper

lymphocyte-1 response.<sup>324</sup> TNF- $\alpha$  variant polymorphisms have been identified in women with recurrent miscarriages.<sup>324,325</sup> Whereas most women with normal pregnancies appear to have a predominant T-helper lymphocyte-2 immune response to undefined trophoblast antigens, some women with recurrent pregnancy loss exhibit a T-helper lymphocyte-1 inflammatory response that may be harmful to an implanting embryo.<sup>327,328,329,330,331</sup>

Approximately 15–20% of women with unexplained recurrent pregnancy loss exhibit an abnormal T-helper lymphocyte-1 cellular immune response to trophoblast antigens in vitro, compared to less than 3% of women with normal reproductive histories.<sup>327,328,329,332,333,334</sup> CD4(+)CD25(+) T cells play a role in preventing fetal rejection; the proportion of these cells is lower in decidua and blood obtained from women with recurrent miscarriages.<sup>335,336</sup> Once again, whether the cytokine secretory patterns of peripheral lymphocytes accurately reflect what is occurring at the maternal-fetal interface and whether T-helper lymphocyte-1 response patterns are the cause or the effect of pregnancy loss remain uncertain and controversial.

Studies have assessed cytokine expression in trophoblast tissue, assuming that altered expression would be a marker for fetal rejection. Indeed, IL expression is increased in placental tissue obtained from patients with recurrent miscarriages,<sup>337</sup> but again, it is difficult to know whether this is a primary or secondary event. Researches for cytokine polymorphisms in women with recurrent miscarriages have not been fruitful.<sup>338,339,340,341</sup>

The idea that abnormal maternal cellular or humoral immune responses to trophoblast antigens may be a cause of recurrent pregnancy loss has stimulated development of two distinctly different immunotherapies for women with unexplained and presumed alloimmune-mediated recurrent pregnancy loss, one immunostimulatory (paternal leukocyte immunization) and the other immunosuppressive (intravenous immunoglobulins).

Paternal leukocyte immunization is based on the beneficial effects that donor or third-party leukocytes have on allograft rejection in transplant patients and evidence that it may decrease the number of circulating NK cells in women with recurrent pregnancy loss.<sup>342</sup> Numerous small randomized and nonrandomized trials and meta-analyses yielded widely varying and conflicting results. Altogether, they suggested that, at best, a relatively small treatment effect (8–10% improvement in live birth rate) had to be weighed against the costs and risks of treatment (injection site reactions, fever, myalgias, platelet and erythrocyte alloimmunization).<sup>302</sup> **A large randomized controlled multicenter trial found no evidence that paternal leukocyte immunization was effective in the treatment of unexplained recurrent pregnancy**

loss, regardless of maternal age, number of previous miscarriages, and whether the couple had a previous live birth, and concluded that paternal leukocyte immunization should not be offered as treatment for recurrent pregnancy loss.<sup>343</sup> A comprehensive meta-analysis of treatment trials drew the same conclusion.<sup>344</sup>

Intravenous immunoglobulins are prepared by isolating and pooling immunoglobulin proteins from the serum of a large number of volunteer blood donors (up to 150 donors per vial) and generally may be regarded as immunosuppressive, acting through a number of different mechanisms.<sup>345</sup> Intravenous immunoglobulins treatment is costly, requires a number of intravenous infusions over the course of pregnancy, and carries risks including transmission of infections (viruses, prions) and anaphylaxis.<sup>346</sup> **A substantial number of randomized trials of intravenous immunoglobulins therapy in women with unexplained recurrent pregnancy loss have now been conducted. Taken together, the results failed to demonstrate that intravenous immunoglobulins are effective in improving pregnancy outcomes for women with unexplained recurrent pregnancy loss.**<sup>302,344,347</sup>

A Cochrane review of randomized trials (12 trials, 641 women) concluded that immunotherapy (including paternal leukocyte immunization, intravenous immune globulin, third-party donor leukocytes, and trophoblast membranes) did not improve the live birth rate compared with placebo treatment.<sup>348</sup>

New treatment options include TNF-inhibiting factor and granulocyte colony-stimulating factor (GCSF). The administration of the cytokine GCSF in a small clinical trial improved the live birth rate in women with recurrent miscarriages, while no beneficial effect on live birth was observed in another study.<sup>349,350</sup>

## **Summary of Key Facts Relating to Alloimmune Factors**

**Maternal immune recognition and response doubtless play an important role in normal pregnancy, and alloimmune disorders may be a cause of otherwise unexplained recurrent pregnancy loss. At present, cytokine dysregulation of immune mechanisms operating at the maternal-fetal interface is the most likely pathophysiologic mechanism involved. However, all current methods for the evaluation of suspected alloimmunopathology, including HLA testing, immune cell evaluation (mixed lymphocyte culture, natural killer cell assays), and cytokine testing (to differentiate those with T-helper lymphocyte-1 and T-helper lymphocyte-2 patterns of immune responses to trophoblast antigens in vitro), must be considered investigational. Furthermore, neither of the two principal immunotherapies advocated for the treatment of presumed alloimmune disorders in**

**women with unexplained recurrent pregnancy loss (paternal leukocyte immunization, intravenous immunoglobulins) has proven effective.**

# INHERITED THROMBOPHILIAS

---

Interest in inherited thrombophilias as a potential cause of recurrent pregnancy loss emerged quite naturally after antiphospholipid syndrome (an acquired thrombophilia) was established as a significant and treatable cause of recurrent pregnancy loss. The pathophysiologic concept is the same: in some women with recurrent pregnancy loss, the thrombogenic changes of pregnancy exaggerate an inherent predisposition to thrombosis, resulting in reduced uteroplacental blood flow, placental thrombosis, and pregnancy loss. Although **there is little argument that pregnancy is a thrombogenic state and** an association between hereditary thrombophilias and fetal loss has been suggested, recent prospective cohort studies have failed to confirm such an association, raising doubt on **the importance of inherited thrombophilias as a cause of recurrent pregnancy loss.**

Viewed simply, pathologic thrombosis results from an imbalance between coagulation and fibrinolysis, reflecting an imbalance between clotting factors, anticoagulant proteins (protein C, protein S, antithrombin III), and fibrinolytic mechanisms. Normal pregnancy is a hypercoagulable state characterized by increased levels of factors V, VII, VIII, and X and fibrinogen, decreased levels of protein S, increased resistance to activated protein C, higher concentrations of plasminogen activator inhibitors (PAI), and an increased tendency to platelet aggregation, all promoting thrombosis ([Table 30.3](#)).

A variety of genetic mutations may result in an inherited predisposition to thrombosis. Among these, the factor V Leiden mutation (G → A at nucleotide 1691)<sup>351,352</sup> and another involving the prothrombin gene (G → A at nucleotide 20210)<sup>353</sup> are the most common. A third relatively common mutation involves the gene encoding the enzyme methylene tetrahydrofolate reductase (C → T at nucleotide 677); homozygotes are predisposed to hyperhomocysteinemia, a known risk factor for thrombosis.<sup>354</sup> Other established inherited thrombophilias include deficiencies of antithrombin III, protein S, and protein C. A deficiency of factor XII (involved in both coagulation and fibrinolysis) is yet another abnormality implicated as predisposing to thrombosis and pregnancy loss.<sup>355</sup>

Protein C is a key component in the anticoagulant pathway and, when activated, inhibits the actions of clotting factors V and VIII; protein S serves as a cofactor to facilitate the actions of activated protein C. Resistance to the anticoagulant properties of activated protein C can be inherited or acquired and, in either case, results in increased

thrombin generation and a hypercoagulable state. Approximately 95% of activated protein C resistance is related to the factor V Leiden mutation, which yields an altered form of factor V that is resistant to the action of activated protein C.<sup>264,356</sup> The prevalence of the factor V Leiden mutation varies between 2% and 10% in Western populations. The risk of systemic thrombosis is increased fivefold in heterozygotes and is 80 times higher in those who are homozygous for the mutation.<sup>264</sup> In some individuals, resistance to activated protein C is acquired rather than inherited.

All risk factors for thrombosis increase risk for pregnancy complications related to thrombosis, including miscarriage, preeclampsia, placental abruption, intrauterine growth restriction, and stillbirth. The association between thrombophilias and pregnancy loss varies with the type of pregnancy loss (early, late) and the thrombophilia. A meta-analysis including data from 31 studies found that although thrombophilias are associated with both early and late pregnancy loss, the association is stronger for second-trimester and later losses than for early miscarriage.<sup>357</sup> The observation is not surprising when one considers that maternal intervillous blood flow does not develop to any appreciable degree before approximately 8 weeks' gestation (at the earliest); thrombosis related to thrombophilia, therefore, is less likely to explain earlier pregnancy losses.<sup>358</sup> The association between thrombophilias and pregnancy loss is also stronger for factor V Leiden, the prothrombin gene mutation, and protein S deficiency than for other thrombophilic defects.<sup>357,359</sup>

Numerous studies have compared the prevalence of various thrombophilias in women with recurrent pregnancy loss to those in parous controls, with conflicting results. Some have observed an increased prevalence of thrombophilias among women with recurrent pregnancy loss and others have not.<sup>359,360,361,362,363,364,365</sup> In one study of 1,000 consecutive Caucasian women with recurrent pregnancy loss, the prevalence of the factor V Leiden mutation in women with early (3.3%) and late pregnancy loss (3.9%) was similar to that observed in a parous control group (4.0%), but the prevalence of acquired activated protein C resistance was significantly greater among women with both early (8.8%) and late miscarriages (8.7%) than in normal parous controls (3.3%).<sup>367</sup> These observations suggest that acquired thrombophilias may be as or even more important than inherited defects as a cause of recurrent pregnancy loss.

Another group of studies has taken the opposite approach and examined the past reproductive performance of women known to carry thrombophilias and, in general, found a relatively strong relationship between maternal thrombophilic defects and adverse late pregnancy outcomes.<sup>368,369</sup> In a prospective study, the live birth rate observed among untreated women with a history of recurrent pregnancy loss or late pregnancy loss and heterozygous for the factor V Leiden allele (38%) was substantially lower than among women with similar reproductive histories having a normal factor V

genotype (69%).<sup>358</sup> Whereas pregnancy losses among women with recurrent pregnancy loss and factor V Leiden occurred both early and late, all losses observed among women without the thrombophilia occurred before 12 weeks' gestation. **The available evidence suggests that thrombophilias predispose to a higher risk of both early and late pregnancy losses.**<sup>370,371</sup> **However, they also demonstrate that reproductive performance is entirely normal for many women who carry thrombophilia. At the present time, it cannot be established who among women with recurrent pregnancy loss that carry thrombophilia is truly at increased risk for pregnancy loss.**

The risk of systemic thrombosis rises when more than one inherited thrombophilia is present, and evidence indicates that the same may be true for the risk of adverse pregnancy outcomes relating to maternal thrombophilias.<sup>368,369,371</sup> The genotype of the embryo or fetus may also have important influence on the risk of pregnancy loss in women with thrombophilias; placental infarction has been observed more often when the fetus also carries the factor V Leiden allele than when it has a normal factor V genotype.<sup>372</sup>

**Routine testing of women with recurrent pregnancy loss for inherited thrombophilias is not currently recommended (ASRM 2012). Screening for inherited thrombophilias (specifically, factor V Leiden and the prothrombin gene mutations, protein C, protein S, and antithrombin deficiencies) seems reasonable when a patient has a personal history of venous thromboembolism in the setting of a nonrecurrent risk factor (such as surgery) or a first-degree relative with a known or suspected high-risk thrombophilia.** In addition to a lupus anticoagulant, anticardiolipin, and anti- $\beta$ 2-glycoprotein 1 for diagnosis of antiphospholipid syndrome (an acquired thrombophilia), screening includes tests for the factor V Leiden and G20210A prothrombin gene mutations. They are the two most common inherited causes of venous thromboembolism and thrombophilias most highly associated with adverse pregnancy outcomes, but race must also be considered. Their prevalence is relatively high among those of European descent, but very low in Asians, Africans, and Native Americans.<sup>373</sup> Measurement of activated protein C resistance is a more global test for detection of both inherited and acquired forms of activated protein C resistance. Screening for the methylene tetrahydrofolate reductase mutation (serum homocysteine) and antithrombin III, protein S, and protein C deficiencies also warrants consideration, based on past and family medical history.

Indications for treatment in women with recurrent pregnancy loss associated with thrombophilia are even less well established. In uncontrolled treatment trials, improved live birth rates have been observed in women with recurrent pregnancy loss and one or more thrombophilic defects after treatment with heparin, alone or combined with aspirin.<sup>280,281,374,375</sup> Although it seems likely that not all such women truly require

treatment, any criteria for more selective or targeted thromboprophylaxis must derive from randomized controlled trials not yet available. Routine empiric aspirin treatment in untested women with recurrent early pregnancy loss has no proven benefit.<sup>361</sup>

# **Summary of Key Facts Relating to Inherited Thrombophilias**

**Inherited thrombophilias resulting from genetic mutations in clotting factors have emerged as a potentially important cause of recurrent pregnancy loss, but a great many women with these mutations have completely normal reproductive performance. Why some with thrombophilias miscarry and others do not is unknown; women with more than one type of mutation or whose fetus inherits the mutation may be at greater risk. At present, which women with recurrent pregnancy loss should be screened for thrombophilias and how they should be evaluated remain unanswered questions. Selected screening for the most common abnormalities in women with otherwise unexplained recurrent pregnancy loss with a suspicious loss after 8 weeks' gestation or after detection of fetal heart activity is reasonable, but routine screening of all women with recurrent pregnancy loss cannot be justified. Whereas preliminary data suggest that treatment with heparin may improve pregnancy outcomes in women with recurrent pregnancy loss who carry thrombophilia, empiric aspirin treatment in untested women has no proven benefit.**

# ENDOCRINE FACTORS

---

Endocrine factors that may predispose to an increased risk of pregnancy loss include thyroid disease, diabetes mellitus, polycystic ovary syndrome (PCOS), and luteal phase deficiency.

# Hypothyroidism

Risk of pregnancy loss may be increased for women with uncorrected overt or even subclinical hypothyroidism.<sup>376</sup> Mild or subclinical disease generally was not considered in the past as having important clinical consequences.<sup>377,378</sup> However, the results of a study of pregnancy outcomes in women with hypothyroidism challenge that notion. The incidence of pregnancy loss was very low in treated hypothyroid women having normal thyroid indices, but markedly increased in women with elevated thyroid-stimulating hormone (TSH) levels, including both women with untreated subclinical disease and those with overt disease who received inadequate exogenous thyroid hormone replacement.<sup>376</sup> The classic TSH threshold definition of hypothyroidism is TSH greater than 5 mIU/L. However, there is conflicting data that TSH levels of less than 5 mIU/L are also associated with increased risk of miscarriage. Several studies have found that elevated TSH levels in pregnancy are associated with an increased risk of miscarriage in patients without a diagnosis of hypothyroidism.<sup>379,380,381</sup> Other studies have shown no increased risk of miscarriage with subtle thyroid abnormalities. In a subset of patients from the first- and second-trimester evaluation of risk (FASTER) trial, 2.2% of patients were found to have TSH  $\geq$  2.5 mIU/L, and the miscarriage risk in this group was no different than the group with TSH less than 2.5 mIU/L.<sup>382</sup> Another study that reviewed 1,200 cycles in infertile women found that there was no difference in miscarriage rate between those with TSH between 2.5 and 4.0 and those with TSH less than 2.5.<sup>383</sup> **These observations suggest that subclinical hypothyroidism is not entirely benign and further justify earlier recommendations to include TSH screening in the evaluation of women with recurrent pregnancy loss.** Available evidence suggests that subclinical hypothyroidism defined as TSH greater than 4 mIU/L is associated with miscarriage and that treatment is associated with improved pregnancy rates. Diagnosis and treatment of even subtle thyroid disease can have important benefits for women with recurrent pregnancy loss.

Remember (see [Chapter 20](#)) that once pregnant, women being treated for hypothyroidism require an increase (20–50%) in thyroxine during pregnancy, beginning as early as the 5th week of pregnancy.<sup>384,385,386</sup> When previously diagnosed hypothyroid women become pregnant, it is best to empirically increase the levothyroxine dose by about 30% as soon as pregnancy is diagnosed, with further adjustments according to the TSH levels.<sup>386,387</sup> **TSH should be monitored monthly and again in the postpartum period, and dosage should be adjusted to keep the TSH level in the lower half of the normal range, less than 2.5 mU/mL in the first trimester and less than 3.0 mU/mL in the rest of pregnancy.** Postpartum, the dose should be immediately decreased to the prepregnancy level. The need for proper monitoring and adequate

treatment cannot be overemphasized. Women with thyroid autoimmunity (presence of thyroid antibodies) must be monitored with TSH levels for at least 6 months after delivery because of their increased risk for postpartum thyroiditis.

# Diabetes Mellitus

Diabetic women with good metabolic control are no more likely than nondiabetic women to suffer pregnancy loss, but diabetic women with elevated blood glucose and glycosylated hemoglobin (A1c) levels in the first trimester are at significantly increased risk for spontaneous miscarriage. Among women with poor diabetic control, miscarriage risk rises with the level of hemoglobin A1c.<sup>388,389,390,391</sup> **In women with recurrent pregnancy loss, evaluation with blood glucose and hemoglobin A1c levels is indicated for those with known or suspected diabetes but is otherwise unwarranted.** Diabetic women with recurrent pregnancy loss and elevated hemoglobin A1c concentrations are best advised to postpone new attempts to conceive until levels return to the normal range.

# Polycystic Ovary Syndrome

A number of studies have shown a correlation between elevated luteinizing hormone (LH) levels and recurrent pregnancy loss.<sup>392,393</sup> In the past, the observation was attributed to the adverse effects of LH itself or the hyperandrogenism induced by LH hypersecretion in women with PCOS.<sup>394,395</sup> However, suppression of LH secretion with a gonadotropin-releasing hormone (GnRH) agonist before ovulation induction with low-dose exogenous gonadotropins had no effect on pregnancy outcome in women with PCOS.<sup>396</sup> Hyperinsulinemia and high levels of PAI activity have been implicated as the proximate cause for the increased incidence of miscarriage (30–50%) observed among women with PCOS.<sup>392,395,397</sup> Metformin is an insulin-sensitizing drug with proven clinical utility for ovulation induction in anovulatory women with PCOS<sup>398,399,400,401</sup> and has also been demonstrated to decrease PAI activity.<sup>402,403,404,405</sup> Accordingly, metformin treatment before conception and throughout pregnancy has been evaluated as one means by which risk of pregnancy loss might be reduced in women with PCOS.

Results of retrospective studies suggested that metformin treatment can reduce or eliminate the increased risk of miscarriage in women with PCOS.<sup>406,407,408,409</sup> However, randomized trials comparing metformin and clomiphene, alone and in combination, have found that clomiphene is clearly superior to metformin and that combined treatment is no better than treatment with clomiphene alone.<sup>410,411,412</sup> In the largest single trial, the live birth rate achieved with clomiphene treatment was significantly higher than that of metformin (22.5% vs. 7.2%), and the results of combined treatment were not significantly different (26.8%).<sup>411</sup> More recently, in a follow-up trial, letrozole was shown to be associated with higher live births than clomiphene in infertile women with PCOS.<sup>413</sup> Although some have advocated metformin treatment to reduce the increased risk for miscarriage in women with PCOS, which might relate to an underlying metabolic disorder,<sup>414</sup> **no differences in the miscarriage rates of women who did or did not receive metformin treatment have been observed in the large randomized trials.**<sup>410,411,412</sup> **A meta-analysis of 17 randomized trials concluded that metformin treatment had no effect on the risk of miscarriage.**<sup>415</sup>

Metformin may be added to the treatment regimen when clomiphene alone fails to restore normal ovulatory function. Metformin treatment can be discontinued after conception or after the end of the first trimester or continued throughout pregnancy in hopes of also reducing the risk for developing gestational diabetes.<sup>416,417,418</sup> Metformin is classified as a category B drug (no teratogenic effects demonstrated in animal studies and no teratogenic or other serious adverse effects have been observed in limited studies in women thus far).<sup>417,419,420</sup> However, treatment with metformin during

pregnancy has been associated with an increased prevalence of preeclampsia and increased perinatal mortality in some studies,<sup>421</sup> although not in others.<sup>422</sup> Currently, **routine** metformin treatment during pregnancy is not recommended for women with PCOS.<sup>422</sup>

# Luteal Phase Deficiency

The many different causes of poor luteal function and methods for the clinical diagnosis of luteal phase deficiency are discussed at length in the context of the evaluation of female infertility in [Chapter 25](#). Discussion here is limited to a summary of the pathophysiology, diagnosis, and treatment of luteal phase deficiency in women with recurrent pregnancy loss.

Several lines of evidence indicate that the success of early pregnancy is dependent on progesterational support from the corpus luteum until approximately 7 weeks' gestation (menstrual dates). Serial measurements of 17-hydroxyprogesterone (produced by the corpus luteum but not by the trophoblast), progesterone, estradiol, and hCG during early spontaneous pregnancies and pregnancies achieved via IVF using donor oocytes in women with ovarian failure indicate that the luteal-placental shift does not occur suddenly but takes place gradually over the interval spanning the 5th through the 9th week of pregnancy.<sup>424,425</sup> Classic studies of pregnancy outcomes in women seeking pregnancy termination who underwent surgical luteectomy at various times during early gestation strongly suggest that pregnancy usually becomes independent of the corpus luteum at approximately 7 weeks' gestation; luteectomies performed earlier in pregnancy uniformly induced spontaneous miscarriage.<sup>426,427</sup>

Progesterone concentrations in both normal and abnormal early pregnancies reflect the combined contributions of the corpus luteum and the developing trophoblast, range widely, and overlap to a large extent.<sup>424,428,429,430,431</sup> **Measurements of serum progesterone levels to determine the quality of luteal function in early pregnancy and to identify pregnancies at risk that might be salvaged by support with exogenous progesterone therapy are futile.** A low progesterone concentration during early pregnancy can reflect a defective corpus luteum, an intrinsically abnormal conceptus, or both. The alternative approach, diagnosis in a nonconception cycle and treatment to correct luteal phase deficiency before the next conception, is possible but subject to all of the limitations and pitfalls of the various diagnostic methods. Serum progesterone concentrations fluctuate widely and cannot be confidently interpreted because corpus luteum progesterone secretion is pulsatile.<sup>432</sup> Endometrial biopsy is invasive, painful, and costly, even if traditional histologic dating were still considered a valid diagnostic tool.<sup>433</sup> Consequently, an abnormally short luteal phase duration (<13 days), best defined by the interval from detection of the midcycle LH surge to the onset of menses, is the most objective and reliable diagnostic criterion. When that criterion is met, a serum prolactin determination is indicated to exclude hyperprolactinemia and to define the best treatment option. Estimates of the prevalence of luteal phase deficiency among women with recurrent pregnancy loss have varied greatly with the method of

diagnosis<sup>51,52,53,55,56,434</sup>; its true prevalence and importance as a cause of recurrent pregnancy loss is unknown, but probably quite low (<10%).

We view luteal phase deficiency as a subtle form of ovulation dysfunction best corrected with the same treatments used for ovulation induction in anovulatory infertile women (Chapter 27). Considering that women with luteal phase deficiency already ovulate, albeit poorly, they generally do not require aggressive treatment. Prolactin and TSH determinations are indicated, and clomiphene citrate is a logical choice in euprolactinemic euthyroid women. There is a large volume of experimental and clinical evidence to indicate that follicular phase FSH levels are low in cycles with a short luteal phase<sup>435,436,437,438,439</sup> and that clomiphene can effectively correct the abnormality.<sup>440,441</sup> Some prefer to treat luteal phase deficiency with exogenous progesterone supplementation beginning 2–3 days after ovulation,<sup>442</sup> but this approach often delays menses, creating false expectations of pregnancy, increasing stress, and inviting disappointment.

# **Summary of Key Facts Relating to Endocrine Factors**

**Endocrine factors are a relatively uncommon cause of recurrent pregnancy loss. Thyroid disorders are easy to identify and treat and should be excluded by measurement of TSH; even subtle abnormalities may adversely affect pregnancy outcome. Evaluation of blood glucose and hemoglobin A1c levels is indicated for women with known or suspected diabetes mellitus, but is otherwise not warranted. The risk of miscarriage is increased in women with polycystic ovary syndrome, but there is no evidence that treatment with metformin reduces that risk; for women with polycystic ovary syndrome and hyperinsulinemia who require ovulation induction, letrozole is the best initial treatment, which may be combined with metformin. Luteal phase deficiency cannot be diagnosed during pregnancy; a consistently short luteal phase duration is the most reliable diagnostic criterion. Clomiphene citrate is an effective treatment for luteal phase deficiency and avoids the confusion, anxiety, and disappointment associated with delayed menses often resulting from exogenous progesterone therapy.**

# INFECTIOUS CAUSES

---

Overall, data regarding the possibility that cervicovaginal infections might be a cause of early pregnancy loss are relatively scarce. Despite periodic reports that have implicated specific infectious agents as risk factors for miscarriages, there remains no compelling evidence that bacterial or viral infections are a cause of recurrent pregnancy loss. Chlamydia trachomatis infection was implicated in one study that found a high prevalence of anti-Chlamydia antibodies among women with recurrent pregnancy loss, possibly reflecting an excessive maternal immunologic reaction to the organism,<sup>443</sup> but a later prospective study found no association between anti-Chlamydia antibodies and spontaneous miscarriage.<sup>444</sup> Others have reported associations between spontaneous miscarriage and genital Ureaplasma (*U. urealyticum*) or Mycoplasma (*M. hominis*) infection.<sup>445</sup> Toxoplasma gondii, Listeria monocytogenes, Campylobacter species, herpes virus, and cytomegalovirus have also been implicated.

There is an association between miscarriage risk and bacterial vaginosis. In one large study, diagnosis of bacterial vaginosis at the first prenatal visit before 14 weeks' gestation was associated with a fivefold increased risk of pregnancy loss before 20 weeks' gestation.<sup>446</sup> Another study involving infertile women attempting pregnancy via IVF observed no difference between conception rates in women with and without bacterial vaginosis, but those with bacterial vaginosis who conceived were twice as likely to miscarry as those without bacterial vaginosis who conceived.<sup>447</sup> A third large study found that bacterial vaginosis did not predict early miscarriage but was associated with a modest increase in risk of pregnancy loss after 13 weeks' gestation.<sup>448</sup> Other evidence that chronic subclinical endometritis is relatively common in women with symptomatic lower genital tract infections, including cervicitis and bacterial vaginosis, suggests a mechanism that might explain the association between bacterial vaginosis and pregnancy loss.<sup>449,450,451</sup>

The available data cannot justify routine serologic testing for past Chlamydia exposure, cervical cultures, or endometrial biopsy in the evaluation of women with recurrent pregnancy loss. However, as in infertile women, further evaluation and treatment are appropriate and prudent in women with recurrent pregnancy loss having clinical cervicitis, chronic or recurrent bacterial vaginosis, or other symptoms that suggest pelvic infection. Uncontrolled studies have suggested that empiric antibiotic treatment may decrease the risk of miscarriage in women with genital mycoplasma infections<sup>452</sup> and in unselected women with recurrent pregnancy loss.<sup>453,454</sup> **Considering the relatively low cost and negligible risks involved, a 2-week course of empiric antibiotic treatment (azithromycin, erythromycin, or doxycycline) is more reasonable than numerous and repeated cultures.**

An analysis of the two large clinical trials that established the efficacy of the bivalent vaccine against human papillomavirus (HPV) types 16 and 18 could detect no increase in the miscarriage rate comparing the vaccinated women with the control group.<sup>455</sup>

# **Summary of Key Facts Relating to Infectious Causes**

**Routine serologic testing, cervical cultures, and endometrial biopsy to detect genital infections in women with recurrent pregnancy loss cannot be justified. Evaluation should be limited to women with clinical cervicitis, chronic or recurrent bacterial vaginosis, or other symptoms of pelvic infection. Empiric antibiotic treatment in women suspected of harboring a genital mycoplasma infection is less costly and less complicated than serial cultures.**

# ENVIRONMENTAL FACTORS

---

Smoking, alcohol, and heavy coffee consumption have been implicated as environmental factors predisposing to pregnancy loss.

Numerous studies have examined the relationship between cigarette smoking and miscarriage risk.<sup>456,457</sup> In sum, they support the conclusion that cigarette smoking increases the risk of spontaneous miscarriage in a dose-dependent manner<sup>458,459,460,461,462,463,464</sup>; the adverse effects of smoking become apparent in smokers who consume as few as 10 cigarettes per day.<sup>457</sup> The mechanisms responsible are uncertain but the vasoconstrictive and antimetabolic actions of some components of cigarette smoke, including nicotine, carbon dioxide, and cyanide, may predispose to placental insufficiency.

Alcohol is a known teratogen with dose-dependent adverse effects.<sup>456,464,465,466</sup> Alcohol consumption exceeding two drinks per day has been estimated to double the risk of spontaneous miscarriage.<sup>456</sup> Although low-level consumption has no measurable impact on the risk of pregnancy loss,<sup>467</sup> there is no clearly established safe threshold. The adverse effects of alcohol may be additive with those of cigarette smoking.

Most, but not all, studies that have examined the relationship between maternal caffeine consumption and miscarriage risk have found that heavy caffeine consumption (>300 mg/day, equivalent to about three cups of coffee) is associated with a modest increase (less than twofold) in risk for spontaneous miscarriage.<sup>468,469,470,471,472,473,474,475</sup>

Couples experiencing recurrent pregnancy loss are sometimes concerned that environmental toxins may have contributed to their reproductive difficulty. Their questions are difficult to answer because information regarding the effects of potential toxins on pregnancy is not readily available. Anesthetic gases, perchlorethylene (a dry-cleaning solvent), other organic solvents,<sup>476</sup> and exposure to heavy metals (mercury, lead) have been implicated as causative agents of miscarriage.<sup>464</sup> Exposure to video terminals is not a factor.<sup>477</sup> Exercise programs do not increase risk, and bed rest will not decrease the risk of recurrent pregnancy loss. Isotretinoin (Accutane) is definitely associated with an increased incidence of spontaneous miscarriage.<sup>478</sup> An increased miscarriage risk has been observed among painters and factory workers, but not among dental assistants and laboratory or gardening workers.<sup>479,480</sup> The use of electric blankets and heated water beds is also not associated with an increased risk of spontaneous miscarriage.<sup>481</sup>

It seems appropriate to list obesity under environmental factors because excess weight is largely a consequence of lifestyle. A body mass index (BMI) equal to or

greater than 25 is associated with a greater risk of miscarriage, and Chinese and British studies have linked obesity with recurrent miscarriages. [482,483,484](#)

# Summary of Key Facts Relating to Environmental Factors

Smoking increases the risk of miscarriage and should be discouraged. Alcohol consumption exceeding two drinks per day and caffeine consumption exceeding 300 mg/day may increase risk for pregnancy loss and are best avoided. Women who have experienced a miscarriage should be cautioned regarding known environmental toxins. An increased risk of miscarriage is one more reason to vigorously confront obesity ([Chapter 19](#)).

# UNEXPLAINED RECURRENT PREGNANCY LOSS

---

Even after a thorough and systematic evaluation, well more than half of all women with recurrent pregnancy loss have no identified predisposing factors that can explain their poor reproductive history, and the large majority does well in the next pregnancy. Those with a previous second-trimester loss have a poorer prognosis and are at increased risk for preterm delivery, stillbirth, and neonatal death.<sup>53,54,55,56,485,486</sup> Frequent communication, cautious optimism, and emotional support during the first trimester of the next pregnancy have their own distinct therapeutic value.<sup>53</sup> With determined efforts, 70–75% of women with unexplained recurrent pregnancy loss ultimately achieve a successful pregnancy.<sup>6</sup> Careful monitoring is warranted because women with recurrent pregnancy loss are also at increased risk for ectopic pregnancy.<sup>487</sup>

Many clinicians offer or recommend empiric exogenous progesterone supplementation during early pregnancy to women with unexplained recurrent pregnancy loss. Any concerned clinician wants to do all that can be done to improve the chances for a successful pregnancy. Considering that two-thirds or more of next pregnancies among women with unexplained recurrent pregnancy loss are likely to succeed, with or without treatment, it is also easy to understand why so many are also convinced that treatment has value when there is no compelling evidence for its effectiveness.<sup>488,489,490</sup> Low-dose aspirin treatment is another commonly recommended treatment for women with unexplained recurrent early pregnancy loss, even though randomized trials have demonstrated that it has no benefit.<sup>270,361</sup> In the doses commonly administered, exogenous progesterone supplementation and low-dose aspirin pose few risks and are difficult to condemn, but without clear evidence for their effectiveness, neither can be recommended.

# **Summary of Key Facts Relating to Unexplained Recurrent Pregnancy Loss**

**Even thorough evaluation will reveal no evidence for a predisposing factor in more than half of all women with recurrent pregnancy loss. Under such circumstances, the longer term prognosis for achieving a successful pregnancy is very good. Emotional support and careful monitoring during early pregnancy help to improve pregnancy outcomes. Empiric treatments with exogenous progesterone or aspirin in women with unexplained recurrent pregnancy loss have no proven value.**

# Evaluation and Treatment for Recurrent Pregnancy Loss

As a quick reference, the [Table 30.4](#) summarizes our recommended evaluation and treatments for factors known to predispose to recurrent pregnancy loss. **Established tests and treatments are shown in bold type. Tests and treatments that must be applied selectively and those not yet firmly established are shown in standard type.**

## **TABLE 30.4 Recommended Evaluation and Treatment for Recurrent Pregnancy Loss**

<b>Category</b>	<b>Evaluation</b>	<b>Treatments</b>
<b>Genetic</b>	<b>Karyotype, both partners</b> Ovarian reserve test Comparative genomic hybridization	<b>Counseling</b> <b>Donor gametes where appropriate</b> Preimplantation genetic diagnosis
<b>Anatomic</b>	<b>Sonohysterography or HSG</b> Magnetic resonance imaging IVP or renal ultrasound	<b>Hysteroscopic septoplasty</b> <b>Hysteroscopic myomectomy</b> <b>Hysteroscopic adhesiolysis</b> Abdominal metroplasty Abdominal myomectomy Cervical cerclage
<b>Immunologic</b>	<b>Lupus anticoagulant</b> <b>Anticardiolipin antibody</b> <b>Anti-β2-glycoprotein I antibody</b>	<b>Aspirin and heparin</b>
<b>Thrombophilias</b>	Factor V Leiden Prothrombin gene mutation Activated protein C resistance Homocysteine Protein C Protein S Antithrombin III	Heparin
<b>Endocrine</b>	<b>TSH</b> <b>Luteal phase duration</b> Blood glucose, Hgb A1c Prolactin	<b>Thyroxine</b> <b>Clomiphene citrate</b> <b>Metformin</b> <b>Dopamine agonists</b>
<b>Infectious</b>	<b>As indicated by symptoms</b>	Empiric antibiotics

# Genetics

The above DNA sequence is obviously a mutant. But the fact that we can recognize this cryptogram as a nucleotide sequence and diagnose a mutant change illustrates the incredible progress made in the understanding of human biology. Molecular genetics is the subspecialty of science devoted to understanding the structure and function of the genome, the full complement of DNA (deoxyribonucleic acid), the macromolecule that contains all the hereditary information.

The Austrian monk Gregor Mendel studied his garden of peas for much of his life at his monastery and was the first to express the principles of heredity in the 1860s. He described dominant and recessive traits and the “laws” of transmission governing the homozygous and heterozygous inheritance of these traits. Mendel’s theories remained unknown until 1900, when they were discovered 16 years after his death. But how far we have come in only 150 years, mostly in the last 50 years!

The pairing and splitting of chromosomes at cell division was proposed in 1903, but it was not until 1946 that Edward Tatum and Joshua Lederberg at Yale University demonstrated in bacteria that DNA carried hereditary information. James Watson and Francis Crick, working at the Cavendish Laboratories in Cambridge, proposed in 1953 the structure of DNA by creating a model based on the parameters provided by Maurice Wilkins and Rosalind Franklin obtained with x-ray crystallography. Crick, Watson, and Wilkins received the Nobel Prize in 1962 (Franklin had died in 1958, and the Nobel Prize is not awarded posthumously).

DNA replication involves many enzyme systems. DNA polymerase was isolated in 1958, and ribonucleic acid (RNA) polymerase in 1960. In 1978, Werner Arber, Hamilton Smith, and Daniel Nathans received the Nobel Prize for their discovery, in the 1960s, of the enzymes for joining or cutting DNA. The use of ligase and restriction endonuclease enzymes permitted the production of recombinant DNA molecules, first accomplished by Paul Berg at Stanford University in 1972.

E.M. Southern of Edinburgh University developed in 1975 the technique to transfer (to blot) DNA from agarose gels onto nitrocellulose filters, enabling DNA fragments to be joined with radiolabeled RNA probes and thus isolated. The cloning of genes or DNA fragments followed the breakthrough discovery that plasmids carrying foreign DNA molecules could be inserted into bacteria, leading to the replication of the foreign DNA.

Through the subsequent development of techniques such as rapid DNA sequencing by Frederick Sanger in 1973 and the polymerase chain reaction (PCR) (attributed to Kary Mullis in 1983), gene discovery and characterization became easier. Soon, full genomes (the complete sets of DNA for entire organisms) were able to be sequenced. The first eukaryotic species to have a fully sequenced genome was the yeast *Saccharomyces cerevisiae*, completed in 1996, followed by many other model organisms and culminating with the Human Genome Project (completed in 2003).

Advances in molecular genetics have revolutionized much of modern medicine, but few specialties have been impacted as much as reproductive endocrinology. From the identification of gene variants that increase the risk of reproductive abnormalities to the broad utilization of preimplantation genetic testing for recurrent and sporadic genetic abnormalities in cultured embryos, a fundamental knowledge of molecular genetics is essential to the modern reproductive endocrinologist. We offer this chapter as a guide to molecular genetics. The purpose of this chapter, therefore, is not to present an intensive course in the basic sciences but rather to review the most important principles and information necessary for clinical practice today.

# AN OVERVIEW OF THE HUMAN GENOME

---

The genome for each species consists of the complete set of DNA sequences on all the chromosomes. There are nearly 3 billion base-pairs in each haploid human genome, and an estimated 20,000–25,000 genes. Representing the smallest functional unit of inherited information, a gene is a contiguous region of DNA that can encode a protein product and contains within its area regulatory sequences that govern its expression. Genes account for only about 2% of human DNA. Although enormously complex at first glance, the entire genetic language is written with only four letters: A, C, G, and T (U in RNA). Furthermore, the language is limited to only three-letter words, known as codons. With four nucleotides, reading groups of three, there are 64 possible combinations. Essentially all living organisms use this code. The genome changes only by new combinations derived from parents or by mutation ([Table 31.1](#)). Finally, the linear arrangement of the entire genome is fragmented into the 23 pairs of chromosomes.

## TABLE 31.1 The mRNA Genetic Code

First Position (5' End)	Second Position				Third Position (3' End)
	U	C	A	G	
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop	Stop	A
	Leu	Ser	Stop	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	glu	Gly	G

# The Structure and Function of DNA

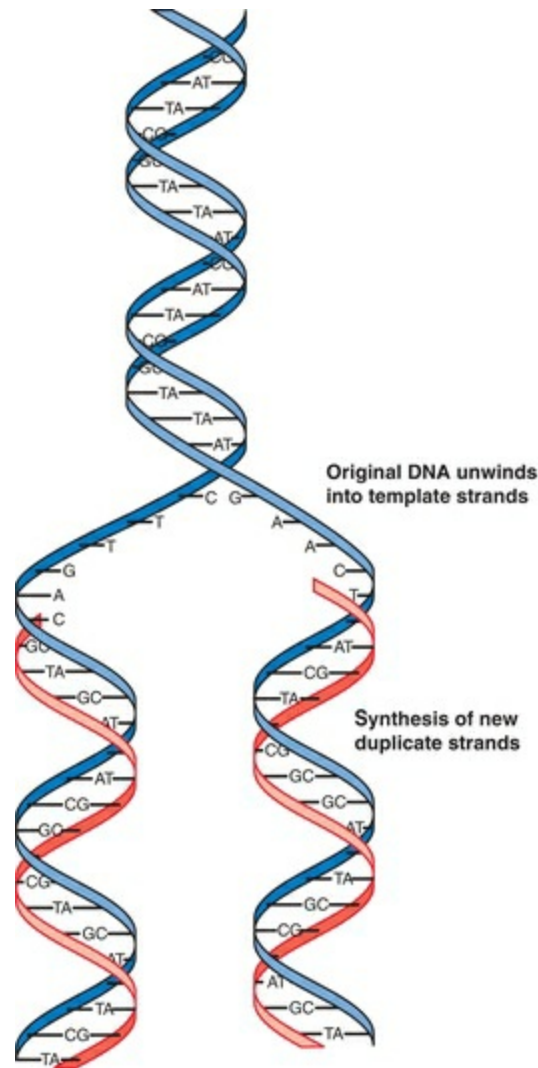

DNA is the material of the gene responsible for coding the genetic message as transmitted through specific proteins. Thus, it is the most important molecule of life and the fundamental mechanism for evolution. Genes are segments of DNA that code for specific proteins, together with flanking and intervening sequences that serve controlling and regulating functions. Each molecule of DNA has a deoxyribose backbone, identical repeating groups of deoxyribose sugar linked through phosphodiester bonds. Each deoxyribose is attached in order (giving individuality and specificity) to one of four nucleic acids, the nuclear bases:

- A purine—adenine or guanine
- A pyrimidine—thymine or cytosine

A nucleotide is the basic building block of DNA. It consists of three major components: the deoxyribose sugar, a phosphate group, and a nucleic acid base. The phosphate-sugar (**Figures 31.1** and **31.2**) linkages are asymmetric; the phosphorus is linked to the 5-carbon of one sugar and to the 3-carbon of the following sugar. Thus, one end is the 5' (5 prime) end and the other the 3' (3 prime) end. By convention, DNA and its nuclear acid sequences are written from left to right, from the 5' end to the 3' end, which is the direction of the transcription process. The 5' end leads to the formation of the amino end of the protein, while the 3' end forms the carboxy end of the protein.

**FIGURE 31.1**

**FIGURE 31.2**

DNA consists of two deoxyribose strands twisted around each other clockwise in a double helix, with the nucleic acids on the inside and the nuclear bases paired by hydrogen bonding; adenine pairs with thymine, and cytosine pairs with guanine. RNA differs from DNA in that it is single stranded, its sugar moiety is ribose, and it substitutes uracil for thymine. Phoebus Levene, a Russian immigrant to the United States working at the Rockefeller Institute of Medical Research from 1905 until he died in 1940, identified the components of DNA (discovering and naming the ribose and deoxyribose sugars) and was the first to suggest the nucleotide structure, research that provided the foundation for the later delineation of the DNA's significance.

How can a cell's DNA, which stretched out measures nearly 2 m long, fit into a cell? Watson and Crick figured this out when they proposed a tightly coiled two-stranded helix, the double helix. Like the centimeter is a measure of length, the base pair (bp) is the unit of measure for DNA. The base pair is either adenine-guanine or

cytosine-thymine, the nucleic acid of one chain paired with the facing nucleic acid of the other chain. A fragment of DNA, therefore, is measured by the number of base pairs, for example, a 4,800-bp fragment (a 4.8 kb fragment). It is estimated that we have nearly 3 billion bp of DNA, only a small portion of which actually encodes proteins.

DNA does not exist within the cell as a naked molecule. The nucleotide chains wind about a core of proteins (histones) to form a nucleosome. The nucleosomes become condensed into many bands, which can be seen in karyotype preparations. This condensation is another important mechanism for packing the long DNA structure into a cell. Many other proteins are associated with DNA, important for both structure and function.

The process of DNA replication begins with a separation of the double-stranded DNA helix, initiated at multiple steps by enzyme action. As the original DNA unwinds into template strands, DNA polymerase catalyzes the synthesis of new duplicate strands, which re-form a double helix with each of the original strands (this is called replication). Each daughter molecule, therefore, contains one of the parental strands. It is estimated that the original DNA molecule present in the fertilized zygote must be copied approximately  $10^{15}$  times during the course of a human lifetime. Rapidity and accuracy are essential. By combining precision with error correction systems, errors that affect the function of the gene's protein are surprisingly rare ([Table 31.2](#)).

## **TABLE 31.2 The 20 Amino Acids in Proteins**

<b>Amino Acid</b>	<b>Three-letter Abbreviation</b>	<b>Single-letter Code</b>
Glycine	Gly	G
Alanine	Ala	A
Valine	Val	V
Isoleucine	Ile	I
Leucine	Leu	L
Serine	Ser	S
Threonine	Thr	T
Proline	Pro	P
Aspartic acid	Asp	D
Glutamic acid	Glu	E
Lysine	Lys	K
Arginine	Arg	R
Asparagine	Asn	N
Glutamine	Gln	Q
Cysteine	Cys	C
Methionine	Met	M
Tryptophan	Trp	W
Phenylalanine	Phe	F
Tyrosine	Tyr	Y
Histidine	His	H

# The Structure of Genes

A gene is composed of a segment of DNA containing exons separated by introns, which are coding and noncoding portions, respectively. Intron-exon patterns tend to be conserved during evolution. For instance, the alpha- and beta-globin genes are believed to have arisen 500 million years ago, with the introns in the same location as they are today.

## Exon

The segment of a gene that yields a messenger RNA (mRNA) product, which codes for a specific protein

## Intron

The segment of a gene not represented in mature RNA and, therefore, noncoding for protein, but capable of regulatory functions

## Codon

A triplet codon is a sequence of three bases in RNA or DNA that codes for a specific amino acid or translational end-point.

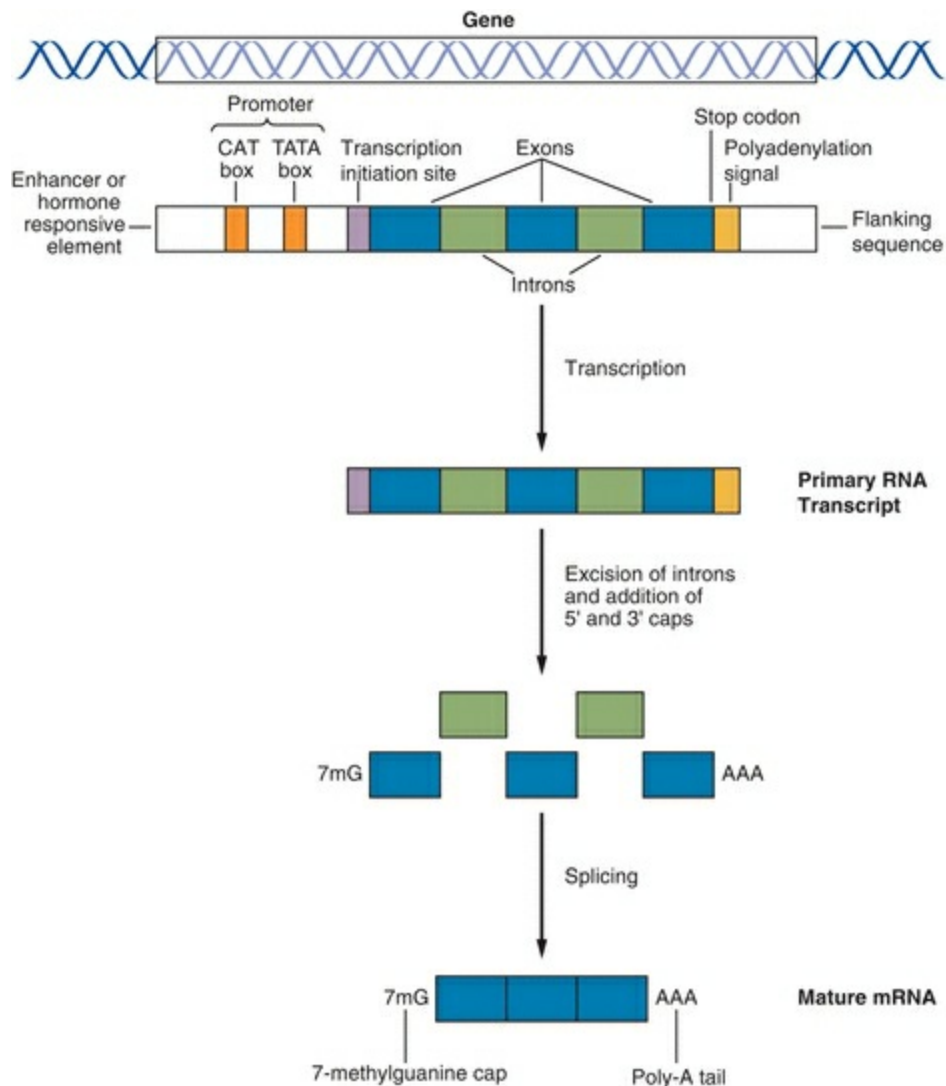

With some exceptions, it was believed that one gene yields only one protein. The one gene–one protein concept was first proposed in 1909 by Archibald Garrod and experimentally supported in the 1940s by George Beadle and Edward Tatum, American geneticists, by linking single-gene mutations to single-enzyme deficiencies. However, through a mechanism known as alternative splicing, the 20,000–25,000 human genes can produce more than 100,000 proteins. As noted above, the introns are not translated into protein products. Only the DNA sequences in the exons are transcribed into mRNA and then translated into proteins. However, variations (alternative splicing) can lead to selective inclusions of exons from a gene and produce related proteins.

Genes also include flanking sequences important for gene transcription. The area that will initiate DNA action (e.g., DNA binding to the hormone-receptor complex) is called an **enhancer** region. The actual area where transcription begins is the **promoter** region. Only a few relatively short nucleotide sequences are promoters, such as the T-A-T-A-A sequence, or TATA box, and the C-C-A-A-T sequence, or CAT box. The promoter sites (the binding sites for RNA polymerase and numerous cofactors) are usually near the start of the coding region of the gene. Enhancer sites are larger than promoter sites and can be located anywhere, even far from the gene, but usually are in the 5' flanking end. At the 3' end, a coding sequence is usually present for the

polyadenosine (poly-A) tail common for most mRNA molecules.

The enhancer sites bind regulatory proteins that serve as signals to regulate gene expression by either increasing or repressing the binding of RNA polymerase in the promoter region (**Figure 31.3**). This is one method of creating unique cellular functions. For example, a hormone target tissue can respond to the hormone because it contains a specific receptor protein that, on binding to the hormone, will bind to a DNA enhancer site. Specific proteins (called transcription factors) bind to enhancer sites and activate transcription. The regulation of gene transcription usually involves DNA sequences in the 5' flanking upstream region of a gene.

**FIGURE 31.3**

Genes that encode proteins contain a **start codon** (AUG), which begins the **open reading frame**, a segment of the gene that encodes the amino acid sequence of the gene

product. The open reading frame ends at a **stop codon** (UGA, UAA, or UAG), which specifies a stop to translation of RNA into protein (like a period at the end of a sentence). Finding and identifying an open reading frame is an important step in analyzing DNA sequences because such a long sequence is usually encountered only in an active gene.

# THE CHROMOSOMES

---

The linear arrangement of many genes forms a chromosome. Chromosomes are packages of genetic material, consisting of a DNA molecule to which are attached large numbers of proteins that maintain chromosome structure and play a role in gene expression. Human somatic cells contain 46 chromosomes (22 homologous pairs of autosomes and 2 sex chromosomes). All somatic cells are diploid, containing 23 pairs of chromosomes. Only gametes are haploid, with 22 autosomes and one sex chromosome. The chromosomes vary in size, ranging from 50 million to 250 million base pairs. Chromosome 1 contains the most protein-coding genes (2,044), and the Y chromosome has the smallest number (63). All contain a pinched portion called a centromere, which divides the chromosome into two arms, the shorter p arm and the longer q arm (in acrocentric chromosomes, the p arm is so small that it can hardly be seen on a karyotype, but it is still present). The two members of any pair of autosomes are homologous, one homologue derived from each parent. The number of chromosomes does not indicate the level of evolutionary sophistication and complexity; the dog has 78 chromosomes and the carp has 104!

A karyotype is an arrangement of the chromosomes into pairs, usually after proteolytic treatment and Giemsa staining to produce characteristic banding patterns, allowing a blueprint useful for location. The staining characteristics divide each arm into regions and each region into bands that are numbered from the centromere outward. A given point on a chromosome is designated by the following order: chromosome number, arm symbol (p for short arm, q for long arm), region number, and band number. For example, 7q31.1 (read as “seven-q-three-one-point-one,” **not** as “seven-q-thirty-one-point-one”) is the location for the cystic fibrosis gene, or its **gene locus**. Because there are 22 pairs of autosomes, most genes exist in pairs. The pairs are homozygous when similar and heterozygous when dissimilar.

# Mitosis

Bacteria are **prokaryotes**, organisms without a true nucleus, with reproduction by cell division. In contrast, humans are **eukaryotes**, organisms with cells having a true nucleus bounded by a nuclear membrane. All eukaryotes, from yeasts to humans, undergo similar cell division and multiplication. The process of nuclear division in all somatic cells is called mitosis, during which each chromosome divides into two. For normal growth and development, the entire genomic information must be faithfully reproduced in every cell.

Mitosis consists of the following stages:

## Interphase

During this phase, all normal cell activity occurs except active division. It is during this stage that the inactive X chromosome (the Barr body or the sex chromatin) can be seen in female cells. DNA replication happens during interphase, in preparation for cell division.

## Prophase

Before replication, one chromosome is composed of one DNA molecule. Following replication, the two of a replicated chromosome are called chromatids. During the later stages of cell division, these chromatids separate longitudinally to become individual chromosomes. Chromatids may be sister or nonsister chromatids. A sister chromatid is either one of the two chromatids of the same chromosome joined together by a common centromere. As division begins, the chromosomes condense, and the two chromatids become visible. The nuclear membrane disappears. The centriole is an organelle outside the nucleus that forms the spindles for cell division; the centriole duplicates itself, and the two centrioles migrate to opposite poles of the cell.

## Metaphase

The chromosomes migrate to the center of the cell, forming a line designated the equatorial plate. The chromosomes are now maximally condensed. The spindle, microtubules of protein that radiate from the centrioles and attach to the centromeres, is formed.

## Anaphase

Division occurs in the longitudinal plane of the centromeres. The two new chromatids move to opposite sides of the cell drawn by contraction of the spindles.

## **Telophase**

Division of the cytoplasm begins in the equatorial plane, ending with the formation of two complete cell membranes. The two groups of chromosomes are surrounded by nuclear membranes forming new nuclei.

# Meiosis

Meiosis is the cell division that forms the gametes, each with a haploid number of chromosomes. Meiosis has two purposes: **reduction** of the chromosome number and **recombination** to transmit genetic information and to promote genetic diversity. Before **meiosis** begins, during S phase of the cell cycle, the DNA of each chromosome is **replicated** so that it consists of two sister chromatids. The two **meiotic** divisions are known as **meiosis I** and **meiosis II**. In meiosis I, homologous chromosomes pair and split apart, each consisting of two sister chromatids. Meiosis II is similar to mitosis, where sister chromatids split and segregate into new cells.

## The First Meiotic Division (Meiosis I)

### Prophase

- **Leptotene: Condensation of the chromosomes.**
- **Zygotene: Pairing of homologous chromosomes (synapsis).**
- **Pachytene: Each pair of chromosomes thickens to form four strands.**

This is the stage in which **crossing over** or **recombination** can occur (DNA exchange of homologous segments between two of the four strands). Chiasmata are the places of contact where crossovers occur (and can be visualized). This movement of blocks of DNA is a method for creating genetic diversity. On the other hand, genetic diseases can result from the insertion of sequences during gametogenesis.

- **Diplotene: Longitudinal separation of each chromosome.**

This is the stage of meiosis where oocytes become arrested in the gonads of a female fetus and remain arrested until the time of ovulation in a postpubertal female. In the male, meiosis starts only after puberty and occurs without an arrest.

### Metaphase, Anaphase, and Telophase of Meiosis I

Humans are diploid meaning that most of their chromosomes come in matched sets known as homologous pairs. The 46 chromosomes of a human cell are organized into 23 pairs, and the two members of each pair are said to be homologues of one another.

The nuclear membrane disappears, and the chromosomes move to the center of the cell. One member of each homologous pair goes to each pole, and the cells divide. In oogenesis, the cell division results in one secondary oocyte and the first polar body, a haploid cell that is smaller than the oocyte and is unable to be fertilized.

Meiosis I is often referred to as reduction division because each new product now has the haploid chromosome number (containing only one of each homologous pair). It is during the first meiotic division that Mendelian inheritance occurs. Crossovers that occur prior to metaphase result in new combinations of genetic material, both favorable and unfavorable.

## **The Second Meiotic Division (Meiosis II)**

The second division follows the first without DNA replication. The end result is the production of four haploid cells. In the developing oocyte, meiosis II arrests at metaphase II and then continues after fertilization. After fertilization, the second polar body is extruded and the fertilized mature oocyte remains ([Figure 31.4](#)).

## FIGURE 31.4

# Gene Function

While the structure of DNA, genes, and chromosomes help us to understand their composition and replication, the power of these structures comes from the functions they encode. Gene expression is composed of the following steps: transcription of DNA to RNA, RNA processing to produce functional mRNA, translation of mRNA on a ribosome to a peptide chain, and protein structural processing to the functional form.

## Transcription

Transcription is the synthesis of single-stranded mRNA from a gene (double-stranded DNA). The amino acid sequence of the protein is coded in the DNA, where a single amino acid is encoded by each triplet codon. RNA polymerase constructs the mRNA by reading the DNA strand (the “antisense” strand) that is complementary to the RNA; thus, the RNA is an exact copy of the other DNA strand (the “sense” strand), which is also called the complementary strand of the DNA molecule (remember, two important differences are that thymine in DNA is replaced by uracil and ribose replaces deoxyribose in RNA).

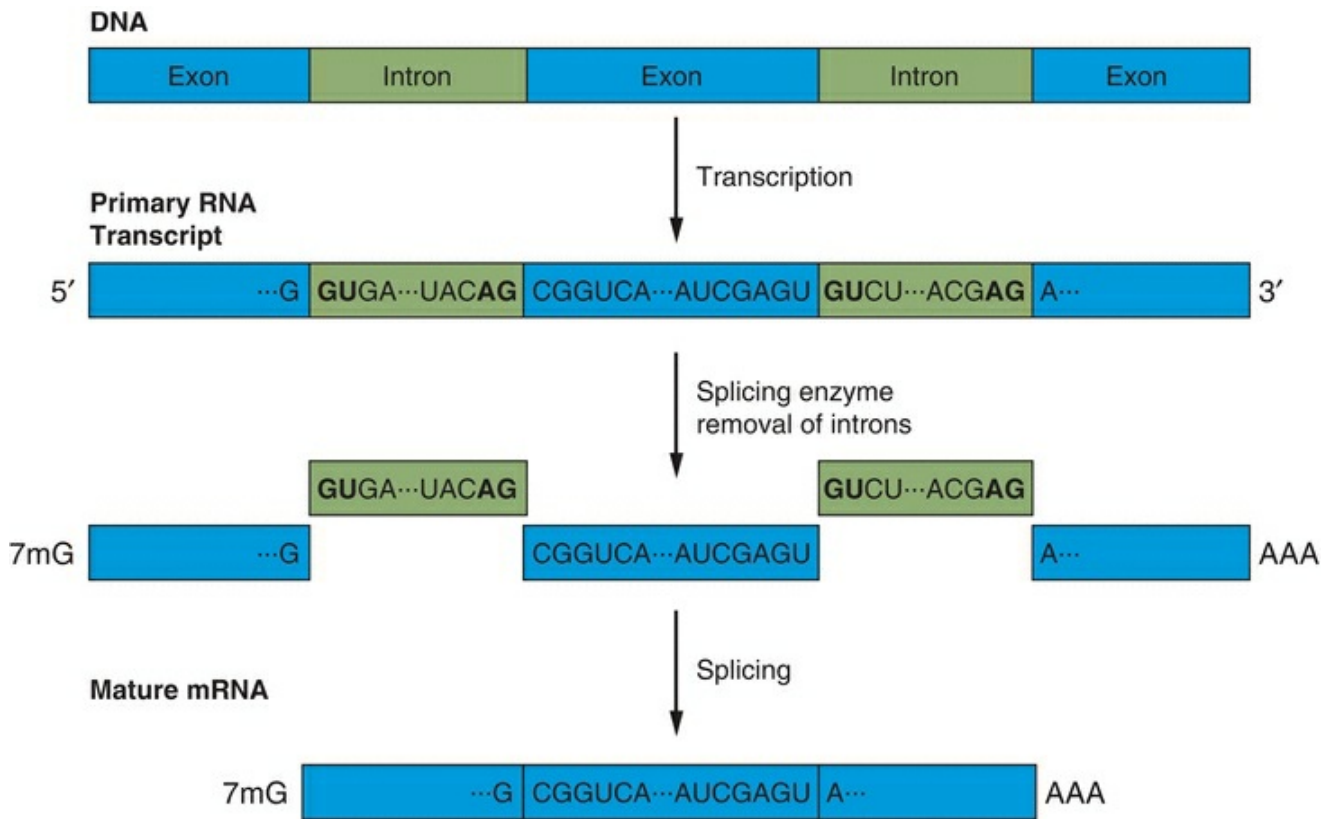

Molecular complementarity is both a difficult and a simple concept to grasp. The simple aspect is the concept of one thing being like another. The difficult part is the necessity to understand and visualize that the complementary molecule is not identical to its template. Thus, the strands of the double helix are not identical. Each DNA strand has a complementary structure, in a sense, one positive template and one negative template, each specifying the other. Each strand, therefore, serves as a template for its complementary DNA (in the process of replication) or complementary RNA (in the process of transcription). Thus, mRNA is synthesized from the negative template, the “antisense” strand, so that it will have the same structure as the positive template, the “sense” strand. Molecular biologists have to think in three dimensions!

Transcription is initiated at the upstream start site, the 5' untranslated flanking region where the two strands of the double helix come apart. The process continues downstream, copying one of the strands until a terminator signal is reached. Once the mRNA is synthesized, it undergoes further processing in the nucleus, with the addition of a 5' cap (a modified nucleotide, 7-methyl guanosine) and a 3' the poly-A tail (long chain of adenines), which stabilize the mRNA by protecting against degradation and facilitate translation. In addition, the intronic regions are excised and the exons are joined together in a process called **RNA splicing**. The start and end of each exon and intron have sequences that, when copied onto the RNA, signal an enzyme to remove the intervening parts. Almost all introns begin with GU and end with AG (GT and AG in the DNA intron). Introns are of varying lengths; a single intron can be longer than the final RNA product. Following capping, tailing, and splicing, the mRNA is ready to be

transported to the cytoplasm (**Figures 31.5** and **31.6**).

**FIGURE 31.5**

**FIGURE 31.6**

## Transcription Factors

Transcription factors are proteins that bind to regulatory elements in DNA (enhancers and promoters) and thus influence gene expression. For instance, the steroid hormone receptors are transcription factors. Gene transcription and the formation of mRNA can

be either stimulated or inhibited through direct interactions with DNA. Transcription factors can further interact with other factors (coactivators and corepressors, also called adapter proteins) to produce cooperative effects. The activity of these proteins can also be affected by phosphorylation triggered by signals from cell-surface receptors (often growth factors). An important concept is to view the final result of hormonal activity and gene expression as a reflection of **cellular context**, the nature and activity of transcription factors as influenced by specific intracellular adapter proteins. This explains how similar agents (and similar transcription factors, e.g., the estrogen receptor) can have different actions in different tissues.

## Translation

The mRNA travels from the nucleus to the cytoplasm, where it directs the assembly of amino acids into proteins (translation) on ribosomes. Each cell has a characteristic but dynamic and always changing **proteome**, the collection of proteins unique for that cell. Amino acids are brought into the process by specific transfer RNA molecules. The specific sequence of three bases at one end of the transfer RNA is complementary to the codon that encodes the specific amino acid. Binding of this area to the mRNA codon places the specific amino acid at the other end into the proper sequence for the protein. The amino acids are placed one at a time as the transfer RNA molecules read the RNA template, beginning at the amino end and finishing at the carboxy end. The process begins at the first AUG triplet and continues until a stop codon (UAA, UAG, or UGA) is reached, whereupon the mRNA falls off the ribosome and degenerates (**Figure 31.7**). The specific linear sequence of amino acids is specified by the genetic coding; in turn, this sequence determines the 3-dimensional form of the protein, the folded structure necessary for function. There are only 20,000–25,000 protein-encoding human genes, but there are more than 100,000 proteins. Obviously a single gene can produce more than one protein, primarily through the process of alternative splicing.

**FIGURE 31.7**

The final expression of a gene may not end with the translation process. Further posttranslational processing of proteins occurs, such as glycosylation (such as for the gonadotropins) or proteolytic cleavage (as happens in the conversion of proopiomelanocortin to ACTH).

In the discussion of regulation of gene expression and translation, micro RNAs (miRNAs) are worth mentioning. miRNAs are 21–22 nucleotide long noncoding mRNAs that repress expression of targeted genes through sequence complementarity, resulting in the degradation of target mRNAs or (more commonly) inhibition of their translation. More than 1,500 evolutionarily conserved miRNAs have been identified and play key roles in physiologic processes as well as pathogenesis of reproductive disorders.

**The mechanisms that produce proteins from genes are similar throughout the biologic world. This means that important knowledge regarding human function can be gained by studying simple organisms, and microbes can be engineered to produce human proteins.**

## Epigenetics

Epigenetics is the study of heritable changes in gene expression that do not involve

changes in DNA sequence. Epigenetic regulation may occur through DNA methylation or by alterations to the histone proteins that are responsible for the overall structure of chromatin. The best characterized DNA methylation process is the covalent addition of the methyl group at the 5-carbon of the cytosine ring resulting in 5-methylcytosine (5-mC). These methyl groups project into the major groove of DNA and inhibit transcription. Although epigenetic modifications do not result in changes to the DNA sequence or the content of genes and chromosomes, they have significant effects on gene function and the resulting phenotype.

# GENETIC AND EPIGENETIC VARIATION

---

The content of an organism's genetic and epigenetic information determines the subsequent functions that they encode. Therefore, genetic and epigenetic variation are both causes of diversity among members of the same species, as well as mechanisms of genetic risk and disease. Variation can arise anew (de novo) via mutation or can be inherited from a parent. Historically, the term "mutation" suggested a pathogenic change, but mutations can also have a phenotypic benefit to an individual. Some suggest the use of the term mutation for rare variants in the population, while using the term polymorphism for those variants with a population frequency greater than 1%. However, some rare variants have no apparent functional consequence and are better characterized simply as rare or private variants. Although there is some dispute over when the term mutation is appropriate, for the purposes of this text, we will reflect the most common usage of the term as a genetic lesion responsible for heritable human disease.

Genetic variation and mutation can occur at the level of a single nucleotide, a portion of a gene, a segment of a chromosome, or an entire chromosome or set of chromosomes. Understanding genetic and epigenetic variation is essential for today's reproductive endocrinologist.

# Single-Gene Sequence Variation

Many genes exist in various forms, called alleles. A change in DNA sequence that results in a change in protein structure or function that is harmful constitutes a pathogenic variant or mutation. Substitution refers to a change in a single nucleotide. Due to redundancy in the genetic code (i.e., there are multiple codons that encode a single amino acid), synonymous single-nucleotide variants do not manifest in changes to the gene product. However, a nonsynonymous substitution in a codon results in the incorporation of the wrong amino acid into a protein, leading to a change or loss in function. A clinical example of such a change is the sickle-cell mutation, in which thymine is substituted for adenine in the beta-globin gene, resulting in the well-known phenotype. Single-base substitutions can also occur within a gene's promoter (thus altering gene expression) or at a splice site (thereby preventing appropriate mRNA splicing and resulting in an altered downstream amino acid sequence), or can even introduce a premature stop codon (causing a truncated protein to be expressed).

If homologous regions of DNA are misaligned, unequal crossover can occur, resulting in deletions and insertions. Deletions and insertions can be as small as single nucleotides or as large as genes or several genes. Single-gene deletions and insertions are commonly referred to as indels. The content and location of such indels dictates their functional impact; for instance, a three-base-pair "in-frame" (i.e., falling between one codon and the next in a sequence) insertion may not have a large impact, but a single base-pair deletion would cause a "frameshift" (i.e., changing the reading frame for every subsequent codon in the gene) and would be very likely to be pathogenic.

Single-gene mutations are generally transmitted according to mendelian inheritance patterns: autosomal dominant, autosomal recessive, X-linked recessive, and rarely X-linked dominant. In autosomal dominant conditions, one abnormal allele for a given gene is all that is needed to yield the disordered phenotype. With two heterozygous parents, each child has a 75% risk of being affected. With one heterozygous parent, each child has a 50% risk of being affected. Examples of autosomal-dominant conditions include Huntington disease, neurofibromatosis, and Marfan syndrome. The effect of an abnormal dominant gene is influenced by **penetrance**, the degree the dominant gene is expressed. Complete penetrance, as opposed to incomplete penetrance, means that the gene is always expressed and always produces a recognizable phenotype.

In contrast, autosomal recessive conditions are phenotypically expressed only in homozygotes where both alleles are abnormal. A child of heterozygote parents has a 25% risk of being affected and a 50% chance of being a heterozygote ("carrier"). Examples of autosomal recessive conditions are cystic fibrosis, sickle cell disease, and congenital adrenal hyperplasia due to a deficiency in 21-hydroxylase. Similarly, X-linked recessive conditions are only seen when there is no normal allele present. In

females, this would require homozygosity for the variant allele. However, in males, the lack of a second X chromosome ensures that all who have the variant allele will manifest the phenotype. Thus, each son of a female carrier has a 50% chance of being affected and each daughter a 50% chance of being a carrier. Red-green color blindness and hemophilia A are examples.

A final type of single-gene mutations worth discussing is mitochondrial DNA mutations. Mitochondria are believed to be descendants of primitive bacteria engulfed by our ancestors, and they still contain some important genes. Each mitochondrion is estimated to contain 2–10 mtDNA copies and with the exception of oocytes and spermatozoa, 100–10,000 copies of mtDNA are estimated to be present in human cells. In mammals, each double-stranded circular mtDNA molecule consists of 15,000–17,000 base pairs, encoding a total of 37 genes. Of these, 13 encode proteins involved in electron transport chain, while the remainders are for ribosomal RNAs (2) or transfer RNAs (22). The mitochondria in sperm are eliminated during fertilization, so there is no paternal transmission of mitochondrial DNA mutations and diseases due to mitochondrial genes (e.g., Leber optic neuropathy) are solely transmitted by the mother.

# Polygenic Traits and Disorders

While single-gene variation can manifest in disease or individual diversity, many genetic traits and disorders are the result of a combination of genetic effects. Polygenic traits, such as height or eye color, are determined by the combined effect of different alleles at multiple genetic loci. Multifactorial genetic disorders result from a number of genetic variants, which, often in combination with environmental effects, can increase the risk of pathology. Most common diseases with a genetic component, such as coronary artery disease and polycystic ovary syndrome, are multifactorial. Additionally, there are some genetic diseases that derive from a specific subset of genetic mutations. Best described are cancers that arise in the setting of coexisting mutations in two genes, popularly known as the “two-hit hypothesis” of carcinogenesis.

# Chromosomal Abnormalities

## Numerical Abnormalities

Numerical abnormalities usually are due to nondisjunction, a failure of separation at anaphase, either during mitotic division or during meiosis. **Aneuploidy** is a chromosome number that is not an exact multiple of the haploid number, for example, monosomy (45,X Turner syndrome) or trisomy (trisomy 13 Patau syndrome, trisomy 18 Edwards syndrome, trisomy 21 Down syndrome, or 47,XXY Klinefelter syndrome). **Mosaicism** indicates one or more cell lines with a different karyotype, usually arising from mitotic nondisjunction (failure of two paired chromosomes to separate) or anaphase lag (omission of a chromatid due to its delayed separation in anaphase) in the postfertilization embryo. **Polyploidy**, multiples of the haploid number of chromosomes, is a significant cause of spontaneous miscarriage.

## Structural Abnormalities

Structural abnormalities can result from DNA replication errors, from meiotic errors during crossover, or from chromosomal breaks induced by radiation, drugs, or viruses. In a **translocation**, there is interchange of material between two or more nonhomologous chromosomes. A balanced translocation is associated with neither gain nor loss of genetic material, and such an individual is a translocation carrier. If the balanced translocation involves the q arms of two acrocentric chromosomes, the translocation is referred to as a Robertsonian translocation. Although carriers of balanced translocations generally have no overt phenotype themselves (as their genetic content is complete, albeit chromosomally rearranged), they are likely to have gametes with unbalanced genetic content, due to the segregation of translocated chromosomes during meiosis. This increases the likelihood of chromosomally unbalanced offspring, which most frequently manifests in pregnancy loss.

Another class of structural abnormalities is insertions, duplications, and deletions. In these abnormalities, a chromosomal segment is moved from one locus to another, duplicated in a neighboring location, or omitted entirely. Large deletions that result in the loss of several essential genes can cause severe pathology (e.g., cri-du-chat syndrome) or pregnancy loss. Smaller deletions and duplications, however, can range from being pathogenic to simply another source of genetic variation found throughout the population. Such deletions and duplications, often referred to as “del dups” or copy number variation (CNV), cover nearly 10% of the human genome.

Other structural abnormalities include chromosomal inversions and ring chromosomes, which can cause pathology by disrupting essential genes or creating an

unbalanced genetic state (i.e., with concomitant deletion or duplication of genetic material).

# Epigenetic Variation and Genomic Imprinting

Variation can also be generated at the epigenetic level. For instance, the DNA methylation pattern varies from one individual to the next, based upon both heritable and environmental factors. In some situations, this variation leads to subtle or unrecognized phenotypic effects. However, when the methylation involves certain genetic loci, it can lead to specific disorders. For instance, aberrant methylation of the H19 gene can result in the Silver-Russell syndrome or Beckwith-Wiedemann syndrome.

Genomic imprinting is a specific epigenetic process that confers persisting influence on genome function based upon the parent of origin for a given allele. For instance, in certain autosomal recessive conditions, the expression, severity, and age of onset are influenced by the gender of the parent providing the mutant gene or chromosome. Because genomic imprinting can silence the expression of an allele from one parent, this can also lead to more severe phenotypes in the setting of a concomitant deletion. This is seen in the Angelman and Prader-Willi syndromes, where a deletion of chromosome 15q11-13 leads to hemizyosity (i.e., only one copy is present) of three notable genes, SNRPN, NDN, and UBE3A. Because these three genes are imprinted, with only the paternal alleles of SNRPN and NDN expressed and the maternal allele of UBE3A expressed, the same 15q11-13 deletion leads to different nonfunctional genes if it is inherited maternally versus paternally. With different genes functionally absent in each scenario, two distinct phenotypes emerge, representing the Angelman and Prader-Willi syndromes.

# TECHNIQUES OF MOLECULAR BIOLOGY

---

An enzyme that breaks the phosphodiester bonds and cuts the DNA molecule into fragments is an endonuclease; a **restriction enzyme** (restriction endonuclease) cuts only at sites with specific nucleic acid sequences. Restriction enzymes were discovered in bacteria in which they form a defense mechanism to cut (and thus inactivate) any foreign DNA (from invading viruses) introduced into the bacterial cell. As part of this protection mechanism, bacteria also contain methylases that methylate recognition sites in native DNA, directing the action of the restriction enzyme to the nonmethylated foreign DNA. Different bacteria have different restriction enzymes with specific action sites. Restriction enzymes are available that cut DNA into pieces (restriction fragments), ranging from many small fragments to a few large pieces, depending on the number of nucleotides in the recognition sequence. The enzymes are named for the organism and strain from which they are derived. The combination of restriction fragments, the merger of two cut pieces of DNA, yields **recombinant DNA**.

**DNA polymerase** is an enzyme that brings single nucleotides into a DNA molecule. A DNA polymerase can form DNA only in the presence of a DNA template; the synthesized DNA will be complementary to the template. RNA polymerase can make RNA, also only in the presence of a DNA template.

A deoxyribonuclease (**DNAase**) can remove nucleotides. By combining DNAase treatment with DNA polymerase action, radiolabeled nucleotides can be introduced into a DNA molecule, producing a **DNA probe**. A DNA probe can be compared with the antibody used in immunoassays. The antibody is specific and recognizes the epitope against which it is formed. The DNA probe specifically detects a sequence of DNA.

**Reverse transcriptase** is DNA polymerase that is RNA dependent. It is called reverse transcriptase because the flow of information is from RNA to DNA, the reverse of the usual direction of flow. This enzyme permits the copying of essentially any RNA molecule into single-stranded DNA; such DNA is called **complementary DNA (cDNA)** because it is a mirror image of the mRNA. Complementary DNA probes are limited by their reading only the exons (remember that introns are excised from RNA via splicing).

DNA and RNA are charged molecules and, therefore, will migrate in an electrical field. Fragments can be analyzed by gel (agarose or polyacrylamide) electrophoresis, the largest fragments migrating the slowest. By convention, the gels are read from top to bottom, with the smallest fragments at the bottom.

# Southern Blot Analysis

DNA is first denatured to separate the two strands and digested by restriction enzymes to produce fragments that are loaded into an electrophoresis gel. The Southern blot method, named after its inventor E.M. Southern, separates the fragments by electrophoresis based on size; the smaller the fragment, the faster the migration. The electrophoresis gel is placed over a thick piece of filter paper with its ends dipped in a high-salt solution. A special membrane (nitrocellulose or nylon) is placed over the gel, and over this is placed a stack of paper towels compressed by a weight. The salt solution rises by wick action into the filter paper; it moves by capillary action through the gel, carrying the DNA with it. The DNA is carried to the membrane to which it binds. The salt solution keeps moving and is absorbed by the paper towels. The nitrocellulose or nylon membrane thus creates a replica of the original electrophoresis pattern. The DNA is fixed to the membrane either by high-temperature baking or by ultraviolet light. Specific labeled DNA or RNA probes then can be introduced for hybridization. **Hybridization** means that a specific probe anneals to its complementary sequence. The fragments with this sequence are then identified by autoradiography. Fluorescent probes can be utilized that can be detected after activation by a laser beam, allowing qualitative and quantitative assessment by a computer. Southern blotting is still a necessary procedure, but it is often replaced by the faster and more sensitive technique of PCR.

**Northern blotting** detects RNA sequences; it is called “Northern” because RNA is the opposite image of DNA. Extracted RNA is separated by electrophoresis and transferred to a membrane (as in Southern blotting) for hybridization with probes of complementary DNA. Northern blotting could be used, for example, to determine whether hormone stimulation of a specific protein in a tissue is mediated by an increase in mRNA, that is, gene expression. Northern blotting can also be replaced by PCR using a reverse transcriptase enzyme.

Electrophoresis to separate and quantitate proteins is called **Western blotting**, and antibodies are used for the hybridization identification process. Like Northern blotting, Western blotting tests gene expression, not just the presence of a gene. The terms **Northern and Western** represent intentional witticisms (a rare event in science) in response to Southern blotting. Hybridization without electrophoresis by placing a drop of the cell extract directly on filter paper is called **dot or slot blotting**.

# Hybridization

When two complementary strands of DNA reassociate, the process is called hybridization. Hybridization allows a specific area of the DNA to be studied using a radiolabeled DNA probe that is specific (via a complementary sequence). The membrane produced after Southern blotting is first treated to block nonspecific binding sites. The membrane is then treated (hybridized) with the labeled probe. The location of bound probe is then identified by autoradiography (for radiolabeled probes) or by colorimetric methods. The sequence of the probe, therefore, determines the sequence at the site of binding. Whenever two products are complementary, hybridization occurs. Thus, complementary DNA can be hybridized to its template mRNA.

In situ hybridization is the technique in which labeled DNA or RNA probes are placed directly on a slide of tissue or cells. A piece of cloned DNA labeled with a fluorescent marker can be utilized; the method is referred to as **FISH** (fluorescence in situ hybridization). The region corresponding to the cloned DNA lights up under fluorescent illumination unless the region has been deleted from one of the chromosomes. Several microdeletion syndromes have been discovered with the FISH technique, for example, the Prader-Willi syndrome.

# DNA Microarrays

DNA microarrays (or simply “arrays”) use the hybridization approaches described above in a multiplex format sometimes referred to as a “lab-on-a-chip.” Thousands of DNA probes are attached to the surface of a glass slide or similar material in a known arrangement. Hybridization of sample DNA causes a detectable reaction, such as chemiluminescence or fluorescence, which denotes the relative amount of hybridization that occurred (these techniques are semiquantitative, comparing the amount of hybridization to that of a reference control). Microarray technology can be used for a variety of experiments and clinical tests, such as the detection of gene expression, single-gene sequence variation, and chromosomal content. Expression arrays hybridize cDNA generated from RNA from a tissue of interest to complementary DNA probes. If the tissue of interest expresses a gene, the labeled signal is easily observed. Single-nucleotide polymorphisms (SNPs) arrays are one type of microarray used for the assessment of sequence variation. Such arrays contain probes representing the known alleles at a given nucleotide position. Homozygosity, heterozygosity, and even aneuploidy can be detected with this approach.

Chromosomal content can also be assessed using array comparative genomic hybridization (array CGH or aCGH), which measures the hybridization between a DNA sample of interest (for instance, from a trophoblast biopsy) and control DNA probes that cover the entire human genome. Aneuploidy and CNV can both be detected with this approach by comparing the sample’s hybridization to that of a known reference control. While array CGH is a powerful tool for detecting numerical and unbalanced chromosomal abnormalities, it is not currently effective for detecting balanced structural chromosomal abnormalities. Because the processing of the sample DNA involves fragmentation of its genome-level structure, balanced structural rearrangements are typically undetectable by array CGH (an analogy would be if someone dropped a stack of papers meant to constitute a book; while one could subsequently ensure that all the pages are accounted for, they could not be sure that the papers were in the proper order before the stack was dropped). Karyotype remains the most effective way to detect balanced structural abnormalities.

# Polymerase Chain Reaction

The PCR is a technique to amplify (relatively quickly) small fragments or areas of DNA into quantities large enough to be analyzed with electrophoresis and blotting methods. This technique produces enormous numbers of copies of a specific DNA sequence without resorting to cloning. The sequence to be amplified must be known. Specific markers (synthesized short sequences of DNA corresponding to each end of the sequence to be studied) are selected that will delineate the region of DNA to be amplified. These flanking sequences are called primers. The DNA sample, the primers, and an excess of free single nucleotides are incubated with a DNA polymerase.

The first step involves separating DNA into its single strands by denaturation with heat (approximately 92°C); then the temperature is lowered (approximately 60°C), causing the primers to stick (anneal) to their complementary regions on the DNA. The temperature is raised to 72°C, and DNA polymerase then synthesizes a new strand beginning and ending at the primers, forming a new double-stranded DNA. Repeating the cycle many times (by fluctuating the reaction temperature) exponentially amplifies the amount of DNA available for study, allowing DNA from small specimens (such as embryonic biopsies) to be adequate for assessment. Because the process requires alternate heating and cooling, a DNA polymerase resistant to heat is an advantage in that periodic replenishment is not necessary. This problem was solved with the discovery of a DNA polymerase (Taq polymerase) from a thermophilic microorganism (*Thermophilus aquaticus*) found in an out-of-the-way Yellowstone National Park hot spring called Mushroom Pool. This high-temperature polymerase allows automation of the process.

Reverse transcription PCR is used to amplify the sequence of small amounts of a specific RNA. The starting template is an RNA molecule, which is converted to its complementary DNA by reverse transcriptase, an enzyme originally discovered in retroviruses. The newly synthesized cDNA is then processed by the standard PCR procedure to yield larger quantities of DNA corresponding to the RNA of interest.

Real-time PCR (also known as quantitative PCR) is now routinely used in clinical laboratories. The method uses fluorescent probes to measure the amount of DNA produced in a PCR while it is occurring. This approach can be used to detect small amounts of specific DNA in rapid fashion, such as in the diagnosis of infectious disease, or combined with reverse transcription to measure the expression of a gene of interest. Unlike the conventional PCR (also called end-point PCR), real-time PCR is capable of providing a reliable quantitative comparison between samples by limiting the analysis to the stage of amplification where the reaction shows linear amplification (cDNA content doubles with each reaction).

# DNA Sequencing

DNA sequencing is the name for the set of approaches that allow the nucleotides in a particular portion of the genome to be identified in order. Sanger sequencing (also known as chain-termination sequencing) was the most common approach to sequencing for most of the past 40 years. An *in vitro* DNA replication reaction is carried out, with a DNA polymerase directing the incorporation of nucleotides beginning at a site directed by a DNA primer. The set of nucleotides for each reaction includes a subset that is modified in such a way that terminates DNA strand elongation. These modified nucleotides (called dideoxynucleotides, or ddNTPs) are typically fluorescently labeled to allow automated detection for more rapid machine-based sequencing. The base-specific fluorescent wavelength is matched to the length of the fragment (as determined by capillary electrophoresis) to determine the DNA sequence.

More recently, advances in DNA sequencing have been made to allow high throughput at decreased costs. Collectively referred to as next-generation sequencing (NGS) or massively parallel sequencing, these approaches are based upon the concept of conducting millions to billions of sequencing reactions at the same time in distinct spatial arrangements. While there are many different methods currently employed for NGS, the majority of these use sequencing by synthesis. In this approach, clonally amplified DNA is kept in distinct spatial compartments, where it acts as the template for a DNA replication reaction. The distinct spatial compartments can be achieved through methods such as emulsion PCR, which uses water-oil emulsion droplets to keep DNA molecules separated, and DNA colony formation, which uses DNA adapters and bridge amplification to produce small clusters of replicated DNA fragments at distinct locations on the surface of a flow cell. Unlike in Sanger sequencing, the NGS replication reactions use a variety of approaches that allow the base-by-base extension of the DNA molecule to be visualized as it occurs.

# Chromatin Immunoprecipitation

Chromatin immunoprecipitation (ChIP) localizes a protein to its binding site on DNA. The technique uses an antibody that is specific to the protein of interest. The DNA that is isolated by the antibody-protein-DNA complex can then be studied by PCR. The specific regions of the genome, bound by the protein of interest can be also determined by using a DNA microarray, a method known as ChIP-on-chip.

# Cloning DNA

Cloning means isolating a gene and making copies of it. A DNA library is a collection of DNA molecules derived from cloning methods. A complementary DNA library is the DNA counterpart of all of the mRNA isolated from a particular cell or tissue. By starting with mRNA, the search for the gene of interest can be focused (instead of searching the entire genome). Such a library is made using reverse transcriptase. The DNA molecules then can be inserted into an appropriate vector (described below), and replicate molecules can be produced. Using probes, the complementary DNA can be selected that matches the gene of interest (keeping in mind that complementary DNA only includes the exons of a gene). Cloning the DNA simply means the production of many identical copies of a specified fragment of DNA. Cloning can also be performed using the PCR. As indicated above, complementary DNA cloning focuses on the DNA counterpart of mRNA; genomic DNA cloning, using a restriction endonuclease, copies the DNA in genes. Cloning also can be used to make multiple copies of probes or unknown DNA fragments.

If the amino acid sequence is unknown, one can work backward. Knowing the specific protein product, antibodies can be produced against the protein. When complementary DNA is inserted into certain vectors, production of the protein can be identified with the antibodies; thus, the DNA fragment will be isolated.

A vector is an entity in which foreign DNA can be inserted. The vector plus the foreign DNA are inserted into a host cell; the host cell produces both the vector and the foreign DNA. The first vectors were bacterial plasmids, circular DNA molecules (minichromosomes) that coexist in the cytoplasm with the bacterial chromosomal DNA. Most noteworthy, they carry genes that code for antibiotic resistance. This enables the bacterial cells that contain the plasmid to be selected by appropriate antibiotic treatment. Plasmid vectors have also been developed that allow selection by color. A variety of bacterial strains have been developed, each for a specific use.

Disruption of the plasmid DNA with restriction enzymes, followed by incorporation of foreign DNA with DNA ligase, produces plasmid DNA molecules (recombinant DNA containing the foreign DNA) that can be replicated. Plasmid vectors can incorporate foreign DNA fragments up to 10 kb in size. Digestion of recovered plasmids with restriction enzymes releases the desired DNA fragment, which can then be recovered by electrophoresis.

Other vectors exist. Bacteriophages (or phages) are viruses that infect and replicate within bacteria. Phage vectors can incorporate larger DNA inserts, up to 20 kb. Cloning DNA with phage vectors follows the same basic design as with plasmids. Larger fragments of foreign DNA are cloned with cosmid vectors, artificially produced combinations of phage and plasmid vectors. Very large fragments, up to 1,000 kb, can

be cloned using yeast artificial chromosomes. This method can work with whole genes.

**Basic Steps for Cloning:**

1. Choose a DNA source: either genomic DNA or complementary DNA.
2. Fragment the DNA by restriction endonucleases.
3. Insert the fragments into vectors.
4. Introduce the vectors into bacteria.
5. Collect the cloned DNA propagated in the bacteria to form a library.
6. Screen the library for the desired sequence. Possible methods include the use of complementary nucleotide probes for fragments that hybridize or the detection of a specific protein produced with antibodies to the protein or by assaying the function of the protein.

# Transgenic Animals

Transgenic animals are produced by inserting cloned genes or complementary DNA into such organisms as bacteria, yeast, worms, or mice. In mammals, the cloned gene or cDNA can be injected into a pronucleus of a fertilized egg where it will be integrated into the chromosomes. The modified embryos are transferred to the uterus of a recipient mother who will deliver progeny with the foreign DNA. Altered biologic behaviors and functions are then attributed to the foreign DNA. Transgenic animals provide animal models for human disease and are an avenue to study the *in vivo* functional effects of genetic variation.

Animal models for the function of a gene often employ the method of “knocking out” a specific gene. Knock-outs are generally created by *in vitro* homologous recombination between a nonfunctional transgene and the native gene of interest in embryonic stem cells. In a straightforward demonstration, it can be determined whether a specific gene and its protein are essential for a specific process (such as normal folliculogenesis) or for life altogether.

Compared to constitutive gene knock-out models, which have gene knock-out in all tissues from the earliest stages of development, conditional knock-out models give greater flexibility and precision. In this type of knock-out, the functional gene is only inactivated at a specific time in development or in a specific cell type.

An alternative to homologous recombination-based transgenesis is the CRISPR/Cas9 method of gene editing. In this system, a targeted guide RNA directs the Cas9 endonuclease to create double-stranded breaks in DNA at a specific site. A repair template DNA specifies the modified DNA sequence, which is incorporated at that site by the intrinsic cellular mechanism of homology-directed repair (HDR). Alternatively, some of the double-strand breaks will be repaired by nonhomologous end joining (NHEJ), which causes random insertions or deletions that lead to gene knock-out. Methods are being developed to optimize the HDR:NHEJ ratio for the intended applications of CRISPR/Cas9.

# Genomics, Proteomics, and the Omics Revolution

With technologic and bioinformatic advances allowing high-throughput assessment of large amounts of data, molecular biology has gone through a period referred to as the “omics revolution.” While genetic research historically has focused on single genes, the complete sequencing and study of entire genomes is referred to as genomics. Beyond just the compilation of massive amounts of sequence data, genomics research allows for a system-level study of gene interactions and expression. The study of genetic variation among members of a species is often called “variomics”; such extensive cataloging of human variation is ongoing, building upon the progress of such publicized efforts as the HapMap Project and the 1000 Genomes Project. Characterization of the range of epigenetic variation in a species is referred to as “epigenomics.”

Genomics and its relatives, however, will not tell the whole story. The protein products of gene expression are altered in the translation process and also by posttranslational modifications such as glycosylation, methylation, and phosphorylation. Thus, a more complete picture can emerge with proteomics, the study of the biologically functional end products, the proteins of a cell or a tissue. Both genomics and proteomics are keys to understanding physiology and diagnosing diseases, and for the design of new drugs.

**Metabolomics** is the study of small molecules within cells, the metabolic products that characterize cells. Crude cellular extracts are subjected to chromatography, spectrometry, or nuclear magnetic resonance measurements to create characteristic chemical fingerprints associated with normal or abnormal cellular function.

The amount of data generated in omics research is enormous, impossible to manage without computer databases. Bioinformatics is the science dedicated to the development of computer algorithms to best organize and analyze this growing wealth of information, and for creating efficient search and retrieval systems. This allows the data to be available to laboratories scattered throughout the world and the study of the information with sophisticated mathematical analysis.

# THE IDENTIFICATION OF GENES

---

To clone an entire gene whose protein product is known, a complementary DNA library is produced. The specific DNA fragment is identified by linking it to the protein. Once identified, the total gene can be screened using the identified complementary DNA, indicating the introns and exons. Another strategy is to synthesize an oligonucleotide probe, basing the sequence on the known amino acid sequence in the protein product (from the peptide sequence, the DNA sequence that codes for that protein can be predicted). This method can be used with just a relatively small piece of the peptide. Complementary DNA can be cloned without producing a library by using the PCR to amplify complementary DNA made from mRNA by reverse transcriptase. Overlapping sequences of the genome can be cloned, using a piece of DNA from each succeeding product, to work across a chromosome in a systematic manner to search for a gene; this is called **chromosome walking**.

The entire sequencing process can be performed by a computer, even searching for open reading frames. Once the sequence of a DNA fragment has been identified, the computer can utilize DNA and protein databases to predict sequence, recognition site, protein translation, and homology with known sequences. The scientist can then select restriction fragment sizes for cloning. Once a gene has been analyzed, it has to be compared with the gene in the disease state. If a variant is of large size, this can be detected by Southern blotting. Minor alterations require comparisons in DNA sequences, which is possible by using polymerase chain amplification to produce specific gene sequences in amounts readily studied.

A gene can be localized to a specific chromosome when its protein product is unknown by studies involving chromosome rearrangements and linkage analysis. Specific diseases are associated with karyotypic changes. Thus, the specific chromosome can be targeted for gene localization. Linkage analysis utilizes restriction fragment length polymorphisms.

# DNA Polymorphism

Southern blotting reveals specific patterns of bands that reflect the varying lengths of the DNA fragments produced by restriction enzyme action. A specific site can exhibit a mutation by having a different pattern (a different length of the DNA fragment on Southern blotting due to sequence difference). These differences in DNA sequences are called **restriction fragment length polymorphisms**. Single-nucleotide polymorphisms, referred to as SNPs, or simply polymorphisms, are usually benign and common variations. The human genome contains about 4.5 million polymorphisms, and more than 3 million have been identified. Although 99.9% of DNA sequences in humans are the same, SNPs can serve as genetic markers for a medically important gene. A polymorphism is governed by the mendelian regulations of inheritance, and if by chance a polymorphism is identified in a patient with a specific disease, the transmission of the disease can be studied. The polymorphism, which is linked to the disease by chance, can be used to study the inheritance of a disease when the genes are unknown. The polymorphism is like a flag that marks specific areas of chromosomes. This method of study requires DNA from at least one affected individual and a sufficient number of family members to trace the polymorphism, either by Southern blotting (for long sequences) or with the PCR (best for short sequences). Correlation of genetic markers (polymorphisms) and phenotype also employs **haplotypes** (similar to a polymorphism but a longer sequence of nucleotides, even a set of several polymorphisms). Efforts using genetic technologies to link SNPs and haplotypes to clinical problems and inherited traits are known as **genome-wide association studies**.

Minisatellites are a form of polymorphisms. Genes concentrate in random areas along chromosomes separated by long sequences of noncoding DNA. Minisatellites are noncoding areas of DNA that repeat in variable numbers, so-called variable number **tandem repeat sequences**, distributed throughout the length of every human chromosome. These areas can be followed by DNA probes, providing a “fingerprint” for specific individuals. This uniqueness is applied in forensic medicine. Microsatellites, as the name implies, are smaller than minisatellites. Usually, microsatellites consist of repetitions of only two nucleotides. DNA polymorphisms now number in the thousands and allow genetic mapping with great precision.

# The Human Genome Project

All of the human genes are collectively known as the genome. Begun in 1990, the goal of the international Human Genome Project was to sequence the human genome, a goal that was reached in draft form in 2001 and 99% of the actual sequence in 2003, more than 2 years ahead of schedule, 50 years after Watson and Crick's publication. The number of protein-encoding genes (20,000–25,000) is smaller than previous estimates. Less than 2% of the human genome with nearly 3 billion nucleotides codes for proteins; therefore, the remainder is a rich resource for evolutionary historians and a target for inducing genetic changes. The number of genes in specific chromosomes varies; the chromosomes that are affected by trisomy, chromosomes 13, 18, and 21, have the fewest genes. (Information on the human genome project is available at [http://www.ornl.gov/sci/techresources/Human\\_Genome/home.shtml](http://www.ornl.gov/sci/techresources/Human_Genome/home.shtml))

Fortunately, the Internet emerged in time to accommodate the enormous data generated by studying the human genome. The National Center for Biotechnology Information (NCBI) maintains a Web site that provides databases as well as the Online Mendelian Inheritance in Man (OMIM) site developed by Victor A. McKusick at the Johns Hopkins University as a guide to human genes and inherited disorders (<https://www.ncbi.nlm.nih.gov/omim>).

The next wave of information will come from projects like the ENCODE project and the 1000 Genomes project. ENCODE is a research consortium organized by the National Human Genome Research Institute of NIH to develop an encyclopedia of the functional elements in the human genome (<http://www.genome.gov/ENCODE>). The 1000 Genomes project provides the genome sequence of 1,000 people from around the world to map DNA variations with a fine resolution (<http://www.internationalgenome.org/data/>).

The human genome map can serve as a foundation for locating sites for heritable factors that predispose for diseases and mutations that cause disease and for integrating the genetic sequencing with biologic functions. Soon, we will be able to have in our possession a personal record of our individual complete genetic blueprint.

The chromosomal locations of genes responsible for hormone production have been mapped. From the cloned DNA sequences, the amino acid sequences can be predicted. Every protein product of a gene represents a potential diagnostic or therapeutic target. And of course, inherited disorders will be subject to characterization and, eventually, gene therapy. However, even after a gene has been identified and genetically mapped, its full characterization remains a difficult and time-consuming task. Full understanding of disorders that involve the interactions of multiple genes will be even more complicated.

# CLINICAL APPLICATIONS

---

The challenge for modern medicine is to make clinical sense of the massive collection of data generated by genomics and proteomics. Understanding the function of genes and proteins will undoubtedly be an accelerating feature of human progress. Knowing an individual's genetic susceptibilities would allow medical diagnosis and treatment to be personalized to a higher degree. Nevertheless, this is a complicated new era and not always straightforward. For example, a genetic susceptibility may carry with it only a small percentage increase in risk for a disease; at what point is intervention merited in terms of benefit and cost, not only for an individual but for society? In addition, gene activity can be turned on and off in response to environmental factors. From the bench to the bedside may be slower than anticipated, but there is no doubt that we are on the verge of translating genomic theory into clinical practice.

# Diagnosing Genetic Disorders

The molecular diagnosis of genetic disorders requires only a small sample of DNA, obtainable from any cells that are nucleated, such as white blood cells or epithelial cells. PCR amplifies the small sample of DNA, allowing a variety of assays to be performed to identify clinically relevant genetic variants. These diagnostic assays can employ a variety of techniques; many utilize the DNA sequencing or hybridization approaches outlined earlier in this chapter. Sequencing approaches can be based upon either Sanger sequencing or NGS, and can even entail whole exome sequencing (WES) if the locus of genetic variation is not clinically apparent. Hybridization approaches can be as simple as single DNA probes that hybridize to allele-specific DNA sequences during real-time PCR or as complex as custom-designed microarrays with probes for a variety of genetic variants related to a certain condition.

Molecular diagnosis is limited by the prevalence of genetic heterogeneity. In other words, many disorders result from different mutations in different people. In contrast, some (like sickle cell disease) always involve the same change. With cystic fibrosis, 70% of patients (of northern European ancestry) have the same 3-base deletion, whereas the remaining 30% have an extremely heterogeneous collection of mutations. The benefit to using a sequencing-based approach for molecular diagnosis is that it can provide a more comprehensive view that does not ignore such novel or rare variants. The inherent downside to this approach, however, is that it can identify variants of unknown significance (VUS), which may be simply benign variants. Understanding the significance of detected rare or novel variants requires close evaluation of their likelihood of pathogenesis, such as by examination of cross-species conservation or segregation of the mutation with an identified disease in a family.

# Preimplantation Genetic Testing

One of the most important clinical applications of genetic techniques in modern reproductive medicine is preimplantation genetic testing. Such testing includes the assessment of embryos for known mutations (classically known as preimplantation genetic diagnosis, or PGD, now called preimplantation genetic testing for monogenic disorders, PGT-M) as well as for aneuploidy, whether due to the parental karyotype or due to age-related factors (classically known as preimplantation genetic screening, or PGS, now called preimplantation genetic testing for aneuploidy, PGT-A). In each of these applications, the in vitro fertilized embryo is biopsied, with some of its cells serving as the source of the DNA template for the assay. This biopsy can be done at several developmental stages, sampling the polar biopsy of the fertilized oocyte, blastomeres at the cleavage stage, or trophectoderm cells in the blastocyst. While polar body biopsy offers the advantage of leaving the embryo undisturbed during sampling, it is only capable of sampling the maternal genetic contribution, and thus is of more limited utility. Cleavage-stage biopsy was the preferred method of biopsy for a number of years but has fallen out of favor due to higher rates of chromosomal mosaicism and concern for detriment to subsequent development of the biopsied embryo. Blastocyst biopsy has become the favored method for many IVF centers, due to the larger DNA yield and improved diagnostic accuracy of this approach.

When the intent of the preimplantation genetic testing is for identification of a known mutation (for instance, in the embryonic offspring of a couple who both carry a harmful recessive mutation), the extracted DNA from the biopsied cells is amplified and genotyped. Genotyping can be done through a variety of sequencing- and hybridization-based approaches, much like genotyping in an affected adult. To reduce the chance of diagnostic error, a selection of informative linked polymorphisms are often genotyped concurrently with the mutation of interest. Consistency of genotype data for all linked polymorphisms strengthens the confidence that the mutation of concern has been accurately diagnosed.

In the case of aneuploidy assessment, the extracted DNA from the biopsy specimen can be assessed using one of many different techniques. Historically, FISH was the preferred method for detection of aneuploidy in embryonic biopsies. Using a limited number of hybridization probes, a subset of chromosomes can be analyzed for numerical abnormalities. Recognition of the incomplete assessment that this provides, along with the availability of high-throughput technologies that allow comprehensive assessment of the chromosomes, has shifted attention away from FISH. Modern approaches to preimplantation genetic testing for aneuploidy include array CGH, SNP arrays, and NGS. While some have expressed continued concern about the diagnostic accuracy of even these more advanced approaches (citing examples of false positives), many view

this approach for embryonic selection as an avenue to reduced time to live birth and increased per-transfer live birth rate, at least in selected populations.

# Personal Genomics

One exciting avenue of ongoing investigation is precision medicine and personal genomics. With decreasing costs for DNA sequencing and genotyping, it is easy to envision a near-future where many people will have their genome sequenced. As we approach that time, the identification of genetic risk factors for a range of disorders has led to the establishment of genetic risk panels for many disease processes, from breast cancer to infertility. The clinical utility of such panels will hinge upon continued research into the absolute risk that they confer, especially when combined with relevant environmental factors. Such knowledge will allow a greater utility for personal genomes when they truly become a common clinical information source.

Related to the concept of personal genomics is pharmacogenomics, the study of genetic variations in pharmacodynamics that can explain different responses to the same dose of a drug. For example, different polymorphisms involved in enzyme synthesis can affect metabolism and clearance. Genetic testing offers the potential to predict drug pharmacokinetics in an individual, which would allow the selection of an appropriate dose to minimize side effects and maximize efficacy.

# A FINAL THOUGHT

---

Molecular progress is inexorable. The future will see preventive medicine by prediction. By knowing an individual's genetic constitution, appropriate and intensive screening can be directed to predisposed conditions. This kind of knowledge will also require social and political considerations. It is not far-fetched to envision lifestyle decisions made based on the information regarding genetic predispositions. Society is developing guidelines regarding the use of this information: by individuals, by employers, by health organizations, and by the government. Scientific progress must be matched by public and professional education to appropriately manage this knowledge.

# Endometriosis

Dr. Karl von Rokitansky was one of the first to describe endometriosis in 1860.<sup>1</sup> While he is credited with the microscopic discovery of the disease, reports dating back to 1690 by the German physician Daniel Shroen describe the characteristic peritoneal appearance of endometriosis. To an extent, he accurately described their location, content, and cause of pain: “ulcers distributed throughout the [peritoneum]... located predominantly in the bladder, intestines, broad ligament, and outside the uterus and cervix... [these sores are] inflammations that had a tendency to form adhesions that linked visceral areas together”.<sup>1</sup> A similar description was made by many other physicians of the 17th, 18th, and 19th centuries, with the additional discovery of the link to monthly menstruation and the presence of ovarian cysts with “blackish vesicles.”<sup>2</sup> However, it was not until the 20th century that Dr. John Sampson—now known as the “father of endometriosis”—described a series of perforating hemorrhagic ovarian cysts he called “chocolate cysts,” coining the term “endometriosis” to describe the peritoneal implants he first envisioned as seedlings derived from disease in the ovary.<sup>3</sup> In addition to naming the gynecologic disorder (endometriosis), he also proposed the theory of retrograde menstruation as the pathogenesis of this disorder.<sup>2</sup> His 1927 publication was one of the most influential and remains the prevailing teaching regarding the theory of endometriosis. Despite its recognition for centuries, the pathogenesis of endometriosis is still poorly understood, but investigations employing modern molecular methods are yielding new insights into the mechanisms of the disease and suggesting new approaches to its diagnosis and treatment.

# DEFINITION OF ENDOMETRIOSIS

---

Endometriosis is a chronic gynecologic disease characterized by endometrial-like tissue outside of the uterus and is associated with pelvic pain and infertility. The ectopic endometrial tissue usually is located in the pelvis but can appear anywhere in the body—the most common sites are the ovaries, anteroposterior cul-de-sac, uterosacral and broad ligaments, fallopian tubes, sigmoid colon, and the appendix.<sup>4</sup> The three main types of endometriosis are peritoneal, deep infiltrating, and ovarian.<sup>5</sup> As an estrogen-dependent disorder, ectopic lesions undergo cycles of growth and bleeding in synchrony with the menstrual cycle. The disease exhibits a broad spectrum of clinical signs and symptoms and is prone to progression and recurrence. Furthermore, it has adverse effects on quality of life and significant economic burden.<sup>6,7</sup>

# EPIDEMIOLOGY OF ENDOMETRIOSIS

---

As there is currently no noninvasive, reliable method for diagnosing endometriosis, the true prevalence of endometriosis is not known. Currently, surgery is considered the definitive method for diagnosis, yet is generally not performed on women without symptoms or physical findings that strongly suggest the disease; accordingly, estimates vary with the indication for surgical treatment. The prevalence of asymptomatic endometriosis is 1–7% in women seeking elective sterilization, up to 60% among women of reproductive age with pelvic pain, and 50–60% of women and adolescents with pelvic pain and/or unexplained infertility.<sup>8,9,10,11,12,13,14</sup> The overall prevalence of endometriosis in reproductive-aged women is approximately 10%.<sup>14,15,16,17,18</sup>

The mean age at time of diagnosis of endometriosis ranges between 25 and 35 years.<sup>19,20</sup> Endometriosis is rare in premenarchal girls but may be identified in 50–70% of adolescents and young women under age 20 with complaints of chronic pelvic pain or dyspareunia.<sup>10,11,21,22</sup> Most cases in young women under age 17 are associated with müllerian anomalies that include cervical or vaginal obstruction.<sup>14,23</sup> Fewer than 5% of women who require surgery for endometriosis are postmenopausal, and most have received estrogen therapy.<sup>24,25,26</sup> The prevalence of asymptomatic endometriosis may be somewhat lower in Blacks and higher in Asians than in White women, although the biologic basis for these differences is not clear.<sup>13,27</sup> Interestingly, the prevalence of endometriosis is inversely related to body mass index.<sup>20,27,28,29,30,31</sup>

Early menarche, short menstrual cycle length, and obstruction of menstrual flow have been associated with increased risk for endometriosis.<sup>14,15,27,32</sup> The correlation between the risk of disease and the volume or duration of menses is less consistent.<sup>15,32,33,34</sup> Pregnancy has a protective effect that decreases with time (the risk of endometriosis increases with the number of years since last childbirth).<sup>35,36</sup> Multiple full-term births and prolonged periods of lactation decrease the risk of endometriosis.<sup>35,36</sup> Assorted epidemiologic studies have suggested that heavy consumption of alcohol and caffeine also may increase risk and that regular exercise and smoking may decrease risk for endometriosis.<sup>15,27,32,37</sup> Primate data have suggested that exposure to the environmental toxins polychlorinated biphenyl (PCB) or dioxin may be linked with endometriosis, but studies in women have yielded inconsistent results.<sup>38,39</sup> Other data suggest that exposures in utero can play a role in development of the disease; the incidence of endometriosis is increased in women having prenatal exposure to diethylstilbestrol.<sup>40</sup> Women with endometriosis also appear to be at increased risk of ovarian cancer.<sup>41</sup> The association is modest, and specific to endometrioid and clear cell types of ovarian cancer.<sup>41</sup> While a relationship exists, the

effect sizes are small, and further research is needed to determine whether or not a direct cause and effect relationship exists.<sup>42</sup>

# PATHOGENESIS OF ENDOMETRIOSIS

---

There is no generally accepted thesis regarding the origin of endometriosis; however, Sampson's theory of retrograde menstruation is the most well-accepted theory.

**The retrograde menstruation and implantation theory holds that endometrial tissue shed during menstruation is transported via the fallopian tubes into the peritoneal cavity where it implants on the surfaces of pelvic organs.** Sampson's classic paper proposing that endometriosis is "due to menstrual dissemination of endometrial tissue into the peritoneal cavity" was published in 1927.<sup>43</sup> Several lines of evidence support the implantation theory as one of the primary mechanisms involved in the pathogenesis of endometriosis.

- Endometriosis is more prevalent in women with obstructing müllerian anomalies than in women with malformations that do not obstruct menstrual outflow.<sup>44</sup> In 80% of women with congenital cervical stenosis and functional endometrium, endometriosis develops.<sup>45</sup>
- Viable endometrial cells recovered from the peritoneal fluid during menses can be grown in cell culture<sup>46,47</sup> and can attach to and penetrate the mesothelial surface of the peritoneum.<sup>48,49</sup>
- The incidence of endometriosis is increased in women with an early menarche and/or short menstrual cycles.<sup>15,27,33,50</sup>
- Endometriosis is observed most commonly in the dependent portions of the pelvis, on the ovaries, in the anterior and posterior cul-de-sacs, and on the uterosacral ligaments, the posterior uterus, and the posterior surface of the broad ligaments.<sup>51,52,53</sup>
- Experimental endometriosis can be induced in mice and nonhuman primates after surgically induced peritoneal menstruation<sup>54,55,56,57</sup> or retroperitoneal injection of menstrual endometrium<sup>58</sup> and in women who receive peritoneal injections of their menstrual tissue.<sup>59</sup>

As the incidence of retrograde menstruation is similar in women with and without endometriosis, several other mechanisms have been proposed: coelomic metaplasia, vascular dissemination, direct transplantation, and altered immunity. More recently, stem cells and genetic origins of the disease are being investigated. No one mechanism explains all cases of endometriosis and each probably contributes, at least to some extent.

The coelomic metaplasia theory, proposed by Fergusson and colleagues in the 1960s,<sup>60</sup> offers an alternative explanation for the same observations. **The coelomic**

**metaplasia theory holds that endometriosis results from spontaneous metaplastic change in mesothelial cells derived from the coelomic epithelium (located in the peritoneum and the pleura). The induction theory is a variation on the same theme and envisions that coelomic metaplasia is induced by exposure to menstrual effluent or other stimuli.** In his original paper, Sampson himself allowed that foci of peritoneal endometriosis also might be “due to some specific irritant present in the cyst contents which stimulates the peritoneal endothelium to a metaplasia with the development of endometrial tissue typical both in structure and function.”<sup>3</sup> A number of observations suggest that endometriosis results from spontaneous or induced coelomic metaplasia, at least in some cases.<sup>61</sup>

- Endometriosis has been described in a premenarchal girl<sup>62</sup> and in women who never have menstruated<sup>63,64</sup> and also occurs in adolescent girls having had relatively few menstrual cycles.<sup>65</sup>
- Because intact endometrial cells have no access to the thorax in the absence of an anatomical defect, the retrograde menstruation/implantation theory cannot explain cases of pleural and pulmonary endometriosis (almost all of which occur on the right side).<sup>66</sup> Metaplasia in the pleura (derived from the coelomic epithelium, like the peritoneum and the müllerian ducts), induced by steroid hormones or chemical stimuli released by degenerating endometrial cells into the peritoneal fluid (which communicates with the thoracic cavity via the right hemidiaphragm), is the more plausible explanation.
- Metaplasia in misintegrated coelomic epithelium (adjacent to the mesenchymal limb buds during early embryogenesis)<sup>67,68</sup> can explain endometriosis in unusual peripheral sites like the extremities (thumb, thigh, knee).<sup>69,70,71</sup>
- Rare cases of endometriosis have been observed in men treated with high doses of estrogen (urinary bladder, abdominal wall).<sup>72,73,74</sup>
- Ovarian surface epithelium and stromal cells, cocultured with estradiol in a three-dimensional collagen gel lattice, form endometrial glands and stroma.<sup>75</sup>
- Eutopic (inside the uterus) and ectopic (outside the uterus) endometria are distinctly different, both morphologically and functionally, which is difficult to reconcile with the notion that endometriotic implants represent autotransplants of normal endometrial tissue.<sup>76</sup>

Although coelomic metaplasia might explain endometriosis in the pelvis, the thoracic cavity,<sup>66</sup> the urinary and digestive tracts,<sup>77,78</sup> the inguinal canal,<sup>79</sup> and the umbilicus,<sup>80</sup> other mechanisms are also invoked to explain cases of extrapelvic endometriosis.<sup>81,82</sup> Evidence indicates that **vascular or lymphatic dissemination of endometrial cells** also

may be involved; menstrual tissue may travel from the endometrial cavity to distant sites through lymphatic channels and veins.<sup>83,84,85,86</sup> Inadvertent **direct transplantation of endometrial tissue** at the time of cesarean section, other pelvic surgery, or episiotomy repair seems the most plausible explanation for endometriosis found in abdominal scars<sup>87,88</sup> and in the perineum.<sup>89</sup>

Alternatively, circulating stem cells originating from the bone marrow might differentiate into endometriotic tissue in various locations.<sup>90</sup> This may explain how ectopic endometrium can occur in locations outside of the pelvis, such as the lung and central nervous system. Initially, it was presumed that de novo development of endometrial tissue occurred from endogenous progenitor stem cells in the endometrium.<sup>91,92</sup> However, more recent clinical and experimental evidence have demonstrated that bone marrow–derived stem cells (BMDSCs) migrate to eutopic and ectopic endometria and differentiate into endometrial cells.<sup>92,93,94,95</sup> In a study of female allogenic bone marrow transplant recipients from a single-antigen mismatched related donor (allowing cells to be identified by HLA type), donor-derived endometrial cells were found in the endometrial biopsies of recipients.<sup>93</sup> In a murine model of transplanted male donor–derived bone marrow cells (identified by the Y chromosome) into female bone marrow, the male-derived cells were found in the endometrium, having differentiated into epidermal and stromal cells.<sup>92</sup> Furthermore, this study demonstrated engraftment of BMDSCs in the ectopic endometrial implants of previously hysterectomized mice, indicating that the endometrial tissue is capable of attracting BMDSCs despite its ectopic location.<sup>92</sup> Insights into the mechanism by which eutopic and ectopic endometrial tissues attract BMDSCs have emerged, with the CXCR4/CXCL12-axis playing a key role. CXCL12, also known as stromal cell–derived factor 1 (SDF1), is a chemokine involved in regulating cell migration.<sup>96</sup> Increased expression of CXCL12 in endometriotic implants attracts stem cells preferentially to endometriotic lesions, preventing their normal migration to the endometrium.<sup>96,97</sup> CXCR4, a chemokine receptor, and its ligand CXCL12 not only are important in stem cell recruitment but can also induce angiogenesis and tissue growth.<sup>96</sup> CXCR7, another receptor for CXCL12, is increased in inflammation and tumor growth.<sup>97</sup> Recently, CXCR7 was found to have increased expression in endometriotic lesions, where it enhances BMDSC recruitment to lesions and perpetuates their growth.<sup>97</sup> Lastly, estrogens enhance recruitment of BMDSCs, through increasing CXCL12; as endometriotic lesions have an increased local estrogenic environment, this provides yet another mechanism by which lesions can further ensure their growth and survival.<sup>98</sup>

Regardless whether pelvic endometriosis results from implantation of viable

endometrial tissue regurgitated into the peritoneal cavity at time of menses or from coelomic metaplasia induced by hormones or from stem cells, several key questions remain. Why does endometriosis develop only in some women when retrograde menstruation occurs in most women? What explains the widely varying presentations of the disease? Why is there such a poor correlation between the extent of disease and the severity of associated symptoms? Studies of the immune function and genetics of women with endometriosis are suggesting answers.

# Immunobiology of Endometriosis

Endometriosis has been associated with headaches, arthralgias and myalgias, allergies, eczema, hypothyroidism, fibromyalgia, chronic fatigue syndrome, and susceptibility to vaginal candidiasis.<sup>99</sup> Although nonspecific, given their presence in patients with known autoimmune disease, a possible link between endometriosis and autoimmune disease has been suggested.<sup>99</sup> A cross-sectional survey of members of the Endometriosis Association found that members with endometriosis had a higher prevalence of hypothyroidism, chronic fatigue syndrome, rheumatoid arthritis, systemic lupus erythematosus, Sjogren syndrome, and multiple sclerosis, compared with the published rates in the general US female population; allergies and asthma also were more common.<sup>100</sup> Although provocative, the results of the study were highly susceptible to recall and ascertainment bias. Others have found no association between endometriosis and autoimmune disease.<sup>32,101</sup>

A higher prevalence of antinuclear antibodies has been reported for women with endometriosis.<sup>102,103</sup> The most common autoantibodies identified have been directed against endometrial antigens,<sup>104,105,106,107,108,109</sup> including transferrin and laminin-1, which also is found in embryonic tissues.<sup>104,110</sup> Such immunologic autoreactivity probably results from inflammation and develops as a consequence of chronic local tissue destruction.<sup>99</sup> As endometriosis is associated with an inflammatory response/environment (as discussed below), it is perhaps not surprising that women with endometriosis can exhibit a hypersensitivity to inflammation at sites distant from pelvic implants.<sup>111</sup>

**Endometriosis is associated with changes in both cellular and humoral immunities, suggesting that impaired immune function may contribute to the development of the disease.** Altered immune function may predispose some women to develop endometriosis or influence the severity of disease in affected women. Although the peritoneal fluid of women with endometriosis contains increased numbers of immune cells, evidence suggests that their actions do more to promote the disease than to prevent it. This may explain why some women with retrograde menstruation develop endometriosis, whereas others do not. Following deposition of endometrial tissue into the peritoneal cavity, the ectopic endometrium must bypass immune defenses, attach to a surface, and ultimately invade and establish a blood supply in order to grow. Numerous immune-mediated mechanisms have been implicated.

Macrophages are a key element of the innate immune response, the part of the immune system that is not antigen specific and does not involve immunologic memory. Macrophages defend the host by recognition, phagocytosis, and destruction of offending microorganisms and also serve as scavengers, helping to clear apoptotic cells and

cellular debris. Macrophages secrete a variety of cytokines, growth factors, enzymes, and prostaglandins that help to mediate their own functions while stimulating the growth and proliferation of other cell types. Macrophages are a normal inhabitant of the peritoneal fluid, and their numbers and activity are much increased in the ectopic implants and peritoneal fluid of women with endometriosis.<sup>112,113,114,115</sup> **Instead of acting as scavengers to eliminate ectopic endometrial cells, activated macrophages and circulating monocytes in women with endometriosis appear to promote the disease by secreting growth factors and cytokines (interleukin [IL]-1, IL-6, and IL-8, tumor necrosis factor [TNF], RANTES, vascular endothelial growth factor [VEGF]) that stimulate proliferation of ectopic endometrium and inhibit their scavenger functions.**<sup>116,117,118</sup>

Natural killer (NK) cells are another important component of the innate immune system and function in two ways. NK cells have receptors for immunoglobulin G (IgG) and kill IgG-bound cells in a process known as antibody-dependent cellular cytotoxicity. NK cells also have killer-activating and killer-inhibiting receptors that, when occupied, direct or inhibit cytotoxic activity. Whereas studies of the numbers of peritoneal NK cells in women with endometriosis have yielded conflicting results,<sup>115,119,120</sup> those investigating NK cell function have consistently observed decreased cytotoxic activity, which is most pronounced in women with advanced stages of the disease.<sup>120,121,122</sup> One of the mechanisms responsible involves overexpression of killer-inhibiting receptors in both peripheral and peritoneal cells in women with endometriosis and overexpression of HLA class I molecules on ectopic endometrial cells, reducing NK cell cytotoxicity.<sup>118,123,124</sup>

Lymphocytes mediate the acquired immune response. B lymphocytes mature in the bone marrow and secrete immunoglobulins, which are antigen-specific antibodies directed against extracellular microorganisms. T lymphocytes help B cells to make antibodies and also eliminate intracellular pathogens by activating macrophages and by killing virus-infected or malignant cells. T cells are of two types, cytotoxic/suppressor T cells (involved in the cellular immune response) and helper T cells (involved in the humoral immune response). The numbers of both T-cell types are increased in the peritoneal fluid of women with endometriosis and in the stroma of ectopic endometrium.<sup>115,125,126</sup> Despite their increased number, the cytotoxicity of these cells is reduced, due to induced apoptosis via the Fas-FasL pathway by the ectopic endometrium.<sup>118</sup>

Cytokines and growth factors are a large family of soluble proteins and glycoproteins secreted by leukocytes and other cells into the extracellular environment where they act on the same (autocrine) or nearby cells (paracrine), serving as messengers both within and outside the immune system in regulation of chemotaxis,

mitosis, angiogenesis, and differentiation. As mentioned above, while an impaired cellular immune response may result in ineffective clearance of refluxed endometrial cells from the peritoneal cavity, cytokines and growth factors appear to promote implantation and growth of ectopic endometrium by facilitating its attachment to the peritoneal surface and by stimulating proliferation and angiogenesis.

IL-1 is a cytokine involved in inflammatory and immune responses and is secreted by activated monocytes and macrophages, T and B lymphocytes, and NK cells. IL-1 has been identified in the peritoneal fluid of women with endometriosis and IL-1 receptor expression is increased in endometriosis-derived stromal cells.<sup>120,121,127,128</sup> IL-1 may promote the development of endometriosis by stimulating the release of angiogenic factors (VEGF, IL-6, IL-8)<sup>129,130</sup> and by helping endometrial cells that enter the peritoneal cavity to escape immunosurveillance by inducing the release of a soluble form of intercellular adhesion molecule-1 (ICAM-1) from endometriotic cells that compete for immune recognition sites on NK and other immune cells.<sup>131,132</sup>

IL-8 is a potent angiogenic cytokine produced by mesothelial cells, macrophages, and endometrial and other cells. Peritoneal fluid levels of IL-8 are elevated in women with endometriosis and correlate with the severity of disease.<sup>133</sup> IL-8 is expressed in endometriotic implants and is up-regulated by IL-1.<sup>130,134</sup> IL-8 stimulates adhesion of endometrial stromal cells to extracellular matrix proteins, matrix metalloproteinase activity, and endometrial stromal cell proliferation in a dose-dependent manner, all of which may help to promote the implantation and growth of ectopic endometrium.<sup>135,136,137</sup>

Monocyte chemoattractant protein-1 and RANTES (regulated on activation, normal T cell expressed and secreted) are two chemoattractant cytokines that recruit macrophages into the peritoneal cavity. Both are secreted by a variety of leukocytes and by mesothelial and endometrial cells, and production of both is increased in ectopic endometrium.<sup>138,139,140</sup> In women with endometriosis, peritoneal fluid concentrations are increased and can correlate with the severity of disease.<sup>141,142</sup> IL-1 up-regulates monocyte chemoattractant protein-1 expression in ectopic endometrial epithelial cells in women with endometriosis and in cultured ectopic endometrial cells,<sup>143,144</sup> an action further stimulated by estrogen.<sup>145</sup> RANTES production by endometriotic implants is stimulated by other peritoneal fluid cytokines.<sup>127</sup>

TNF- $\alpha$  is a cytokine produced by activated lymphocytes, macrophages, and NK cells, among others. TNF- $\alpha$  is expressed in ectopic endometrial epithelial cells and is up-regulated by IL-1. IL-1 and TNF- $\alpha$  can also initiate an inflammatory response, and TNF- $\alpha$  peritoneal fluid concentrations are increased in women with endometriosis. The observations that TNF- $\alpha$  increases adherence of cultured stromal cells to mesothelial

cells suggests it may facilitate attachment of ectopic endometrium to the peritoneum in women with endometriosis; however, caution is warranted prior to making definitive conclusions as a separate research group noted the opposite effect.<sup>146,147</sup>

To implant and grow, ectopic endometrium must establish a blood supply. VEGF is an important mediator of local angiogenesis produced by monocytes and macrophages.<sup>148</sup> The growth factor stimulates proliferation of vascular endothelial cells and also acts as a chemoattractant for monocytes; it plays an important role in vascularization of endometriotic lesions.<sup>148,149</sup> VEGF is produced primarily in endometrial glands and is up-regulated by a variety of factors including estrogen and IL-1.<sup>148</sup> Peritoneal fluid VEGF concentrations are increased in women with endometriosis and are usually highest in advanced stages of the disease.<sup>150,151</sup> VEGF also is expressed in endometriotic lesions, more so in active red lesions than in inactive “powder-burn” implants.<sup>152</sup>

## Key Points: The Immunobiology of Endometriosis

- A wide variety of immunologic abnormalities have been described in women with endometriosis. The peritoneal fluid of affected women contains increased numbers of immune cells, but instead of acting to efficiently remove refluxed endometrial debris from the peritoneal cavity, they promote the disease via two basic mechanisms. Defects in cellular immune mechanisms (mediated by macrophages and NK cells) impair normal recognition and clearance of refluxed endometrial debris via the immune/inflammatory response, thereby affording endometrial cells and tissue fragments the opportunity to attach to peritoneal mesothelial cells and to invade into the extracellular matrix where they can persist and proliferate. Immune cells in the peritoneal fluid of women with endometriosis also secrete a wide variety of humoral factors (cytokines and growth factors) that stimulate attachment and proliferation of ectopic endometrium and local angiogenesis. Altered immune function may thus predispose to the development of endometriosis or to more severe disease. While it is clear that immunologic abnormalities are a consequence of endometriosis, they certainly also play an important role in its pathogenesis.

# Genetics of Endometriosis

In both humans<sup>153,154,155</sup> and nonhuman primates,<sup>156</sup> endometriosis tends to cluster within families, suggesting that genetic factors probably influence susceptibility to developing endometriosis. The disease frequently is observed in monozygotic and dizygotic twin pairs<sup>157,158,159</sup> and exhibits a similar age of onset in affected nontwin sisters.<sup>160</sup> **Endometriosis is 6 to 7 times more prevalent among the first-degree relatives of affected women than in the general population.**<sup>161,162,163,164</sup> All of these observations suggest that endometriosis has a genetic foundation and that a predisposition to the disease is inherited as a complex genetic trait for which the phenotype reflects interactions between allelic variants of susceptibility genes and environmental factors.<sup>165,166</sup> Gene expression profiling has identified candidate susceptibility genes relating to implantation failure, infertility, and progesterone resistance.<sup>167,168</sup> Family linkage studies and genome-wide association (GWA) studies have identified several risk loci for endometriosis.<sup>169,170,171,172,173,174,175,176</sup> However, the precise genes and their role in endometriosis have not been fully elucidated. In total, the contribution of individual loci identified in the GWA studies explains only a very small percentage of endometriosis cases. Endometriosis is likely a complex polygenic disease involving multiple loci, each with a small effect size.

Recently, a polymorphism in the K-ras gene was reported in a subset of women with resistant endometriosis.<sup>177</sup> K-ras is a signal transduction molecule mutated in several cancers, leading to increased cell proliferation, survival, and migration. In mice expressing an oncogenic variant, spontaneous endometriosis develops, and increased expression of KRAS was found in the eutopic endometrium of women with endometriosis.<sup>178</sup> It is important to note that this polymorphism is likely associated with a more aggressive form of endometriosis in women, rather than the spontaneous development of endometriosis. Overall, it appears more likely that altered gene expression in endometriotic lesions is acquired, as can be seen in animal models of the disease where normal endometrium (i.e., no genetic predisposition to disease) is transplanted into the peritoneal cavity.<sup>56,179</sup>

# Molecular Mechanisms

While the exact molecular mechanism of endometriosis remains elusive, given the phenotype of endometriosis, it seems plausible that genes predisposing to the development of endometriosis might include any that direct processes controlling the survival of detached endometrial cells, their attachment to and invasion of peritoneal surfaces, proliferation, neovascularization, or the inflammatory response. The ectopic endometrium of women with endometriosis exhibits abnormal expression of numerous gene products that are relevant to the pathogenesis of the disease. Compared to normal endometrium, ectopic endometrial implants produce excessive amounts of estrogen, prostaglandins, and cytokines.<sup>180,181,182</sup> Similar but subtler abnormalities are observed in the eutopic endometrium of women with endometriosis. **These observations suggest that abnormalities, either intrinsic or acquired, to the endometrium of women who develop endometriosis may predispose to cell survival, ectopic implantation, proliferation, and chronic inflammation.**

Retrograde menstruation occurs in most women, but endometriosis develops in only a few. The survival of refluxed endometrial debris might result from immune dysfunction, as discussed above, or may reflect a molecular abnormality in the eutopic endometrium of women with endometriosis,<sup>183</sup> as discussed below. In any case, eutopic endometrial cells from women with endometriosis are resistant to apoptosis, which is the normal but complex gene-regulated physiologic process of programmed cell death that contributes to endometrial breakdown and turnover during the late secretory and menstrual phases of the cycle.<sup>184,185</sup> Ectopic endometrium appears even more resistant to apoptosis.<sup>186</sup> **Resistance to apoptosis may improve the survival of endometrial cells entering the peritoneal cavity and also help to explain why ectopic endometrium is resistant to macrophage-mediated immune surveillance and clearance.**

In normal women, levels of endometrial estrogen and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) production are low because activity of the enzymes aromatase (mediating estrogen synthesis) and cyclooxygenase-2 (COX-2, mediating prostaglandin synthesis) is low. Moreover, during the secretory phase of the cycle, progesterone stimulates 17 $\beta$ -hydroxysteroid dehydrogenase (17 $\beta$ HSD) activity, which converts estradiol to the less potent estrogen, estrone.<sup>18</sup> In women with endometriosis, aromatase and COX-2 activity are increased in eutopic endometrium and greatly elevated in ectopic endometrial tissue implants. Tissue levels of estradiol are high, due to increased aromatase and decreased 17 $\beta$ HSD activity, and tissue levels of PGE<sub>2</sub> are increased because COX-2 activity is elevated.<sup>18</sup> **The eutopic endometrium and ectopic endometrium of women with endometriosis thus differ from normal endometrium in at least three distinct and**

important ways (as discussed in the section that follows), exhibiting (1) high local estrogen production, (2) high local prostaglandin production, and (3) resistance to the actions of progesterone.

## Estrogen Production

There is little question that estrogen plays an important role in the pathogenesis of endometriosis. With rare exception, the disease arises only after menarche and regresses after menopause.<sup>187</sup> **Substantial evidence indicates that both estrogen production and metabolism are altered in endometriosis in ways that promote the disease.**<sup>18,188,189</sup>

Estrogen in women with endometriosis derives from three major sources. As in normal women, estrogen is secreted by the ovary into the circulation and released directly into the peritoneal cavity at ovulation and is produced in adipose and skin via conversion of circulating androgens. However, in women with endometriosis, substantial amounts of estrogen also are synthesized locally, in endometriotic tissue, which expresses a complete set of steroidogenic enzymes, including aromatase.<sup>190</sup>

The overproduction of estrogen in endometriotic stromal cells is linked with another of the functional abnormalities observed in the tissue, high local production of prostaglandins. PGE<sub>2</sub> stimulates the expression of all of the genes encoding the steroidogenic enzymes required for synthesis of estradiol from cholesterol in endometriotic stromal cells, including, in particular, STAR (encoding the steroidogenic acute regulatory protein, STAR) and CYP19A1 (encoding aromatase).<sup>190</sup> Stromal cells in both normal and ectopic endometria express all of the PGE<sub>2</sub> receptor subtypes (EP<sub>1</sub>, EP<sub>2</sub>, EP<sub>3</sub>, and EP<sub>4</sub>).<sup>188</sup> In endometriotic stromal cells, activation of the EP<sub>2</sub> receptor (by PGE<sub>2</sub>) increases intracellular levels of cyclic adenosine monophosphate (cAMP), which induces STAR and CYP19A1 expression.<sup>188,190,191</sup> PGE<sub>2</sub> or a cAMP analog increases STAR and aromatase levels and activity in endometriotic stromal cells, but not in normal endometrial stromal cells.<sup>182,190,191</sup> These observations indicate that PGE<sub>2</sub>- and cAMP-dependent steroidogenesis in endometriotic stromal cells requires downstream effectors that are absent or opposed by other inhibitory mechanisms in normal endometrial stromal cells, which exhibit no steroidogenic activity.

The key downstream effector molecule in endometriotic tissue is steroidogenic factor-1 (SF-1), which is absent in normal endometrium. In endometriotic stromal cells exposed to PGE<sub>2</sub>, SF-1 binds to and assembles an enhancer transcriptional complex, which interacts with the promoters of STAR and CYP19A1 and induces their expression.<sup>190</sup> In normal endometrial stromal cells, the absence of any steroidogenic

response to PGE<sub>2</sub> can be attributed to the absence of SF-1 and to the presence of transcriptional inhibitors of the STAR and CYP19A1 gene promoters. These repressors include the Wilms tumor 1 transcription factor (WT1)<sup>192</sup> and CCAAT/enhancer binding protein β (C/EBPβ), levels of which are much higher in normal endometrium than in endometriotic tissue. In the absence of SF-1, a transcriptional complex of inhibitors binds to and suppresses steroidogenic promoters in endometrial cells.<sup>190</sup>

## Prostaglandin Production

Prostaglandins are locally produced hormones involved in inflammation and pain. Both PGE<sub>2</sub> and prostaglandin F<sub>2α</sub> (PGF<sub>2α</sub>) are overproduced in the uterine and endometriotic tissues of women with endometriosis.<sup>193</sup> PGF<sub>2α</sub> stimulates both vasoconstriction and myometrial contractions, resulting in pain and dysmenorrhea. As in most cells, production of prostaglandin H<sub>2</sub> (PGH<sub>2</sub>) in the myometrium, endometrium, and endometriotic tissue is catalyzed by COX, which has two isoforms.<sup>194</sup> COX-1 primarily drives basal prostaglandin synthesis and COX-2 is involved in inflammation. PGH<sub>2</sub> is metabolized to other prostaglandins by cell-specific enzymes; in the uterus, PGH<sub>2</sub> is converted to PGF<sub>2α</sub> (by prostaglandin F synthase) and PGE<sub>2</sub> (by prostaglandin E synthase).<sup>193</sup>

In both ectopic and eutopic endometria in women with endometriosis, COX-2 is up-regulated to a greater extent than in endometrial stromal cells from disease-free women,<sup>195,196</sup> resulting in increased PGE<sub>2</sub> production that induces local estrogen synthesis (as discussed above) and causes inflammation, resulting in pain<sup>182,191,197,198</sup>; prostaglandin E synthase activity also may be increased.<sup>18</sup> COX-2 expression and PGE<sub>2</sub> production in uterine and endometriotic tissues are stimulated by IL-1b, PGE<sub>2</sub> (an autocrine action), VEGF, and estradiol (via estrogen receptor β).<sup>18,199,200,201</sup> Altogether, these complementary and redundant mechanisms maintain high levels of PGE<sub>2</sub> production in endometriotic tissue.

The high levels of PGE<sub>2</sub> in endometriotic tissue induce a classical inflammatory response, characterized by increased production of cytokines, metalloproteinases, and chemokines. Increased levels of inflammatory cytokines (IL-1β, IL-6, and TNF-α) promote adhesion of shed endometrial tissue to peritoneal surfaces, and proteolytic membrane metalloproteinases promote their implantation.<sup>140,167,180,202,203,204,205</sup> Increased levels of chemokines (monocyte chemoattractant protein 1, IL-8, and RANTES) attract increased numbers of granulocytes, NK cells, and macrophages,<sup>139,140,167,180,202,203,206</sup> and autoregulatory positive feedback loops

perpetuate the process.

## Progesterone Resistance

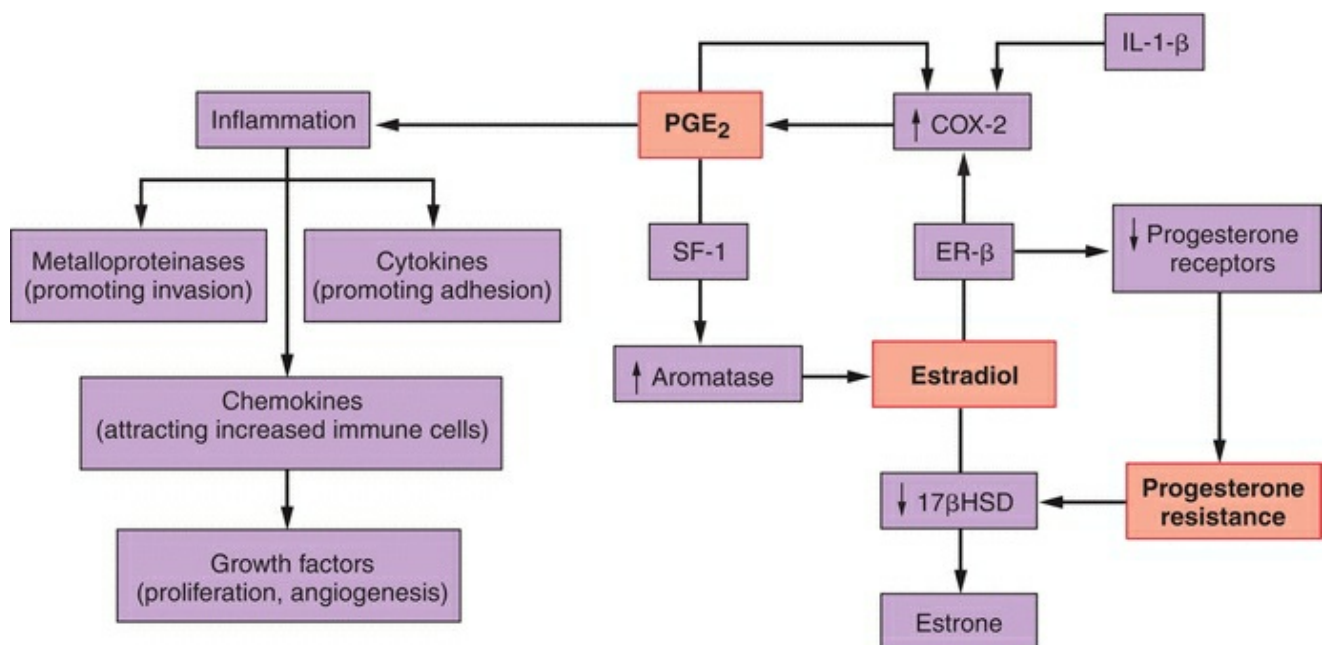

As discussed in [Chapter 3](#), the endometrium consists of two layers—the functionalis and basalis. The functionalis layer undergoes cycles of shedding and regrowth with each menstrual cycle, while the basalis layer remains and serves as a reservoir of cell for the functionalis layer. Estrogens and progesterone control the cellular composition and function throughout the menstrual cycle. Estrogen normally stimulates proliferation and endometrial thickening, while progesterone normally triggers inhibition of estrogen-dependent proliferation and induces decidualization of stromal cells, counteracting estrogens effects.<sup>18</sup> In the normal menstrual cycle, progesterone induces differentiation of both endometrial epithelial and stromal cells.<sup>207,208,209</sup> In the epithelium, progesterone stimulates secretion, and in the stroma, progesterone induces decidualization. Progesterone acts as an antiestrogen in a paracrine fashion, by stimulating retinoic acid production in the stroma,<sup>210,211,212</sup> which then induces 17 $\beta$ HSD activity in the epithelium,<sup>213,214,215,216</sup> resulting in the conversion of estradiol to the less potent estrogen, estrone. Although circulating progesterone levels in women with endometriosis are similar to those of women without endometriosis, ectopic lesions do not respond appropriately to progesterone.<sup>217</sup> Progesterone resistance was first suggested following studies demonstrating that progesterone treatment did not cause conversion of estradiol to the less potent estrone.<sup>218</sup> Similarly in endometriotic stromal cells, progesterone does not induce retinoic acid production,<sup>219,220</sup> resulting in reduced epithelial 17 $\beta$ HSD activity. As a result, tissue estradiol levels are elevated because high local aromatase activity drives production, and low 17 $\beta$ HSD activity impairs its metabolism.<sup>221</sup> In addition, progesterone-induced prolactin production is reduced in ectopic endometrium, offering further support of progesterone resistance.<sup>221</sup>

Progesterone mediates its effects through progesterone receptors (PR) A and B, which function as ligand-activated transcription factors. Aberrant expression of the two PR isoforms may explain the altered response to progesterone (i.e., progesterone resistance), and Attia and colleagues were the first to demonstrate decreased PR-B compared to PR-A expression in endometriotic lesions.<sup>222</sup> PR-A is a dominant repressor of PR-B, whereas PR-B has strong ligand-induced transcriptional activity.<sup>223</sup> During the normal menstrual cycle, levels of both PR-A and PR-B increase progressively during the proliferative phase and decrease after ovulation, indicating that estradiol stimulates PR production, yet in endometriotic tissues, this trend is not followed.<sup>18</sup> Moreover, endometriotic tissue contains lower levels of PR than does normal endometrium, thus suggesting that progesterone resistance is mediated in part by

decreased PR.<sup>191,222,224,225</sup>

Additional research has identified several other potential mechanisms of progesterone resistance.

As noted earlier, endometriosis is a chronic inflammatory state. Progesterone normally acts as an anti-inflammatory agent in uterine cells. In endometriosis, there is an influx of proinflammatory cytokines, activating nuclear factor kappa-light-chain-enhancer of activated B (NF- $\kappa$ B) cells. NF- $\kappa$ B proteins are transcription factors controlling genes involved in cell proliferation, adhesion, apoptosis, and inflammation. NF- $\kappa$ B accentuates the inflammatory response seen in endometriosis and antagonizes the effects of progesterone.<sup>226</sup> NF- $\kappa$ B is hypothesized to be chronically activated in endometriosis.<sup>227</sup> The ultimate effect is decreased responsiveness to progesterone, leading to a chronic cycle of increased NF- $\kappa$ B expression with decreased PR expression and decreased progesterone action. The proinflammatory environment may also adversely affect PR function through alterations in its chaperone proteins, as well as receptor coregulators.<sup>228,229,230</sup> Gene expression profiling of the endometrium of women with and without endometriosis has identified a number of genes linked to the actions of progesterone that are down-regulated (in those with endometriosis) during implantation when progesterone levels normally peak suggesting that the eutopic endometrium of women with endometriosis also is progesterone resistant (**Figure 32.1**).<sup>167,168</sup>

**FIGURE 32.1**

# Epigenetic Changes

Epigenetic changes involving DNA methylation, histone methylation/acetylation, as well as changes in coregulators (activators, repressors, enhancers, microRNAs [miRNAs]) may contribute to progesterone resistance through regulation of genes involved in endometrial differentiation. Homeobox A10 (HOXA10) is hypermethylated (and thus silenced) in eutopic endometrium of women with endometriosis.<sup>56</sup> HOXA10 is a target gene of progesterone and is necessary for implantation. In women with endometriosis, HOXA10 does not exhibit the normal peak in expression following ovulation.<sup>179</sup> The PR-B promoter site is also hypermethylated in ectopic endometrium of women with endometriosis, explaining another mechanism by which PR expression is lower in women with endometriosis, resulting in progesterone resistance.<sup>231</sup> In knockout studies, absence of PR-B results in unchecked proliferation of immortalized endometrial stromal cells, which in endometriosis may explain to some extent the ability of lesions to implant and grow (**Figures 32.1**).<sup>232</sup>

Additional support for a role of altered methylation/epigenetic changes comes from work by Wu et al.,<sup>233</sup> demonstrating overexpression of DNA methyltransferases (which catalyze DNA methylation) in human ectopic endometrium, suggesting that aberrant methylation patterns contribute to the endometriosis phenotype. Furthermore, the very high levels of SF-1 observed in endometriotic tissue (>12,000 times greater than in normal endometrium) appear related to a cytosine-phosphate-guanine (CpG) island at its promoter, which is heavily methylated in normal endometrial stromal cells and unmethylated in endometriotic stromal cells.<sup>234</sup> Whereas an inhibiting transcription factor binds to the methylated SF-1 promoter, preventing its interaction with transcriptional activators, a stimulating transcription factor binds to the unmethylated SF-1 promoter in endometriotic cells and activates it.<sup>235</sup>

The more than 100-fold higher levels of ER- $\beta$  in endometriotic tissue, compared to normal endometrium, are also associated with hypomethylation of a CpG island at the promoter region of the ER- $\beta$  gene, causing high levels of expression. In endometriotic stromal cells, ER- $\beta$  occupies the ER- $\alpha$  promoter and suppresses its activity. ER- $\beta$  also binds to the PR promoter, which down-regulates PR expression, leading to progesterone resistance.<sup>236</sup>

Alterations in microRNA (miRNA) expression represent another mechanism of epigenetic regulation. miRNAs are small, noncoding RNA molecules that bind to mRNA where they block translation or degrade mRNA, thereby inhibiting protein expression. Several miRNAs are aberrantly expressed in endometriosis. These miRNAs increase inflammation by stimulating cytokine production in macrophages. miRNA-9,<sup>128</sup> predicted to target a gene coding an antiapoptotic protein, is overexpressed in the

eutopic endometrium of women with endometriosis. Similarly, miRNA-135 is differentially expressed in endometriosis and endometrium of women with endometriosis leading to impaired endometrial receptivity. miRNA-196a<sup>237</sup> was also overexpressed in the eutopic endometrium of women with endometriosis, with PR-B (its target) significantly decreased. Similarly, miRNA-29c was found to be increased in ectopic endometrium—its target is FK506-binding protein (a progesterone-regulated protein responsible for decidualization), further implicating a role for epigenetic modifications in mediating progesterone resistance. miRNA let7 is decreased in endometriosis leading to enhanced expression of KRAS and other genes that increase invasion and proliferation.<sup>177,238</sup> miRNAs are emerging as key regulators of endometriosis pathogenesis.

## Key Points

The working molecular model for the pathogenesis of endometriosis centers on the following:

- Increased survival of refluxed endometrial cells (resistance to apoptosis), inducing inflammatory and immunologic changes.
- Functional abnormalities in eutopic and ectopic endometrial cells (high local production of estrogen and prostaglandins, progesterone resistance).
- Epigenetic modifications (hypomethylation of the promoters for SF-1 and ER- $\beta$ , hypermethylation of PR-B, HOXA10, and aberrant miRNA expression). Ultimately, inflammatory and immune responses, angiogenesis, apoptosis, and progesterone response are altered in ways that promote the survival, attachment, and proliferation of ectopic endometrial tissue.

# Mechanisms of Pain

Pain is one of the most common symptoms associated with endometriosis. The mechanisms involved are difficult to determine, for a number of reasons. Pain itself is subjective and difficult to measure, especially when it is chronic. Chronic pelvic pain, defined as the presence of pain below the umbilicus for more than 6 months, is a common gynecologic problem, accounting for up to 10% of gynecologic office visits.<sup>14</sup> In endometriosis, pelvic pain is most often chronic and associated with dysmenorrhea in 50–90% of cases; dyspareunia, deep pelvic pain, and lower abdominal pain (with or without back/groin pain) are also common.<sup>14</sup> The pain usually worsens over time and can change in pattern.<sup>14</sup> When bladder and bowel symptoms are present, they are usually cyclic.<sup>239</sup> In addition, those having disease adjacent to or within the rectal wall also may have dyschesia.<sup>240</sup>

The pain associated with endometriosis has been attributed to three primary mechanisms:

- The direct and indirect effects of focal bleeding from endometriotic implants
- The actions of inflammatory cytokines in the peritoneal cavity
- Irritation or direct infiltration of nerves in the pelvis

Among these, neural irritation or invasion has received the majority of recent attention. **The intensity of pain associated with deep infiltrating endometriosis relates to the depth of penetration and to the proximity or direct invasion of nerves.**<sup>241,242,243,244</sup>

Whereas neural inflammation or invasion might explain the pain of women with deep infiltrating endometriosis, it cannot be the mechanism that produces pain in women who have superficial peritoneal/ovarian disease.<sup>239</sup> **The pain associated with mild disease more likely relates to inflammation resulting from cyclic focal bleeding in and around peritoneal implants or from the actions of inflammatory cytokines released by the larger numbers of macrophages and other immune cells in the peritoneal fluid of women with endometriosis.** However, there is no correlation between stage, site, or the morphologic characteristics of pelvic endometriosis and pain.<sup>245,246</sup> The explanation for why many women with advanced endometriosis have little or no pain and those with mild disease may have incapacitating pain remains unclear. The cause may relate to the fact that severe disease is generally chronic and may be less metabolically active. There also is evidence to suggest that persistent neural input from endometriotic tissues may cause central sensitization of the nociceptive system (neurons that receive painful stimuli), manifested by somatic hyperalgesia (increased sensitivity to pain) and areas of referred pain in some women

with endometriosis.<sup>247</sup> What is not known, however, is if endometriosis directly causes central sensitization or if some women with endometriosis are already sensitized, offering an explanation for experiencing pain from minimal disease. In a murine model of endometriosis, it was found that endometriosis induced pain sensitization by modulating gene expression in regions of the brain controlling pain response.<sup>248</sup>

One additional mechanism that may be involved in the pain associated with endometriosis relates to evidence that the hormonal milieu influences pain perception. Numerous studies have examined measures of pain perception across the menstrual cycle. A meta-analysis including 16 such studies concluded that somatic sensory pain thresholds and tolerance are near their lowest levels just prior to and during menses.<sup>249</sup> Interestingly, although perhaps not surprisingly, estradiol itself increases endometriosis-associated pain, likely through lesion growth. Aromatase expression in endometriotic lesions may explain recurrent disease/pain even when ovarian-produced estradiol levels are low.<sup>250</sup> Conversely, progesterone modulates pain by decreasing neuronal activity (as seen with high doses of progestins).<sup>251</sup>

# Mechanisms of Infertility

Endometriosis is strongly associated with infertility; the prevalence of endometriosis increases dramatically to as high as 50% in women with infertility, and 30–50% of women with endometriosis have infertility.<sup>4</sup> The fecundity rate in young women with untreated endometriosis is estimated to be anywhere from 2% to 10%, compared with 20% of normal reproductive-age couples without infertility.<sup>4</sup> Numerous observations support a relationship between endometriosis and infertility:

- The overall prevalence of endometriosis is greater in infertile than in fertile women.<sup>15,16</sup>
- Infertile women are more likely than fertile women to have moderate to severe disease<sup>16</sup>; the prevalence of minimal endometriosis in infertile women with normal and azoospermic male partners is comparable.<sup>252</sup>
- Although reduced to a similar extent in untreated women with minimal and mild endometriosis and women with unexplained infertility, monthly fecundity decreases further with increasing severity of disease.<sup>253,254,255,256,257</sup>
- Monthly fecundity of women with minimal and mild endometriosis receiving treatment with exogenous gonadotropin stimulation and intrauterine insemination (partner sperm) is lower when compared to women without disease.<sup>258,259</sup>
- Women with minimal and mild endometriosis are significantly more likely to conceive after surgical treatment than untreated women.<sup>260,261</sup>
- IVF pregnancy rates are negatively correlated with endometriosis severity.<sup>262</sup>

**Taken together, these observations support the conclusion that endometriosis decreases fertility to an extent that correlates roughly with the severity of disease.**

Infertility associated with endometriosis has been attributed to several mechanisms, including distorted anatomy, inflammation, and aberrant endometrial gene expression. The distorted anatomy can inhibit or prevent ovum release and capture after ovulation, and there is reasonably good experimental evidence that endometriosis decreases fertility when it results in grossly distorted pelvic anatomy. In monkeys with peritoneal autografts of endometrium, cumulative pregnancy rates were significantly lower in animals that developed moderate or severe endometriosis (12%) than in others with minimal or mild disease or in controls (40%), and none of the animals with ovarian adhesions conceived.<sup>263</sup> Similarly in a mouse endometriosis model, fertility was inversely correlated with the amount of induced disease. Furthermore, decreased fertility in women with advanced endometriosis also could result from premature depletion of the ovarian follicular pool (due to ovarian surgery or destruction).<sup>264,265,266</sup>

Excess production of prostaglandins, metalloproteinases, cytokines, and chemokines results in chronic inflammation that impairs ovarian, tubal, or endometrial function, leading to disorders of folliculogenesis, fertilization, or implantation. The presence of endometriomas (and resultant inflammation) affects oocyte production and ovulation, while the peritoneal inflammatory milieu itself can also damage oocytes and sperm, decrease tubal motility, and have toxic effects on an embryo.<sup>267,268</sup> In the endometrium, the abnormal presence of aromatase and progesterone resistance can cause an increased and unopposed estrogenic state, which adversely affects endometrial development and receptivity for implantation.<sup>188,269</sup> Progesterone resistance also results in constitutively active matrix metalloproteinases.<sup>270</sup> Matrix metalloproteinases are usually inhibited by progesterone in the secretory phase; however, in endometriosis, their chronically active state can lead to inappropriate matrix breakdown that does not support implantation. In addition, Wnt7a (involved in estrogen-mediated uterine growth in mice likely through epithelial-stromal signaling) is up-regulated in the eutopic endometrium.<sup>167,271</sup> It is postulated that aberrant activation of the Wnt pathway negatively impacts endometrial development during the time of the implantation window, likely by adversely affecting the normal epithelial-stromal polarity.<sup>272,273</sup> There is also increasing evidence that ectopic implants can lead to implantation failure through aberrant endometrial gene expression in the eutopic endometrium. An example of this is the HOXA10 gene, expression of which is necessary for endometrial receptivity.<sup>274</sup> In a murine model of endometriosis, the presence of ectopic lesions resulted in decreased expression of HOXA10 in the eutopic endometrium of these mice.<sup>56</sup> In women without endometriosis, cyclical endometrial expression of this gene peaks during the window of implantation in response to estrogen and progesterone.<sup>275,276,277,278</sup> However, women with endometriosis do not exhibit the midluteal rise as would be expected, which may partially explain their infertility.<sup>273</sup> Another explanation could be that the reprogrammed and ectopic cells can migrate from the ectopic implants back to the eutopic endometrium.<sup>279</sup> Such bidirectional movement between eutopic and ectopic tissue could lead to the aberrant gene expression in the eutopic tissue and subsequent implantation failure. Similarly, stem cells may travel from implants to eutopic endometrium, but with improper incorporation into endometrium.<sup>279,280</sup> Lastly, significant suppression of  $\beta 3$  integrin has been reported in the endometrium of women with early-stage endometriosis.<sup>281</sup> This decrease in  $\beta 3$  integrin expression may be associated with impaired embryonic-endometrial interactions.

**The association between endometriosis is likely multifactorial, involving mechanical, inflammatory, cell signaling, and epigenetic origins.** Results of the many observational studies of IVF outcomes in women with endometriosis have varied but offer some useful insights. A 2002 meta-analysis of observational studies concluded that

infertile women with endometriosis were less likely to achieve success than women with tubal factor infertility (OR = 0.56, CI = 0.44–0.70); outcomes were worse in severe than in mild disease.<sup>282</sup> The ovarian response to gonadotropin stimulation in women with endometriosis was less robust than in women with tubal disease; both the peak estradiol concentration and number of oocytes retrieved were lower. Fertilization and implantation rates also were decreased, compared to those in women with all indications for IVF or to women with isolated tubal factor infertility.<sup>282</sup> The results further suggested that the adverse effects of endometriosis on fertility were not related solely to anatomical factors. Compared directly, women with severe endometriosis had a lower peak estradiol level, oocyte yield, pregnancy rate, and implantation rate than women with mild disease. In contrast, fertilization rates in women with advanced endometriosis were higher than in those with mild disease.<sup>282</sup> In a more recent 2013 meta-analysis of 27 observational studies, it was found that fertilization rates were significantly reduced in stage I/II of endometriosis, as were implantation rates and clinical pregnancy rates in stage III/IV endometriosis.<sup>283</sup> However, results of these analyses remain controversial, as subsequent studies have yielded conflicting data, observing outcomes not significantly different from those in women with unexplained infertility.<sup>284,285</sup> In a population-based retrospective cohort study of cycles from the Society for Assisted Reproductive Technology (SART) Clinical Outcome Reporting database from 2008 to 2010, women with isolated endometriosis (11% of study sample) had comparable live birth rate to women with other infertility diagnoses; the majority of women with endometriosis had a concomitant infertility diagnosis, and these women had lower implantation rates.<sup>286</sup> Data from 2015 SART indicate that the average live birth rate per retrieval of patients undergoing IVF-embryo transfer was 43.9% in women with endometriosis. Live birth rates were comparable to those for women with diagnoses of tubal factor (43%), male factor (45%), and unexplained infertility (49%).<sup>287</sup> It is important to note, however, that there is decreased detection and reporting of endometriosis; laparoscopy is no longer a routine part of the infertility evaluation leading to missed diagnosis, especially of mild to moderate disease. While endometriosis was detected in 40–50% of infertile women undergoing laparoscopy as part of the evaluation, it is now reported in under 5% of IVF patients.

The overall lower implantation and pregnancy rates observed in women with endometriosis after IVF could reflect poor oocyte quality and subsequent embryogenesis or decreased endometrial receptivity. Studies of IVF outcomes in donor oocyte recipients offer a means to distinguish the two possibilities. Donor oocytes from healthy women yield similar results in recipients with and without endometriosis; however, those with ovarian insufficiency or who are at the end of the reproductive age range are likely seeing spontaneous regression of disease; this cannot rule out an implantation defect as most data suggest the existence of an endometrial defect in endometriosis.

Oocytes from women with endometriosis yield poorer results than those from healthy donors in disease-free recipients.<sup>288,289,290,291,292</sup> Embryos derived from oocytes retrieved from women with endometriosis also have fewer blastomeres and exhibit a higher incidence of arrested and abnormal development than those derived from women without the disease.<sup>291,293</sup> Taken together, these observations suggest that the lower implantation and pregnancy rates observed in women with endometriosis may result from both abnormalities of oocyte quality and subsequent embryogenesis and from altered endometrial receptivity.

A wide assortment of studies has been aimed at identifying differences in the follicular environment in women with and without endometriosis that might explain the presumed poor oocyte quality in women with the disease. Studies have compared the numbers and types of resident immune cells; the production of various hormones, growth factors, and cytokines; and the expression of numerous genes in follicular fluid and cultured granulosa cells obtained from women with and without endometriosis, but no consistent differences have been observed.<sup>294</sup>

Gene expression profiling (as discussed earlier) has identified a number of gene products that may be abnormally up- or down-regulated in the endometrium of women with endometriosis during the putative implantation window, including various cell adhesion molecules, matrix metalloproteinases, transcription factors, growth factors, enzymes, and steroid hormone receptors.<sup>167,168,295</sup> If endometriosis does have adverse effects on endometrial receptivity, evidence suggests they can be overcome by IVF treatment regimens in most women.

Retrospective studies have observed an increased risk for early pregnancy loss in women with endometriosis.<sup>296,297,298</sup> However, in appropriately controlled studies, miscarriage rates in untreated women with endometriosis have been in the ranges normally expected and no higher than in treated women.<sup>260,299,300</sup>

# DIAGNOSIS OF ENDOMETRIOSIS

---

Classically, the diagnosis of endometriosis requires surgical visualization of lesions and histologic evidence of ectopic endometrial glands and stroma. Although endometriosis is a common disorder, it remains difficult to diagnose. In a prospective study of over 1,000 women with and without endometriosis, there was a 6.7-year delay between symptom presentation and diagnosis of endometriosis.<sup>6</sup> Unfortunately, despite substantial advances in our understanding of the pathogenesis of endometriosis, there is not yet any reliable noninvasive alternative to laparoscopy for diagnosis of the disease. Current research is aimed at identifying potential biomarkers for the disease.<sup>301</sup>

# Clinical Diagnosis

The clinical symptoms of endometriosis include dysmenorrhea, nonmenstrual pelvic pain (NMPP), dyspareunia, dyschezia, cyclic bowel or bladder symptoms, infertility, and chronic fatigue. A 2008 cross-sectional survey of 1,000 women with endometriosis found that dysmenorrhea (79%) and pelvic pain (69%) were the most common symptoms leading to diagnosis.<sup>302</sup> Comparing women with minimal and mild endometriosis to those with more advanced stages of disease, dyspareunia was significantly more common in women with limited disease (51% vs. 39%), whereas infertility (22% vs. 30%) and an ovarian mass (7% vs. 29%) led to a diagnosis more often in those with advanced endometriosis.<sup>302</sup> A large case-control study conducted in the United Kingdom comparing the prevalence of specific symptoms in women with and without endometriosis observed that a greater proportion of women with endometriosis had abdominal/pelvic pain, dysmenorrhea, or menorrhagia (73% vs. 20%).<sup>303</sup> Compared to controls, women with endometriosis had increased risks of abdominal/pelvic pain (OR = 5.2, CI = 4.7–5.7), dysmenorrhea (OR = 8.1, CI = 7.2–9.3), menorrhagia (OR = 4.0, CI = 3.5–4.5), infertility (OR = 8.2, CI = 6.9–9.9), dyspareunia and/or postcoital bleeding (OR = 6.8, CI = 5.7–8.2), ovarian cysts (OR = 7.3, CI = 5.7–9.4), irritable bowel syndrome (OR = 1.6, CI = 1.3–1.8), and pelvic inflammatory disease (OR = 3.0, CI = 2.5–3.6).<sup>303</sup> These data demonstrate that whereas specific symptoms are associated with endometriosis, the same symptoms are not uncommon in women without the disease. They also reveal that endometriosis can coexist with or be misdiagnosed as irritable bowel syndrome or pelvic inflammatory disease. It is not surprising that diagnosis can be delayed for several years.<sup>304</sup>

Dysmenorrhea and pain that are new in onset, progressive, or severe strongly suggest endometriosis.<sup>305</sup> The dysmenorrhea associated with endometriosis often begins before onset of menstrual flow and usually persists throughout menses, sometimes even beyond. The pain usually is diffuse, located deep in the pelvis, dull, and aching and may radiate to the back and thighs or be associated with rectal pressure, nausea, and episodic diarrhea.<sup>306</sup> Pain may be more common, severe, and associated with dyspareunia and painful defecation in women with deep infiltrating disease involving the cul-de-sac and rectovaginal septum.<sup>240,307,308,309</sup> Dyspareunia associated with endometriosis usually is new in onset and most intense with deep penetration immediately prior to menstruation.<sup>310,311</sup> One-half to two-thirds of women with endometriosis and pain have intermenstrual pain.<sup>245</sup>

**The severity of endometriosis does not correlate with the number and severity of symptoms; women with advanced disease may have few or no symptoms and those with minimal or mild disease may have incapacitating pain.**<sup>245,310,311</sup> However,

in women with deep infiltrating endometriosis, the severity of pain generally correlates with the depth and volume of disease.<sup>240,307,310</sup> Extrapelvic endometriosis may be associated with a wide assortment of cyclic symptoms that reflects the organs involved (abdominal scars,<sup>312,313</sup> the gastrointestinal and urinary tracts,<sup>78,314,315,316</sup> the diaphragm,<sup>317</sup> the pleura,<sup>318</sup> and peripheral nerves<sup>319</sup>).

**There has been a gradual shift toward diagnosing endometriosis on a clinical basis.<sup>320,321</sup> While surgery is currently required for definitive diagnosis, endometriosis should be suspected in any woman reporting symptoms of cyclic, progressively worsening pain. Furthermore, medical treatment of dysmenorrhea/clinically diagnosed endometriosis certainly is appropriate before considering surgical evaluation and treatment for suspected endometriosis.<sup>322</sup> A trial of treatment with a nonsteroidal anti-inflammatory drug (NSAID), ideally with a combined oral contraceptive (COC), progestin only contraceptive, or gonadotropin-releasing hormone (GnRH) antagonist, is reasonable when the symptoms do not suggest an acute process.**

## **Physical Examination**

Physical findings in women with endometriosis vary widely and, when present, can relate to the location and extent of disease.<sup>310</sup> The external genitalia are typically normal. Occasionally, speculum examination may reveal characteristic blue-colored implants or red proliferative lesions that bleed on contact, both usually in the posterior fornix. Whereas deep infiltrating endometriosis involving the rectovaginal septum frequently is palpable, it is not often visible and may have no obvious signs.<sup>308</sup> In addition, in moderate to severe disease, the uterus often is retroverted and can exhibit decreased mobility or fixation, suggesting involvement of the cul-de-sac. Women with ovarian endometriomas can have a tender, fixed, adnexal mass. Focal tenderness, thickening, induration, and nodularity of the uterosacral ligaments (palpable at the 4 o'clock and 8 o'clock positions at the base of the cervix) are the most common, and frequently the only, physical findings.<sup>323,324</sup> Physical examination has its greatest diagnostic sensitivity when performed during menstruation, but even then, a normal examination does not exclude the diagnosis.<sup>325</sup> **Overall, compared to surgical diagnosis of endometriosis, physical examination has relatively poor sensitivity, specificity, and predictive value and should not be used as a means to rule out endometriosis.<sup>326</sup>**

# Noninvasive Diagnostic Testing CA-125

CA-125 is a cell surface antigen expressed by derivatives of the coelomic epithelium (including the endometrium) and is well established as a useful marker for the monitoring of women with epithelial ovarian cancer. Levels of CA-125 often are elevated in women with advanced endometriosis,<sup>327,328,329</sup> but also during early pregnancy and normal menstruation, and in women with acute pelvic inflammatory disease or leiomyomata. Serum CA-125 concentrations vary somewhat across the menstrual cycle; in general, levels are highest during the menstrual phase and lowest during the midfollicular and periovulatory phases of the cycle.<sup>325,330,331</sup> However, studies of cycle-dependent assay sensitivity and reproducibility have yielded conflicting results, so there is no one best time to perform the test.<sup>326</sup>

Serum CA-125 has been inappropriately advocated as a screening test for diagnosis of endometriosis, but a meta-analysis including 22 studies using surgically diagnosed disease as the gold standard concluded that the marker performs rather poorly.<sup>332</sup> Cutoff values that provide 90% overall specificity have no more than 52% sensitivity.<sup>333</sup> As a screening test for advanced stages of endometriosis, stages III and IV have a sensitivity of 63% compared to 24.8% for stages I and II.<sup>333</sup> **Overall, the serum CA-125 concentration does not have the necessary sensitivity to be an effective screening test for the diagnosis of endometriosis.**

Whereas the serum CA-125 generally is not a reliable predictor of the effectiveness of medical therapy,<sup>334,335</sup> a sustained elevation of serum CA-125 after surgical treatment predicts a relatively poor prognosis.<sup>336,337</sup>

## Circulating microRNAs

Several studies have noted aberrant miRNA expression in cancers, cardiovascular disorders, inflammatory diseases, and gynecologic disease.<sup>338,339,340,341,342,343,344</sup> Thousands of miRNAs circulate in the bloodstream and hence offer the possibility to serve as precise biomarkers of disease.<sup>345</sup> While the mechanism by which miRNA levels are altered is not fully understood, their serum/plasma levels correlate with levels in cancer tissues, suggesting that miRNAs are shed from tissue and released into the circulation.<sup>346,347</sup> As mentioned earlier, miRNAs are differentially expressed in eutopic and ectopic endometria. Microarray expression profiling has also demonstrated altered systemic serum miRNA concentrations in women with endometriosis.<sup>301,348,349</sup> Recently, using a prospective case-control study, miRNA microarray and qPCR analysis of serum samples in women with and without endometriosis diagnosed at time of laparoscopy found that many miRNAs were aberrantly regulated in endometriosis.<sup>301</sup>

Measurement of these miRNAs may represent a novel, noninvasive diagnostic test for early detection and intervention of endometriosis, and is currently under development.

# Imaging

Transvaginal ultrasonography can be helpful in identifying women with advanced endometriosis. **Transvaginal ultrasonography can detect ovarian endometriomas, but cannot image pelvic adhesions or superficial peritoneal foci of disease.** Endometriomas can have varying ultrasonographic features but appear typically as cystic structures with diffuse low-level internal echoes surrounded by a crisp echogenic capsule. Some have internal septations or thickened nodular walls.<sup>350,351</sup> When the characteristic features are present, transvaginal ultrasonography has 90% or higher sensitivity and almost 100% specificity for detection of endometriomas.<sup>352,353</sup> Transvaginal or transrectal ultrasonography can be especially helpful when deep infiltrating disease involving the bladder, the uterosacral ligaments, or the rectovaginal septum is suspected.<sup>354,355,356,357,358,359,360,361</sup>

**Like transvaginal ultrasonography, magnetic resonance imaging (MRI) can be helpful in the detection and differentiation of ovarian endometriomas from other cystic ovarian masses, but cannot reliably image small peritoneal lesions.**<sup>356,362,363</sup> For detection of peritoneal implants, MRI is superior to transvaginal ultrasonography but still identifies only 30–40% of the lesions observed at surgery. For detection of disease documented by histopathology, MRI is approximately 70% sensitive and 75% specific.<sup>364</sup> The principal advantage MRI has over ultrasonography is its ability to distinguish more reliably between acute hemorrhage and degenerated blood products. Whereas endometriomas usually exhibit a relatively homogeneous high signal intensity on T1-weighted images and a hypointense signal on T2-weighted images (“shading”), acute hemorrhage generally has low signal intensity on both T1- and T2-weighted images.<sup>326</sup> However, an interval 6-week observation, during which hemorrhagic cysts will typically regress, followed by repeat TVUS accomplishes the same goal. Gadolinium contrast offers no additional diagnostic value.<sup>365</sup> MRI also can be used to aid in the diagnosis of deep infiltrating and rectovaginal disease.<sup>366</sup> **Neither ultrasound nor MRI can be used to rule out endometriosis.**

# Surgical Diagnosis

**Laparoscopy with histologic examination of excised lesions has traditionally been the gold standard for the diagnosis of endometriosis.** The optimal time during the menstrual cycle to perform laparoscopy is not clear, although some may recommend that surgery generally should not be performed during or within 3 months after hormonal medical treatment.<sup>354</sup> Greater awareness of the varied appearance of endometriotic lesions has doubled the frequency with which endometriosis is diagnosed with laparoscopy when a careful and systematic examination is performed.<sup>367,368</sup>

The classic peritoneal implant is a blue-black “powder- burn” lesion (containing hemosiderin deposits from entrapped blood) with varying amounts of surrounding fibrosis, typically observed on the ovaries and on peritoneal surfaces in the cul-de-sac, uterosacral ligaments, and ovarian fossa.<sup>369</sup> **However, the majority of implants are “atypical,” appearing white and opaque, red and flame-like, or vesicular.** Less commonly, disease may be found in ovarian adhesions, peritoneal defects, or involving the appendix.<sup>367,368,369,370,371</sup> Red lesions are highly vascular and proliferative and represent an early stage of disease.<sup>372</sup> Pigmented lesions represent more established or advanced disease. Both are metabolically active and more commonly associated with symptoms. White lesions are less vascular and active and less often symptomatic.<sup>372,373</sup> Studies involving serial laparoscopy have suggested a natural progression in the appearance of endometriotic lesions over time, and revealed that a variety of lesions may be observed at any one time in an individual.<sup>374,375</sup>

Strict histologic criteria will confirm the surgical diagnosis of endometriosis in approximately 50–65% of excised lesions.<sup>369,376</sup> When diagnosis is in doubt, biopsy of suspicious areas should be performed to prevent misdiagnosis; lesions that can be confused with endometriosis include endosalpingiosis, mesothelial hyperplasia, hemangiomas, adrenal rests, inflammatory changes (from infectious causes), and splenosis.<sup>377</sup> **Histologic examination of excised lesions can confirm surgical impressions and is preferred, but not required, to establish the diagnosis with reasonable certainty.** Conversely, a negative laparoscopy is relatively reliable for excluding endometriosis, although it cannot rule out microscopic disease.<sup>378</sup> Occult disease is not uncommon in women with pelvic pain; based on this, even laparoscopy cannot be considered a true gold standard for the diagnosis of endometriosis.

Endometriomas usually appear as smooth, dark cysts, typically associated with adhesions and containing a dense brown chocolate-like fluid (hemosiderin from ovarian/endometriotic hemorrhage).<sup>307,379</sup> Larger endometriomas frequently are multilocular. Careful visual inspection of the ovaries (and imaging) generally are highly

reliable for detection of endometriomas.<sup>380,381</sup> Whereas ovarian endometriomas usually are accompanied by numerous other visible peritoneal lesions,<sup>382</sup> deep infiltrating endometriosis is largely retroperitoneal, often not readily apparent, and frequently isolated; it may even represent a distinct entity, arising from müllerian rests within the rectovaginal septum.<sup>383,384</sup>

## Classification and Staging Systems

A uniform classification system for endometriosis that considers both the distribution and severity of disease is useful, because both treatment and prognosis in women with endometriosis are determined, to some extent, by the disease severity. A valid uniform classification also is crucial for comparing the results of treatment trials performed in different centers.

In 1979, the American Fertility Society (now the American Society for Reproductive Medicine, ASRM) introduced a classification system based on surgical findings at laparoscopy or laparotomy that was modeled after those used for grading malignant disease.<sup>385</sup> The system assigned a point score, based on the size, depth, and location of lesions and associated adhesions. The classification system was revised in 1985,<sup>386</sup> and again in 1996, to acknowledge the varying morphology of endometriosis and to improve consistency in scoring and the prognostic value for women with pain or infertility (**Figure 32.2**).<sup>387</sup> The current version of the revised classification system is the most widely accepted classification tool, but still has serious limitations.<sup>388</sup> Chief among them is the relatively poor correlation with clinical symptoms and pregnancy rates.<sup>389,390</sup> Further revisions of the classification scheme are anticipated as our understanding of the pathogenesis of infertility advances and likely will include empirically derived weights and thresholds to define stages of disease; other factors may be incorporated if they prove to have prognostic value.<sup>391</sup>

Reprinted from **American Society for Reproductive Medicine**. Revised American Society for Reproductive Medicine classification of endometriosis: 1996. Fertil Steril 67:817-821, 1997, with permission from Elsevier.<sup>387</sup>

The classification of endometriosis used most commonly in clinical practice is descriptive and relatively simple:

- Stage I: Minimal endometriosis—isolated superficial disease on the peritoneal surface with no significant associated adhesions
- Stage II: Mild endometriosis—scattered superficial disease on the peritoneal surface and ovaries, totaling less than 5 cm in aggregate, with no significant associated adhesions
- Stage III: Moderate endometriosis—multifocal disease, both superficial and invasive (including endometriomas >1 cm), that may be associated with adhesions involving the fallopian tubes and/or the ovaries
- Stage IV: Severe endometriosis—multifocal disease, both superficial and invasive, including large ovarian endometriomas, usually associated with adhesions, both filmy and dense, involving the fallopian tubes, ovaries, and cul-de-sac

In 2005, the Enzian classification system was developed to better describe deep infiltrating lesions. Like the ASRM classification, it consists of four stages, which are further subdivided into three groups (**Figure 32.3**).<sup>392</sup> In 2009, a new staging system was proposed, called the endometriosis fertility index (EFI), by combining the factors that best predicted pregnancy (without IVF) after analysis of clinical and surgical data (275 variables) collected from 579 infertile patients with endometriosis.<sup>390</sup> The EFI score (0–10, with 0 representing the poorest and 10 the best prognosis) was validated by collecting comparable data from an additional 222 patients, calculating the score for each, and observing good correlation between actual and predicted (estimated from life table analysis) pregnancy rates. The key element of the new staging system, absent from its forerunners, is a numerical measure of functional anatomy, based on careful assessment of the tubes (extent of serosal injury, mobility, and patency), fimbriae (extent of injury, architecture), and ovaries (size, extent of surface injury). The EFI score predicts cumulative pregnancy rates over 3 years after surgery, which range from a low of 10% (EFI 0–3) to a high of 75% (EFI 9–10) (**Figure 32.4**).<sup>390</sup> Based on the original report, the method has promise as a clinical tool for developing treatment plans in infertile patients with a surgical diagnosis of endometriosis. Ultimately, the clinical utility of the EFI will hinge on additional independent validation and its general acceptance by clinicians. In 2017, the World Endometriosis Society met and developed consensus statements on the classification of endometriosis and proposed a classification system toolbox that could be used by all surgeons in each endometriosis surgical case.<sup>393</sup> This toolbox includes the revised ASRM criteria and the Enzian and the EFI classification systems.<sup>392</sup> The goal is to use these classification tools to ensure that clear information is obtained from the surgery, as well as enhance patient understanding of their diagnosis.<sup>393</sup>

### ESTIMATED PERCENT PREGNANT BY EFI SCORE

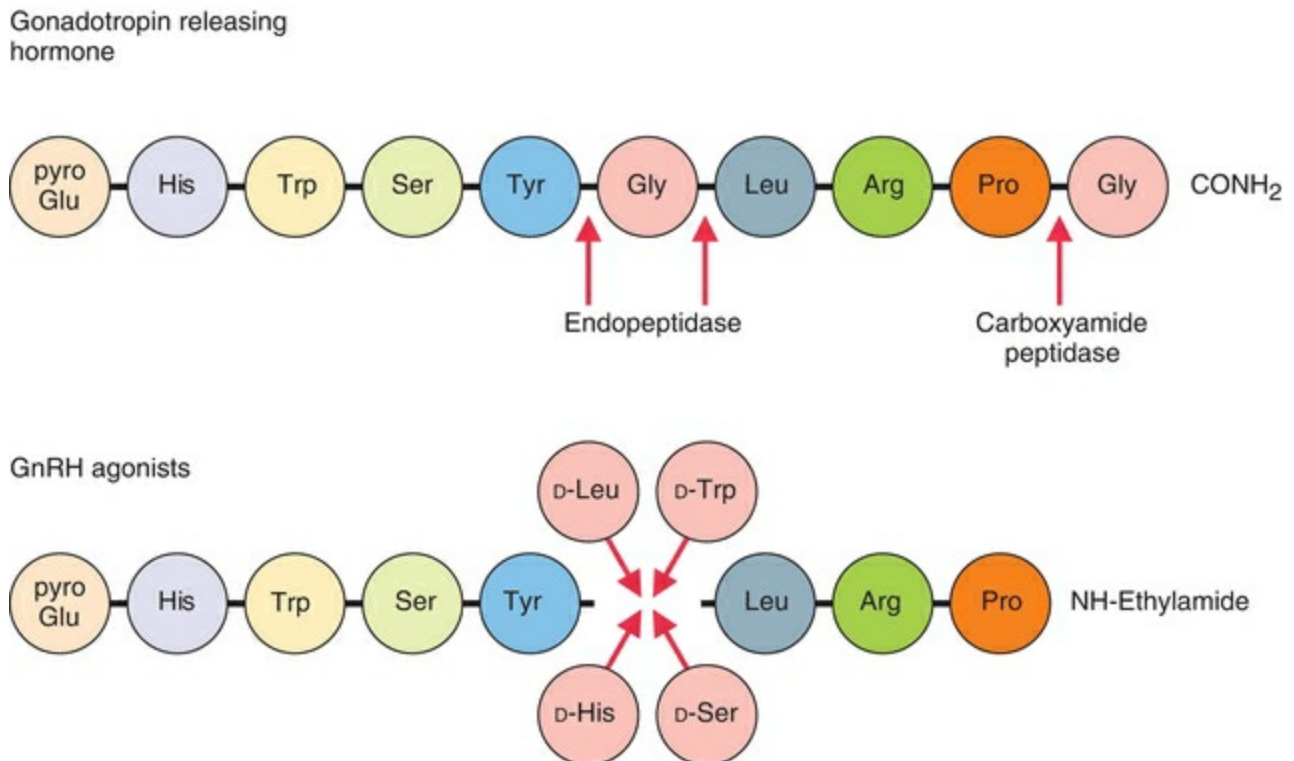

## Key Points

- Careful clinical evaluation can identify women likely to have endometriosis but has not traditionally been used to establish the diagnosis. Treatment may be initiated based on clinical diagnosis.
- Although a serum CA-125 concentration may provide corroborative evidence of disease, the sensitivity of the test is too low to make it an effective screening tool.
- Transvaginal ultrasonography and MRI are both highly sensitive and specific for detection of ovarian endometriomas but cannot reliably image peritoneal implants of disease.
- In the majority of women, the diagnosis of endometriosis ideally can be made after a careful and systematic history and physical examination, with laparoscopic examination infrequently needed for diagnosis alone.
- Laparoscopy should be considered a therapeutic option rather than necessary for diagnosis.

# TREATMENT OF ENDOMETRIOSIS

The treatment of endometriosis depends on its clinical manifestations, which currently fall into two categories: pelvic pain and/or infertility. Because both can be very difficult to assess objectively, the results of treatment trials must be interpreted carefully. To be truly informative, studies of the effects of treatments on pain should use a validated objective measure of pain, follow subjects over a prolonged interval because the recurrence of pain is time dependent, and employ a placebo control because the placebo effect in studies of pain is often quite large (30–50%). Studies of the effects of treatments on the volume of endometriosis are equally difficult to conduct and interpret because disease may regress spontaneously and also may recur or advance after discontinuation of therapy. Studies of the effects of treatments on fertility must consider that most women with endometriosis and infertility are only subfertile, not sterile; they can conceive, but do so less efficiently. Ideally, cycle fecundity over a defined interval of time should be compared to that in a group of similarly affected but untreated women ([Figures 32.5](#) and [32.6](#)).

**FIGURE 32.5**

**FIGURE 32.6**

Treatment for endometriosis can be expectant and can involve one or a combination of medical treatments, conservative or definitive surgery, or a combination of medical and surgical treatments. Expectant management generally is reserved for patients without significant symptoms and for those approaching menopause. However, even those with few symptoms benefit from treatment aimed at preventing progression of the disease.<sup>394</sup> Because endometriosis normally regresses after menopause, due to the marked decrease in ovarian estrogen production, perimenopausal women with mild symptoms may choose expectant management or treatment limited to nonnarcotic analgesics, for the short term. Young women with significant symptoms generally will require more aggressive medical or surgical treatment.

# Medical Treatment

Women with pelvic pain, suspected endometriosis, and no other indication for surgical treatment can be managed effectively with empiric medical treatment without establishing a surgical diagnosis.<sup>395</sup> Initial empiric medical therapy usually involves treatment with NSAIDs and oral contraceptives (OCs; combined or progestin only). If treatment with NSAIDs and OCs does not significantly improve pain, second- and third-line medical therapies or laparoscopic surgery is employed.

Traditional medical therapies for endometriosis have been based on Sampson's theory of retrograde menstruation and implantation and on the simple premise that ectopic endometrium may be expected to respond to treatment in much the same way as normal eutopic endometrium. Consequently, the objectives of treatment have been to reduce or eliminate cyclic menstruation, thereby decreasing peritoneal seeding and the likelihood that new implants will develop, and to suppress the growth and activity of the endometrium, anticipating that the same would occur in the endometriotic tissue derived from it. Interventions that reduce ovarian estradiol production are the most reliable ways to cause atrophy of endometriotic lesions and the most effective treatment for pain. These simple operational concepts have shaped medical treatments for endometriosis for decades, but our growing understanding of the pathogenesis of endometriosis at the molecular level is now beginning to suggest new treatment strategies aimed at the mechanisms of disease.

## Nonsteroidal Anti-Inflammatory Medications

Nonsteroidal anti-inflammatory medications are the most commonly used first-line medication for endometriosis, typically in conjunction with OCs. In a Cochrane review, when NSAIDs were compared to placebo, there was no evidence of a positive effect on pain relief, nor clear evidence that women taking NSAIDs did not require additional (alternative) analgesia.<sup>396</sup> However, a serious limitation of this review was that it included only one trial of 24 women; no additional larger trials have been conducted. As such, NSAIDs continue to be prescribed, but usually in combination with hormonal therapy such as an OC.

## Estrogen-Progestin Contraceptives

Estrogen-progestin contraceptives have been a mainstay of the medical treatment of symptomatic endometriosis almost since their introduction.<sup>397</sup> Even today, they are the most commonly prescribed treatment for the disease. Continuous treatment can eliminate menses and is the preferred method for those with dysmenorrhea. Continuous treatment has been termed "pseudopregnancy" because combined estrogen-progestin therapy

induces amenorrhea and endometrial decidualization and resembles the high progesterone environment of pregnancy widely believed to improve or suppress endometriosis. Although estrogen stimulates the growth of endometriosis, modern OCs are progestin dominant and contain lower doses of estrogen. Limited evidence indicates that estrogen-progestin contraceptives also may enhance apoptosis of eutopic endometrial tissue in women with endometriosis.<sup>398</sup> Overall however, OCs are not considered cytoreductive therapy—once medication is stopped, the ectopic lesions likely resume their cyclic growth and inflammatory activity.<sup>399</sup>

Estrogen-progestin contraceptives are a good initial choice for symptomatic women who also need contraception. They can be expected to provide effective relief from pain associated with endometriosis in up to two-thirds of affected women, particularly when taken continuously.<sup>400,401,402,403,404,405</sup> Through their suppressive actions, they may also help to prevent progression of endometriosis. There is no evidence that any formulation is superior, although one should use only monophasic regimens. One advantage estrogen-progestin contraceptives have over other medical therapies is they can be taken indefinitely. OCs are best used continuously or in a long-cycle regimen, to help minimize pain symptoms related to menses. In long-cycle regimens, active pills are usually taken for at least 90 days continuously, followed by a 7-day pill-free interval, to help prevent breakthrough bleeding and associated pain. Many use these regimens without a pill-free interval for years and stop for 7 days only in response to breakthrough bleeding.

## Progestins

Progestins have long been used to treat symptomatic endometriosis because they inhibit endometrial growth (and presumably the growth of endometriotic tissue), by first inducing decidualization and then atrophy.<sup>406,407</sup> In high doses, they also can inhibit pituitary gonadotropin secretion and ovulation, inducing amenorrhea. A large variety of different progestins are available, including those derived from progesterone-like medroxyprogesterone acetate and others derived from 19-nortestosterone, with norethindrone as the prototype. Suppression of endometrial matrix metalloproteinases (recognized as contributing to the pathogenesis of endometriosis) could be another useful action.<sup>408</sup> Although matrix metalloproteinase activity in eutopic endometrium of women with endometriosis is unusually resistant to progesterone suppression,<sup>409</sup> the higher doses used in the treatment of endometriosis may be sufficient to overcome the effect.

Several different progestins have been used effectively for the treatment of pain (dysmenorrhea, dyspareunia, intermenstrual pain) associated with endometriosis.<sup>410,411,412,413,414</sup> Medroxyprogesterone acetate can be administered orally

(30–100 mg daily) or by injection (150 mg IM every 3 months); however, the breakthrough bleeding associated with the injectable depot form often is accompanied by pain.<sup>415</sup> A single randomized controlled trial demonstrated that high doses of medroxyprogesterone acetate (oral 100 mg daily for 6 months) induced complete remission of all visible endometriosis in 50% of women, compared to 12% of those who received placebo, and incomplete remission in 13%, compared to 6% of placebo-treated controls.<sup>412</sup> Side effects of progestins include nausea, weight gain, fluid retention, breast tenderness, irregular bleeding, and depression. Breakthrough bleeding is common (35–50%) but generally well tolerated and usually can be eliminated by treatment with short courses of supplemental estrogen (conjugated estrogens [CEs] 1.25 mg or estradiol 2.0 mg daily for 7–10 days). Depression is not uncommon (approximately 5%) and can be severe enough to require discontinuation of treatment. Norethindrone acetate (5–15 mg daily) and megestrol acetate (40 mg daily) also have been used in the treatment of endometriosis and have side effects similar to those of medroxyprogesterone acetate.<sup>416,417</sup> The levonorgestrel-releasing intrauterine device is another option that may have particular value for women with deep infiltrating rectovaginal endometriosis,<sup>418,419,420,421,422</sup> with newer studies demonstrating the benefit of reducing pain and dysmenorrhea recurrence following surgical therapy.<sup>423</sup> Limited evidence indicates that the etonogestrel subdermal implant can also be effective for decreased pain associated with endometriosis.<sup>424,425</sup> Dienogest, a fourth-generation progestin, has also been studied as a medical therapy option for endometriosis. Several trials have demonstrated that dienogest is effective in improving endometriosis-associated pain and may even help overcome progesterone resistance by increasing the number of PR.<sup>426,427,428,429</sup> Dienogest is available in Europe, Australia, and Japan, but not in the United States.

Progestins can have adverse effects on serum lipoprotein levels. The 19-nortestosterone–derived progestins decrease HDL significantly; the effects of medroxyprogesterone acetate are less severe.<sup>430,431</sup> However, these effects are unlikely to have any clinical importance over a relatively short interval of months in this low-risk population. At higher doses, the suppressive effects of progestins on the hypothalamic-pituitary-ovarian axis may be sufficient to induce a hypogonadal state, resulting in spinal bone mineral depletion amounting to 2–4% over an interval of 6–12 months; longer-term treatment may result in even greater loss, but recovery usually is rapid after treatment is discontinued and any impact on fracture risk is unlikely.<sup>432</sup>

## **Gonadotropin-Releasing Hormone Analogues**

### **GnRH Agonists**

GnRH agonists are derived from native GnRH by substituting a D-amino acid for the native L-amino acid at position 6 in the decapeptide (**Figure 32.5**). The substitution yields an agonist resistant to degradation, increasing its half-life and time of receptor occupancy. Pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion requires a pulsatile hypothalamic GnRH stimulus, which allows receptor concentrations to be replenished between pulses; a constant intravenous infusion of GnRH generates an initial response (“flare”), followed by down-regulation of receptor concentrations, which desensitizes the pituitary to continued stimulation. Long-acting GnRH agonists (leuprolide, nafarelin, goserelin, buserelin, triptorelin) have the same effect, inducing a hypogonadotropic hypogonadal state that has been dubbed “pseudomenopause” or “medical oophorectomy,” although both terms are misnomers.<sup>433,434</sup> In menopause, the ovaries produce no estrogen because they are depleted of follicles and cannot, and after oophorectomy, the ovaries are altogether absent; in both cases, serum gonadotropin levels are markedly elevated. In contrast, women under treatment with GnRH agonists do not produce estrogen because their ovaries receive no effective gonadotropin stimulation; levels of both FSH and LH are very low. GnRH agonists are effective for the treatment of endometriosis because they induce a hypogonadal state, which deprives existing disease of estrogen support, and amenorrhea, which prevents new peritoneal seeding. Several clinical trials have demonstrated that approximately 85% of women with endometriosis and pelvic pain who are treated with GnRH agonists experience relief of their pain.<sup>435</sup>

GnRH agonists can be administered intramuscularly, subcutaneously, or intranasally, the route varying with the specific drug. Administration of a GnRH agonist 1 week prior to the patient’s menses helps minimize the flare effect. Approximately 75% of women are rendered hypogonadal within 4 weeks of treatment and almost all are by 8 weeks.<sup>436</sup> The side effects of GnRH agonists are those of hypogonadism and include hot flashes, progressive vaginal dryness, decreased libido (both estrogen production and androgen production are suppressed), depression, irritability, fatigue, headache, changes in skin texture, and bone mineral depletion (13% after 6 months of use without add-back).<sup>429</sup> Over 80% report vasomotor symptoms and 30% report vaginal symptoms and headache.<sup>437</sup> GnRH agonist therapy does not have significant adverse effects on serum lipids and lipoprotein concentrations like those associated with danazol or high-dose progestin treatment.<sup>438,439</sup>

In efforts to prevent the bone mineral depletion that accompanies GnRH agonist therapy, a number of different “add-back” treatment strategies have been developed. The “estrogen threshold hypothesis”<sup>440</sup> notes that endometriosis lesions grow when serum estradiol concentration is in the premenopausal range (30–300 pg/mL) and regress when estradiol levels are in the menopausal range (<20 pg/mL). Treatments that

achieve estradiol levels in the range of 20–30 pg/mL are associated with amenorrhea and regression of endometriosis lesions and fewer hypoestrogenic side effects. The add-back regimens are based on the notion that the level of estrogen required to support endometriosis is greater than is required to prevent vasomotor symptoms or bone mineral depletion. Norethindrone can be used alone without additional estrogens as this progestin is unique in having estrogenic metabolites and a well-documented effect on bone density that is distinct from other progestins.<sup>441</sup> Norethindrone acetate 5 mg is the only FDA-approved add-back regimen, although several other estrogen plus progestin combinations exist and can be used in a similar manner to minimize hot flashes and bone loss.<sup>239</sup> Low-dose combined estrogen-progestin add-back regimens (CEs 0.625 mg and medroxyprogesterone acetate 2.5 mg daily or norethindrone 5.0 mg daily)<sup>442,443</sup> Estrogen-only add-back is inadvisable as estradiol promotes lesion growth; a clinical trial (oral estradiol, 1 mg daily) was terminated early due to observations of recurrent pain in treated subjects.<sup>444</sup> **Evidence from randomized trials indicates that hormone add-back regimens protect bone and reduce symptoms of estrogen deficiency without sacrificing control of pain associated with endometriosis.**<sup>436,445,446,447,448,449,450</sup>

Whereas some choose not to begin add-back therapy until pain is under control, this is not recommended as evidence demonstrates that delaying add-back therapy is unnecessary and starting add-back at time of GnRH agonist does not adversely affect pain control.<sup>239,450</sup> Pain of lesser or equal intensity may recur soon after cessation of treatment; the recurrence rate is at least 10–20% per year.<sup>410,451,452,453</sup> The overall cumulative recurrence rate 5 years after treatment with a GnRH agonist is approximately 55%, lower for women with minimal and mild endometriosis (37%) than for those with advanced disease (74%).<sup>454</sup>

In a large uncontrolled trial, leuprolide treatment decreased the volume of endometriosis in almost 90% of women.<sup>455</sup> Numerous other studies comparing a GnRH agonist with danazol have concluded they have equal efficacy<sup>451,456,457,458,459,460</sup> Another comparing a GnRH agonist (leuprolide) to a progestin (lynestrenol) observed a greater decrease in disease in women treated with the GnRH agonist.<sup>461</sup> Treatment with a GnRH agonist can potentially decrease the size of endometriomas, but does not eliminate them.<sup>462</sup> **GnRH agonists are proven effective in relieving pain in women with endometriosis; all agonists appear equally efficacious.**<sup>437,456,463</sup>

## GnRH Antagonist

Elagolix is the first oral nonpeptide GnRH antagonist available for the treatment of endometriosis-associated pain. As opposed to GnRH agonists, antagonists do not

stimulate the receptor, and therefore, there is no flare effect. They directly block the GnRH receptor and therefore can function rapidly, and partial dose-dependent reduction in gonadotropins is readily achieved. Partial reductions of estradiol levels can be used to treat endometriosis without need for add-back, especially at low doses of the GnRH antagonist. In the two completed phase III trials, a low dose (150 mg/day) and high dose (200 mg twice/day) resulted in significant improvement in endometriosis-associated pain, compared to placebo.<sup>464</sup> While both doses were effective, the higher dose had the greatest improvement, especially with respect to dyspareunia. Lastly, the reduction in dysmenorrhea for both doses was greater than the reduction noted for NMPP, which may be due to the fact that dysmenorrhea is typically due to changes in ovarian hormones, while the causes of NMPP are more complex.<sup>464</sup> Elagolix is rapidly bioavailable after initiation of therapy, and suppression of estradiol levels, while dose dependent, occurs within 24 hours.<sup>465</sup> Given the reduction in estradiol levels, hot flushes and other vasomotor symptoms were seen in some subjects; however, these were generally mild and not as severe as typically seen with GnRH agonists. There were more hot flushes (more so in the higher dose group) compared to placebo, but discontinuation due to hot flushes occurred in less than 1% of women using low dose and less than 3% using high dose.<sup>464</sup> Changes in bone mineral density are seen with high-dose therapy requiring limitation to 6 months of therapy or consideration of add-back therapy as with the GnRH agonists.<sup>464</sup> There were also decreases in endometrial thickness and higher amenorrhea rates in women taking elagolix compared to placebo.<sup>464</sup> In the two 6-month extension studies, which followed women in the high- and low-dose groups for an additional 6 months of treatment, vasomotor symptoms and changes in BMD were comparable or less to that seen with GnRH agonists.<sup>466</sup> In addition, after stopping elagolix, BMD returns toward baseline levels.<sup>466</sup> Given their rapid onset, oral administration, absence of flare effect, and the availability of two doses for individual tailoring of therapy, elagolix may be considered the first choice for patients not responding to OCs or those with side effects from progestins. It is important to note that elagolix, at either dose, does not result in complete suppression of ovulation; thus, concomitant contraception is needed in women who are at risk for pregnancy.<sup>465</sup>

## Danazol

Danazol is the first drug ever approved for the treatment of endometriosis in the United States in the 1970s.<sup>467</sup> It is an orally administered isoxazole derivative of 17 $\alpha$ -ethinyltestosterone that acts primarily by inhibiting the midcycle urinary LH surge and inducing a chronic anovulatory state; however, it also inhibits a number of steroidogenic enzymes and increases free testosterone levels (**Figure 32.6**).<sup>468,469,470,471</sup> The many different effects of danazol combine to yield a high-androgen, low-estrogen environment

that inhibits growth of endometriosis. The amenorrhea that commonly results from danazol treatment also likely decreases new peritoneal seeding.<sup>472</sup>

Danazol has proven effective for reducing endometriosis-related pain (dysmenorrhea, deep dyspareunia, intermenstrual pain) in up to 90% of treated women<sup>412,473</sup>; the median time to recurrence of pain after discontinuation of treatment is approximately 6 months.<sup>473</sup> Studies examining the effect of danazol on endometriotic implants (typically assessed after 6 months of treatment) have consistently observed a decrease in the volume of disease ranging between 40% and 90%.<sup>451,456,467,475,476,477</sup> One randomized controlled trial observed regression of disease in 60% of danazol-treated women and in 18% of those who received placebo.<sup>412</sup>

**Although danazol is effective for the treatment of pain associated with endometriosis, the recommended doses (400–800 mg daily) have substantial androgenic and hypoestrogenic side effects that limit its clinical utility.** The most common are weight gain, fluid retention, fatigue, decreased breast size, acne, oily skin, hirsutism, atrophic vaginitis, hot flushes, muscle cramps, and emotional lability. Some can be expected, occurring in up to 80% of women taking danazol, but less than 10% have side effects sufficient to warrant discontinuation of treatment.<sup>478</sup> Danazol crosses the placenta and is a known teratogen; it has been associated with virilization of female fetuses in utero; thus, patients who are taking danazol must use a reliable method of contraception.<sup>479</sup> The androgenic actions of danazol also can deepen the voice irreversibly.<sup>480,481</sup> Adverse changes in the lipid profile reflect the drug's androgenic effects; total cholesterol and low density lipoprotein (LDL) levels are increased and the high density lipoprotein (HDL) concentration is lowered, but these effects pose no significant risk over a relatively short term of treatment. Rarely, danazol treatment may result in liver damage or arterial thrombosis.<sup>478,482</sup> Lower doses of danazol are better tolerated but also possibly less effective.<sup>483,484</sup> Danazol can be administered vaginally, with fewer systemic side effects and up to an 80% improvement in pain symptoms.<sup>485,486,487,488,489,490,491</sup>

## Aromatase Inhibitors

As endometriotic implants produce aromatase, the enzyme required to convert androgens to estrogens, aromatase inhibitors offer another medical approach to management of endometriosis.<sup>18,250,492</sup> Available third-generation aromatase inhibitors include anastrozole and letrozole. While most of the literature on their use comes from breast cancer patients, aromatase inhibitors can block estrogen production in the ovary and endometriotic lesions.<sup>492,493</sup>

Several small studies have used anastrozole (1 mg/day) or letrozole (2.5 mg/day) effectively for the management of endometriosis-associated pain.<sup>250,494,495,496,497,498,499</sup> Given that the reduction in estradiol causes an increase in FSH production and resultant follicular development, **aromatase inhibitors are never a first-line treatment and must be administered with an agent that down-regulates the ovaries in premenopausal women.**<sup>500</sup>

A randomized trial comparing treatment with a GnRH agonist alone to combined treatment with a GnRH agonist and anastrozole in the postoperative management of women receiving surgical treatment for endometriosis found both treatment groups to be effective. However, the addition of anastrozole prolonged the time to symptom recurrence significantly; 14/40 (35%) cases recurred with the GnRH agonist alone, while only 3/40 (7.5%) treated with GnRH agonist plus anastrozole recurred during 24 months of follow-up.<sup>501</sup> Of note, bone loss after 6 months of treatment with GnRH agonist plus anastrozole was significant and persisted even after completion of therapy; none of the women became osteopenic or osteoporotic however. The administration of an aromatase inhibitor plus norethindrone acetate (or norethisterone acetate) has also been found to effectively manage endometriosis-associated pain, including pain related to endometriosis involving the intestines.<sup>495,502,503,504</sup> Aromatase inhibitors with COCs are also effective in relieving pain, with no adverse effects on hematologic, hepatic, renal, lipid, or bone density.<sup>497,503</sup> Aromatase inhibitors have also been used successfully in treating postmenopausal endometriosis, although data are limited to a few case reports.<sup>493,505</sup> The side effects associated with third-generation aromatase inhibitors include headache, joint stiffness, hot flushes (less so compared to GnRH agonists), and leg cramps, but overall aromatase inhibitors seem to be well tolerated.<sup>500</sup>

It is important to note that although studies have demonstrated effectiveness of aromatase inhibitors in treating endometriosis-associated pain, treatment with these agents is still considered investigational, and larger multicenter randomized trials are needed in order to more accurately determine safety/efficacy.<sup>239,493</sup>

## Future Therapeutics

### Hormonal

Recent work has focused on the potential utility of selective progesterone receptor modulators (SPRMs) in the management of endometriosis-associated pain. SPRMs, as their name suggests, can have agonist or antagonist effects on the PR, depending on the tissue target.<sup>506</sup> Mifepristone—the most clinically studied given its use for induction of medical abortions—was found to decrease pain symptoms and induce amenorrhea in

endometriosis patients.<sup>507,508</sup> Additional SPRMs are currently undergoing investigation for treatment of endometriosis-associated pain.

Similarly, selective estrogen receptor modulators (SERMs) may have a role in the treatment of this estrogen-driven disease. Bazedoxifene (BZA; a selective estrogen receptor modulator) alone or paired with a CE in a murine model of endometriosis not only induced regression of endometriotic lesions but also caused degradation of the ER.<sup>509,510</sup> Given that BZA acts as an antiestrogen in the endometrium, these findings are not unexpected. In a case report of BZA-CE use for the management of endometriosis-associated pain, BZA-CE caused complete resolution of pelvic pain, with no adverse effects on the reproductive tract.<sup>511</sup> BZA-CE has also been used successfully as add-back therapy for women using GnRH agonists.<sup>512</sup> While randomized clinical trials are needed to prove efficacy and safety, BZA-CE may represent a novel therapeutic agent for endometriosis-associated pelvic pain, without the unwanted side effects of existing therapies.

Lastly, as endometriosis is a heterogeneous disorder, recent research has focused on an individualized hormonal approach to management of endometriosis-associated pain. In a retrospective study involving women undergoing surgical treatment for endometriosis-associated pain, it was found that PR status (as determined by immunohistochemistry of surgically obtained endometriosis lesions) was strongly associated with response to progestin-based therapy.<sup>513</sup> Women were categorized into three groups based on their PR expression level—high, medium, or low. All women with high PR responded to progestin-based therapy, while only 21% and 6% of women in the medium and low PR group, respectively, responded to progestin-based therapy.<sup>513</sup> While this work requires confirmation in larger prospective trials, it suggests that receptor status in endometriosis could be used in a manner analogous to the use of ER/PR status in breast cancer for tailoring hormonal-based regimens. Such an individualized approach to endometriosis management would negate trialing progestin-based therapy to determine progesterone resistance.

## **Nonhormonal and Investigational**

All of the regimens above use hormonal manipulation to suppress endometrial growth and alter menstrual cyclicality. Future therapies should be more disease specific and target endometriosis without altering reproductive hormone production or fertility. Immune conjugate (ICON) targets tissue factor that is aberrantly expressed in mouse endometriotic lesions, which causes regression of disease, likely through devascularization.<sup>514</sup> Several antiangiogenic agents such as statins, COX-2 inhibitors, dopamine agonists, and peroxisome proliferative-activated receptor agonists are undergoing evaluation in animal models and in vitro; however, clinical evidence is not

yet available.<sup>506,515</sup> There is also research underway aimed at targeting and correcting the altered molecular pathways in patients with endometriosis, such as aberrant miRNA expression and aberrant methylation patterns.<sup>516</sup> Lastly, therapy to block mesenchymal stem cell recruitment to ectopic endometrium is also under investigation.<sup>96,97</sup>

## Key Points

- **Established medical therapies for the treatment of pain associated with endometriosis include estrogen-progestin contraceptives, progestins, GnRH analogues, and danazol.**
- **Typically, OCs are the first line of therapy with GnRH antagonists becoming the optimal second-line therapy in those who fail OC treatment or have troubling progestin-related side effects.**
- **Treatment decisions must be individualized, after carefully considering the severity of symptoms, the extent of disease, the desire for future pregnancy, age, side effects, and costs.**
- **Research is ongoing for the development of new therapeutic agents.**

# Surgical Treatment

**The objectives of surgical treatment for endometriosis are to restore normal anatomical relationships, remove all visible and deep disease to the extent possible, and prevent adhesions.**

Laparoscopy is considered the standard surgical approach. Compared to laparotomy, laparoscopy offers the advantages of better visualization, less tissue trauma and desiccation, smaller incisions, and a speedier postoperative recovery.<sup>517</sup> Postoperative adhesions and complications also may be less than after laparotomy.<sup>517</sup> Most importantly, the results achieved with laparoscopy are equivalent to or better than laparotomy.<sup>519</sup> In cases of severe endometriosis with extensive adhesive disease, however, surgical approach is surgeon dependent.

## Conservative Surgery

Peritoneal implants of endometriosis may be ablated with bipolar electro-surgical instruments or excised by sharp dissection.<sup>520</sup> A Cochrane review including seven randomized controlled trials compared different laparoscopic surgical methods (including excisional vs. ablative techniques) with diagnostic laparoscopy and found that pain improved with operative laparoscopy compared to diagnostic laparoscopy alone—by 100%, 70%, and 40% in women with moderate, mild, and minimal endometriosis, respectively.<sup>521</sup> In comparing excision versus ablation for surgical management of endometriosis, there was no clear superiority of one method over another.<sup>521</sup> However, those favoring excision over ablation emphasize that because the depths of disease and ablation cannot be determined, the risk that treatment may be inadequate is greater when disease is ablated rather than excised. Furthermore, excisional surgery allows for a histologic diagnosis. Strict adherence to the same microsurgical principles that governed reconstructive pelvic surgery before the advent of modern laparoscopic techniques improves operative outcomes—use of magnification, minimum tissue trauma and exposed suture, and meticulous hemostasis.

The optimal surgical approach to managing deep infiltrating endometriosis (DIE) requires careful preoperative planning and discussion with the patient.<sup>521</sup> DIE, defined as endometriosis that penetrates greater than 5 mm under the peritoneal surface, includes rectovaginal lesions, as well lesions involving the bowel (3–37%), urinary tract (52%), and uterosacral ligaments (60–90%).<sup>523,524,525</sup> These infiltrating lesions are a significant cause of pelvic pain. Given that surgery in these locations requires careful surgical technique, patients with DIE should be referred to tertiary care centers not only to help minimize intraoperative complications but also to avoid incomplete surgery and need

for repeat surgery; often, a multidisciplinary surgical team is needed.<sup>522,525</sup> In experienced hands, surgical excision of the disease generally achieves excellent results. Over 3 years, postoperative recurrence rates for dysmenorrhea, deep dyspareunia, and pelvic pain range from 15% to 30% and are lowest when any involved vaginal or rectal lesion is also removed.<sup>526</sup>

Endometriomas should be excised if they cause pain and/or become enlarged and risk torsion; excision is also an option in patients with infertility. Two randomized clinical trials have shown that excision (compared to drainage or ablation) results in overall greater pain relief, lower recurrence of endometriosis-associated pain, and lower recurrence of endometrioma formation.<sup>527</sup> A 2008 systematic review concluded that laparoscopic excision of the cyst wall was associated with a lower rate of recurrence of the endometrioma (OR = 0.41, CI = 0.18–0.93); a decreased requirement for further surgery (OR = 0.21, CI = 0.05–0.79); reduced recurrence of dysmenorrhea (OR = 0.15, CI = 0.06–0.38), dyspareunia (OR = 0.08, CI = 0.01–0.51), and NMPP (OR = 0.10, CI = 0.02–0.56), and an increased pregnancy rate in women who previously were infertile (OR = 5.21, CI = 2.04–13.29).<sup>527,528</sup> Careful surgical technique is important because ovarian function can be compromised by excision of excessive tissue or damage to hilar vessels, as demonstrated by postoperative AMH levels.<sup>529,530</sup> Regardless of surgical procedure (i.e., complete excision vs. combination of excision and ablation), AMH levels can be adversely affected; however, it does not appear to impair ovarian response/fertility.<sup>527</sup> The risk of ovarian failure after excision of bilateral ovarian endometriomas is approximately 2.5%.<sup>531</sup> Lastly, even in the setting of asymptomatic greater than 4 cm endometriomas, removal may be recommended given the association of endometriomas with endometrioid and clear cell cancer of the ovary.<sup>14,522</sup>

Adjuvant presacral neurectomy (PSN) and laparoscopic uterosacral nerve ablation (LUNA) have been advocated for the management of dysmenorrhea and severe central pelvic pain unresponsive to medical or previous surgical treatment for endometriosis. PSN involves interrupting the sympathetic innervation of the uterus at the level of the superior hypogastric plexus, and LUNA involves the destruction of the midportion of the uterosacral ligaments. While PSN may be considered for women with central pelvic pain desiring conservative surgery, LUNA is no longer recommended as it has not resulted in compelling evidence of pain improvement.<sup>532</sup> Operative complications and postoperative bowel or bladder dysfunction, although uncommon, do occur and can be debilitating.<sup>533,534</sup> PSN should be reserved for highly selected individuals, who must be counseled very carefully.

**Unfortunately, as with medical treatment, recurrent disease and pain after local excision or ablation of endometriosis are common; the cumulative probability**

of recurrence is between 40% and 45% at 5-year follow-up, while the probability of requiring repeat surgery is 15–25% by 2 years and 45–55% by 5–7 years.<sup>535,536,537,538</sup> A study involving second-look laparoscopy after surgical treatment of minimal or mild endometriosis found that disease most often recurs in the same or adjacent areas of the pelvis, suggesting either incomplete excision during the initial surgery or favored implantation in certain locations.<sup>539</sup> The incidence of recurrent disease may be higher after surgical treatment in the luteal phase than in the follicular phase because refluxed endometrial cells may be more likely to implant at sites of unhealed peritoneal trauma when the interval from surgery to next menstruation is short.<sup>540</sup> In addition, despite meticulous surgical technique, surgery itself can result in pelvic adhesions, which can become a primary cause of continued pelvic pain.

## Definitive Surgery

In women with advanced, symptomatic endometriosis who have completed childbearing and those in whom medical and conservative surgical treatment fails, definitive surgical treatment deserves consideration. In highly selected women having no significant ovarian disease, hysterectomy alone can be considered, although the risk of recurrent disease requiring additional treatment is approximately sixfolds higher when oophorectomy is not performed, as the estrogen produced by the ovary(ies) stimulates endometriotic lesion growth.<sup>541</sup> In women undergoing hysterectomy and bilateral salpingo-oophorectomy (BSO), 90% of women experience long-term relief.<sup>239</sup> A risk factor for persistent or recurrent endometriosis and pain is incomplete excision of disease in women with extensive or residual disease.<sup>541,542</sup> **While no prospective study has demonstrated that estrogen therapy alone causes recurrence of disease, given that endometriosis is an estrogen-dependent disorder, endometriosis represents a condition where even after hysterectomy estrogen plus progestin therapy should be administered for menopausal hormone therapy.**<sup>542,543</sup> Lastly, in those with persistent pain following hysterectomy with BSO, consideration of possible ovarian remnant syndrome is warranted. Ovarian remnant syndrome involves persistent or recurrent disease and pain associated with residual functional ovarian tissue. The syndrome is not altogether rare and occurs most frequently when the ovaries are enlarged or densely adherent to the pelvic sidewalls and dissection is technically difficult.<sup>544,545,546</sup> Ovarian remnant syndrome is suspected when serum levels of FSH are less than 30 IU/dL and estradiol levels are greater than 20 pg/mL.<sup>547</sup> In postmenopausal women, serum measurements are less helpful, and even in premenopausal women, values may fluctuate. Thus, adjunct tests include transvaginal ultrasound and/or MRI for

visualization of a pelvic mass.<sup>547</sup> Ultimately, surgical evaluation and tissue biopsy are needed for confirmation and treatment.<sup>547</sup>

## Postoperative Medical Therapy

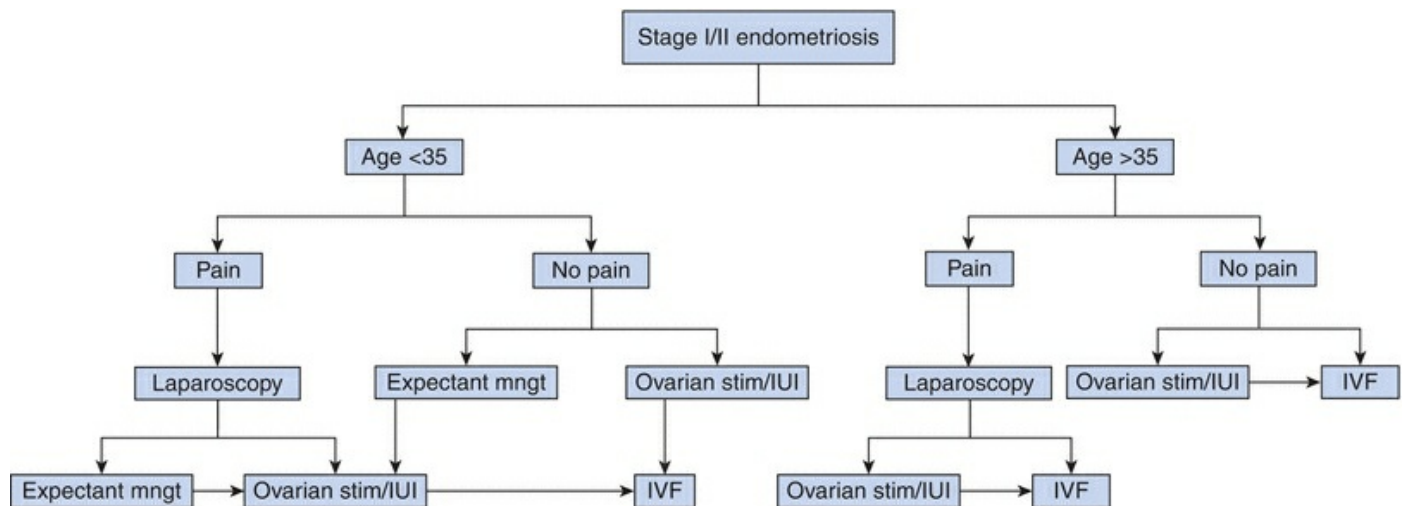

Similar to what can occur in cancer, recurrence of endometriosis can be due to regrowth of residual or microscopic endometriotic lesions. Alternatively, recurrence may be due to de novo lesion formation. Regardless of the cause, given the known risk of recurrence following conservative surgery for endometriosis, studies have addressed the potential benefit of medical treatment following surgery. Initial studies did not appear to demonstrate effectiveness of postsurgical hormonal-suppressive therapy; however, these studies discontinued medication after 3 or 6 months.<sup>548</sup> As previously noted, existing therapies simply suppress endometriosis; they are not cytoreductive. Thus, once treatment stops, lesions can resume growth. As such, recent work has focused on tertiary prevention. In a meta-analysis of 15 studies of long-term hormonal therapy following surgical management, there were lower recurrence rates of dysmenorrhea and endometrioma(s).<sup>548,549</sup> While additional studies are needed in order to determine the most effective postsurgical hormonal therapy for a given patient, this data is promising, and as such, we routinely recommended postsurgical hormonal therapy in an attempt to prevent recurrence of disease/pain. **An exception to postsurgical hormonal therapy however is in women who are attempting to conceive immediately following surgery; but in women who wish to delay conception, suppressive hormonal therapy is still encouraged.**

## Multimodal Approach

In some women, medical therapy and surgery are not sufficient for effectively eliminating endometriosis-related symptoms. For those with complex pelvic pain syndromes, a multidisciplinary approach including psychological counseling, pelvic floor physical therapy, acupuncture, transcutaneous electrical nerve stimulators, implantable nerve stimulators, and/or trigger point injections with anesthetic agents may be beneficial.<sup>548</sup> Lastly, while no large clinical trials have evaluated the use of complimentary therapies to treat endometriosis-associated pelvic pain, women with endometriosis have reported that nutritional and exercise programs help alleviate pain symptoms. Nutritional interventions such as avoiding red meat, as well as transsaturated and saturated fats, have been reported to reduce pain symptoms, as have structured exercise programs. Chinese herbal medication has also been effective in clinical trials.<sup>550</sup>

# TREATMENT OF ENDOMETRIOSIS-ASSOCIATED INFERTILITY

There are several treatment options available to women with endometriosis who are seeking fertility. While not routinely recommended, expectant management is an option for women who are hesitant to pursue ovarian stimulation with or without intrauterine insemination (IUI) or IVF. As mentioned earlier, the fecundity rate of women with endometriosis is lower than in the noninfertile reproductive population; however, women with endometriosis can conceive without intervention. As the overall likelihood of success with expectant management is less, it should only be considered in women who do not have advance-stage disease and who are less than 35 years of age (Figure 32.7).

Reprinted from **Kodaman PH**. Current strategies for endometriosis management. *Obstet Gynecol Clin North Am* 42(1):87, 2015, with permission from Elsevier.<sup>522</sup>

Medications used to treat endometriosis-associated pain are predominantly hormonal and suppress ovulation. In a Cochrane review of 25 trials using ovulation suppressive agents (COCs, progestins, danazol, GnRH agonists) in an effort to improve fertility in women with endometriosis, there was no benefit to use of ovulation suppression.<sup>550</sup> Use of ovulation suppression agents increased time to conceive. The one exception is the use of GnRH agonists or COCs for suppression of endometriosis in patients undergoing IVF. A Cochrane review of three randomized controlled trials using a GnRH agonist for 3–6 months prior to IVF found that both the clinical pregnancy and live birth rates were significantly higher in the GnRH agonist group compared to the control group.<sup>552,553</sup> In a pilot trial assessing effect of 6–8 weeks of COC use prior to IVF in women with

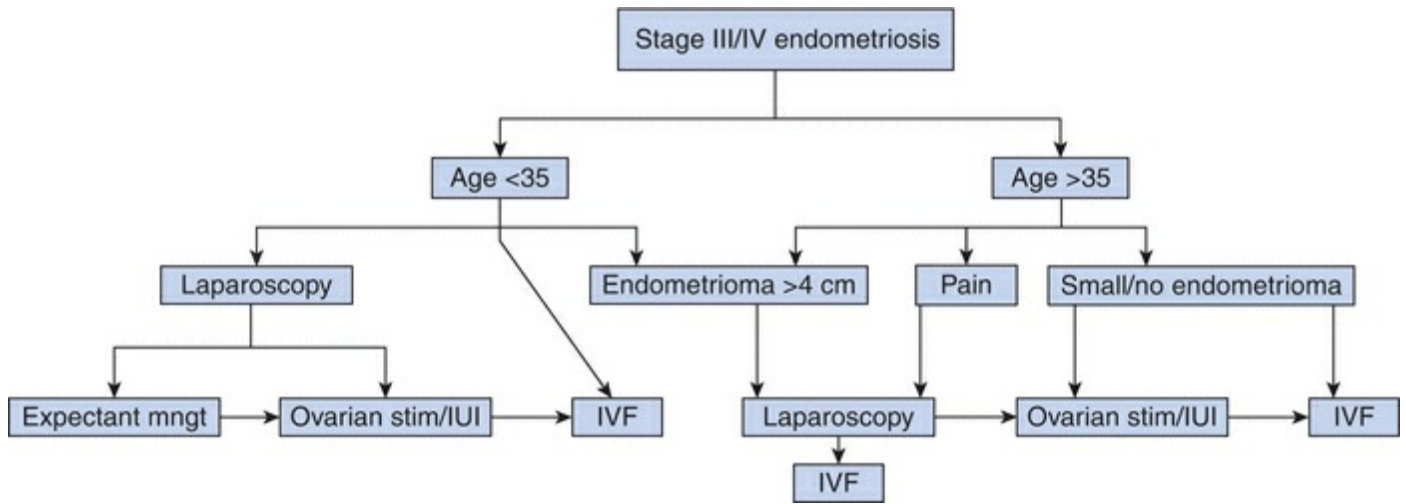

endometriosis, it was found that COC use significantly increased the odds of pregnancy.<sup>554</sup> Furthermore, COC use may be as effective as GnRH agonist, although larger randomized trials are needed to confirm this.<sup>554</sup>

# Surgical Treatment

The effects of surgery on fertility in women with minimal and mild endometriosis have been examined in two randomized controlled trials. In a multicenter Canadian trial, women with unexplained infertility had diagnostic laparoscopy, and those with minimal or mild endometriosis were randomized to treatment (excision or ablation of disease) or expectant management and followed for 36 weeks or until 20 weeks of gestation if pregnancy occurred during follow-up.<sup>260</sup> The chance of pregnancy in treated women was twice that in untreated women (OR = 2.03, CI = 1.28–3.24). Overall, 50/172 (0.29) women randomized to treatment achieved an ongoing pregnancy, compared to 29/169 (0.17) of those managed expectantly, yielding a treatment effect of 0.12 and a number needed to treat (the inverse of the treatment effect) of 8.3, rounded upward to 9. **The results suggest that approximately nine infertile women with minimal or mild endometriosis must undergo surgical treatment to achieve one additional pregnancy.** However, in a second smaller Italian trial of similar design (n = 96), no difference between treatment and no treatment was observed.<sup>555</sup> A meta-analysis combining the data from both studies concluded that surgical treatment of minimal and mild endometriosis may improve fertility (OR = 1.64, CI = 1.05–2.57); the number needed to treat was 12.<sup>261</sup> In women with mild to moderate disease, surgical treatment with removal of endometrial implants has the potential benefit of decreasing inflammation, which may improve fertility (**Figure 32.7**). For women with endometriomas, the literature is clear—the cumulative pregnancy rate 1–3 years after surgical treatment is approximately 50% for women with endometriomas, and response to gonadotropins is also improved.<sup>519,556,557,558,559</sup>

In severe disease, potential benefits of surgery include lysis of adhesions and ideally resultant restoration of normal pelvic anatomy; two randomized controlled trials demonstrated that laparoscopy was beneficial for advance-stage disease.<sup>560,561</sup> In addition, for women who are in pain and attempting to conceive, surgical intervention should be an option prior to proceeding with ovarian stimulation/IUI or IVF, as available regimens can exacerbate pain (**Figure 32.8**). In a prospective cohort study involving 169 infertile women under age 38 with symptomatic deep infiltrating endometriosis, the pregnancy rate achieved with IVF was significantly higher in women who chose to have preliminary surgical treatment.<sup>562</sup> Although the advantages of surgical treatment in infertile women with severe endometriosis seem obvious, there are few randomized controlled trials assessing the potential benefits, and more research is needed. The use of adhesion barriers reduces adhesion formation after surgical treatment in infertile women,<sup>563</sup> but there is no convincing evidence that adhesion barriers or other adhesion prevention strategies improve pregnancy rates after surgical

treatment. <sup>563,564</sup>

# Ovarian Stimulation and Assisted Reproductive Technology

In patients with minimal to mild endometriosis with patent tubes, ovarian stimulation (with clomiphene citrate, letrozole, or gonadotropins) with or without intrauterine insemination can be tried, as fertility rates are increased.<sup>14</sup> This method is preferred when the patient does not have distorted anatomy; however, no more than four cycles are recommended, as each can stimulate endometriotic lesions (**Figure 32.7**). As mentioned earlier, IVF success rates in women with endometriosis are similar to those with tubal and male factor and unexplained. It still remains unclear how much endometriosis affects pregnancy rates when compared to other causes of infertility; **however, in vitro fertilization is currently the most effective treatment of endometriosis-associated infertility, especially in women with advanced disease (Figure 32.8).**

# ENDOMETRIOSIS AS A SYSTEMIC DISORDER

---

While emphasis is placed on endometriosis as a gynecologic/pelvic disorder, it is important to recognize that endometriosis is a systemic disorder, with effects on the brain, metabolic and inflammatory processes, and sexual health.<sup>565</sup> In addition to altered pain sensitization, women with endometriosis have an increased incidence of anxiety and depression.<sup>248</sup> This is likely related to endometriosis modulating gene expression in regions of the brain controlling emotional and behavioral changes.<sup>248</sup> Similarly, and as previously mentioned, women with endometriosis have a lower BMI than women without endometriosis. This finding may be related to endometriosis' effect on hepatic gene expression.<sup>566</sup> A low BMI in a murine model of endometriosis was found to be due to altered expression of genes in the liver that regulate metabolic pathways.<sup>566</sup> Endometriosis is also considered a proinflammatory condition. As discussed earlier in the chapter, differential expression of miRNAs can influence cytokine expression of macrophages, thereby further promoting an increase in inflammation.<sup>128</sup> As miRNAs are stable, and can circulate in the bloodstream, this provides further support for the ability of endometriosis to have systemic effects distant from sites of ectopic endometrium in the pelvis. Furthermore, an increased inflammatory response can increase the risk of cardiovascular disease and cancer.<sup>567,568</sup> Lastly, while studies following therapeutic intervention assess pain symptoms, few have assessed their effect on sexual function, which depends not only on the symptom of dyspareunia but also on physical and mental comorbidities.<sup>568</sup> The effects of endometriosis are not isolated to the lesions in the pelvis. Although current medical and surgical methods will effectively treat local disease, it is imperative to identify appropriate therapies that will also target the systemic aspects of this disease, in an effort to improve the overall health and well-being of women suffering from this chronic, debilitating disease.

# Ectopic Pregnancy

Ectopic pregnancy remains an important cause of maternal morbidity and mortality. However, because modern diagnostic methods now permit early recognition of most ectopic pregnancies, contemporary treatments are more conservative than in the past. The focus of attention has shifted from emergency surgery for the control of life-threatening hemorrhage to medical treatments aimed at avoiding surgery and preserving reproductive anatomy and retaining potential for future fertility. This chapter will review the history, epidemiology, and pathogenesis of ectopic pregnancy and discuss current methods for diagnosis and treatment.

# HISTORY OF ECTOPIC PREGNANCY

---

The modern management of ectopic pregnancy is arguably one of medicine's greatest success stories. Ectopic pregnancy was first described in the 11th century and, for centuries thereafter, often was a fatal complication of pregnancy. In medieval times, ectopic implantation was viewed as the consequence of violent emotion, usually fright or surprise, experienced during coitus in the cycle of conception.<sup>1</sup> The first documented unruptured ectopic pregnancy was described in the results of an autopsy performed on a female prisoner condemned to death and executed in 1693. Ectopic pregnancy and infertility were first linked in 1752, when an extrauterine pregnancy was reported in an infertile sex worker. By the mid-19th century, autopsy observations had raised suspicion that ectopic pregnancy might be related to pelvic infection.

Early treatments were designed to kill the ectopic conceptus and included starvation, purging, bleeding, and even use of strychnine. Attempts to destroy the abnormally located gestation by passing electrical current into an ectopic gestational sac were made often with ensuing sepsis and death. Isolated reports of abdominal surgical procedures in women with ectopic pregnancies first appeared in the early 17th century, but not again until more than 100 years later. The first known surgical procedure for ectopic pregnancy was performed in France, in 1714. In the United States, John Bard of New York (1759) and William Baynham of Virginia (1791) were the first to perform abdominal surgery for ectopic pregnancy.<sup>1</sup> However, during the first 80 years of the 18th century, only 5 of 30 women who underwent abdominal surgery for ectopic pregnancy survived; those not treated had a greater chance for survival (1 in 3)!

In 1849, W.W. Harbert of Kentucky was the first to suggest early surgical intervention to stop fatal hemorrhage.<sup>2</sup> Unfortunately, the diagnosis of ruptured ectopic pregnancy came too late for most. In 1876, John Parry of Philadelphia aptly described the prognosis for women with ectopic pregnancy in his era<sup>3</sup>:

...when one is called to a case of this kind, it is his duty to look upon his unhappy patient as inevitably doomed to die, unless he can by some active measure wrest her from the grave already yawning before her.

After witnessing the death and autopsy of several women with ectopic pregnancies, Robert Lawson Tait of London discovered the source and means to control hemorrhage in women with ruptured ectopic pregnancies and performed the first deliberate laparotomy to ligate bleeding vessels in 1884.<sup>4</sup> Within little more than a year, Tait accumulated a relatively large and successful experience with the procedure.

Over subsequent years, the advent of aseptic techniques, anesthesia, antibiotics, and blood transfusions combined to save the lives of many women; however, fatalities remained common due to late diagnosis and delayed intervention. Even during the first half of the 20th century, maternal mortality from ectopic pregnancy in the United States was between 2% and 4%. Although immediate salpingectomy and blood transfusion dramatically improved outcomes in women with ectopic pregnancy, the impact of modern methods for diagnosis and treatment developed over the last 30 years has been far greater. Even in the developed world, as recently as the 1970s, almost 15% of women with ectopic pregnancies presented in hypovolemic shock; by the early 1980s, these occurrences were down to fewer than 5%, allowing health care providers to focus on strategies aimed at preserving fertility.

# EPIDEMIOLOGY OF ECTOPIC PREGNANCY

---

The incidence of ectopic pregnancy is approximately 1.5–2% of all pregnancies. The incidence increased dramatically, by about sixfold, between 1970 and 1992. At the same time, the risk of death related to ectopic pregnancy decreased by almost 90% (from 35.5 to 3.8 deaths/10,000 ectopic pregnancies).<sup>5</sup> In 1989, less than 2% of all pregnancies were ectopic, but related complications accounted for 4–10% of all pregnancy-related deaths and were **the** leading cause of maternal death during the first trimester.<sup>5,6</sup> Recognizing the increasing trend toward outpatient surgical and medical management of ectopic pregnancy,<sup>7,8,9</sup> the Centers for Disease Control and Prevention, in 1992, combined data from the National Hospital Discharge Survey and the National Hospital Ambulatory Medical Care Survey and estimated the incidence of ectopic pregnancy at 19.7/1,000 reported pregnancies.<sup>6</sup>

Efforts to determine accurately more recent trends in the incidence of ectopic pregnancy have proven very difficult, because the numbers of ectopic pregnancies managed in the outpatient setting (not captured in hospital discharge surveys) and involving multiple health care visits (confounding data from ambulatory care surveys) have increased dramatically.<sup>10</sup> Moreover, the incidence of ectopic pregnancy is expressed as the number of ectopic pregnancies per 1,000 pregnancies, but pregnancies not resulting in delivery or hospitalization are not counted; furthermore, the vast majority of failed pregnancies now are managed entirely in the outpatient setting. Nonetheless, available evidence suggests that the incidence of ectopic pregnancy is relatively stable.<sup>11,12,13</sup> Whereas the use of ovulation-inducing drugs and assisted reproductive technologies (ARTs) has increased significantly in recent years (both are known risk factors for ectopic pregnancy) and contemporary methods permit more accurate and earlier diagnosis than in the past (resulting in fewer ectopic pregnancies escaping detection in those with access to health care), advances in detection and treatment of sexually transmitted infections have, at the same time, also helped to minimize sequelae of undiagnosed and untreated infection-related damage to the fallopian tubes (a major risk factor for ectopic pregnancy).<sup>12,14,15</sup>

Racial and socioeconomic disparities in the incidence of ectopic pregnancy are recognized. Ectopic pregnancy rates are higher among minorities than in whites and are also higher in socioeconomically disadvantaged populations, in all age groups. For all races, ectopic pregnancy rate increases progressively with age and is 3–4 times higher for women aged 35–44 than for those aged 15–24.<sup>5,16,17</sup>

# Risk Factors

Although many women with ectopic pregnancies have one or more recognized risk factors (Table 33.1), almost half of all diagnosed with an ectopic pregnancy have none.<sup>18,19,20</sup> A comprehensive analysis of case-control and cohort studies, using women with intrauterine pregnancies or nonpregnant women as controls, has helped to define their relative importance.<sup>21,22,23</sup>

## TABLE 33.1

Medical History	Prior ectopic pregnancy STIs: Gonorrhea, chlamydia Genital tuberculosis History of infertility
Developmental	In utero DES exposure Salpingitis isthmica nodosa (SIN)
Environmental	Smoking Alcohol consumption ( $\geq 10$ g daily) Early initiation of oral hormonal contraceptives (age < 16)
Surgical History	Tubal ligation Tubal surgery (salpingostomy, fimbrioplasty, tubal recannulation) Postoperative adhesions from pelvic surgery
Iatrogenic	Intrauterine contraceptive device use

**Risk for ectopic pregnancy is increased as much as 10-fold for women with a previous ectopic pregnancy compared to the general population.** The overall risk for recurrence is approximately 15%, reflecting both the underlying tubal pathology that led to the first ectopic pregnancy and the damage or trauma resulting from its treatment. Data from several studies indicate that the overall risk of recurrence is approximately 10% for women with one previous ectopic pregnancy and at least 25% for women having two or more.<sup>12,24,25,26,27,28</sup> In a study comparing the recurrence risks associated with medical and surgical treatment for previous ectopic pregnancy, the risk of recurrence was approximately 8% after medical treatment with methotrexate (single-dose regimen), 10% after a salpingectomy, and 15% after a linear salpingostomy.<sup>29</sup> Approximately 60% of women who have an ectopic pregnancy will subsequently

achieve a successful intrauterine pregnancy.<sup>28,30,31</sup>

**Risk for ectopic pregnancy is increased at least threefold for women with documented tubal pathology.**<sup>21,22,32</sup> In most cases, the damage results from sexually transmitted infections, gonorrhea and chlamydia being the most common. Salpingitis damages the endosalpingeal mucosa, causing agglutination of mucosal folds and intraluminal adhesions that may entrap a migrating embryo, leading to ectopic implantation. Risk for ectopic pregnancy is increased twofold for women with circulating chlamydia antibodies, and the majority of women with ectopic pregnancies have high levels.<sup>33,34,35,36</sup> In a retrospective cohort study of women with previous documented chlamydia infection, the risk of hospitalization for ectopic pregnancy was increased more than twofold for women with two previous infections and more than fourfold for those having three or more.<sup>37</sup> Overall, women with surgically documented salpingitis have a fourfold increased risk of ectopic pregnancy; the risk is approximately 10% after one episode of pelvic infection and increases progressively with each subsequent infection.<sup>38</sup>

**Risk for ectopic pregnancy is increased at least twofold for women exposed to diethylstilbestrol (DES) in utero.**<sup>21,39,40</sup> Numerous abnormalities of tubal anatomy have been observed in DES-exposed women, including shortened and convoluted tubes, constricted fimbria, and paratubal cysts,<sup>41,42</sup> but whether such abnormalities relate directly to the increased risk for ectopic pregnancy is unknown. DES was banned from future use in 1971 after its association with vaginal clear cell adenocarcinoma was recognized,<sup>43</sup> but the youngest DES-exposed women are still in their late reproductive years and occasionally may be encountered.

**The incidence and absolute risk of ectopic pregnancy are reduced with all methods of contraception.**<sup>44,45,46</sup> For any method, the ectopic pregnancy rate (pregnancy rate multiplied by the proportion of pregnancies with ectopic implantation) is lower than for women using no contraception (2.6 ectopic pregnancies/1,000 women-years). Among the most common methods of contraception, estrogen-progestin contraceptives and vasectomy are associated with the lowest absolute incidence of ectopic pregnancy (0.005 ectopic pregnancies/1,000 women-years). Rates are still very low, but about 60 times higher for tubal sterilization (0.32/1,000 women-years) and 200 times higher for the intrauterine device (IUD; 1.02/1,000 women-years).<sup>45,46,47</sup> The risk for ectopic pregnancy in women who conceive while using barrier methods or oral contraceptives is no different than in pregnant controls.<sup>46</sup>

Most of the available data relating to the risk of ectopic pregnancy associated with the IUD derive from older studies involving IUDs no longer in use.<sup>22,48</sup> Only two IUDs

currently are marketed in the United States, a copper-bearing device and the levonorgestrel intrauterine system (LNG-IUS). Both are highly effective in preventing intrauterine and ectopic pregnancy with cumulative 5-year pregnancy rates that compare favorably with those observed in women after tubal sterilization (0.5–1%).<sup>49,50,51,52,53,54</sup> **However, if pregnancy does occur with an IUD in situ, the risk for ectopic pregnancy is as high as 53%.**<sup>55,56</sup> Logically, the IUD should be expected to protect better against intrauterine than extrauterine implantation. Consequently, a greater proportion of pregnancies that occur will be ectopic. In one study of outcomes in 64 documented pregnancies in women with a LNG-IUS, one-half were ectopic.<sup>55</sup>

The U.S. Collaborative Review of Sterilization, involving more than 10,000 women who had a tubal sterilization, found that the 10-year cumulative probability of pregnancy after sterilization was 18.5/1,000 procedures.<sup>57</sup> **Data from the same cohort and others indicate that approximately one-third of all pregnancies resulting from sterilization failure are ectopic.**<sup>58,59,60</sup> The overall 10-year cumulative risk of ectopic pregnancy after tubal sterilization is approximately 7.3/1,000 procedures, but the risk varies with the surgical method. Bipolar coagulation is associated with the highest risk (17.1/1,000 procedures) and postpartum partial salpingectomy with the lowest (1.5/1,000 procedures). For all methods other than postpartum partial salpingectomy, the probability of ectopic pregnancy is greater for women sterilized under age 30 than for older women. The 10-year cumulative probability of ectopic pregnancy for women sterilized by bipolar coagulation before age 30 (31.9/1,000 procedures) is more than 25 times the rate for postpartum partial salpingectomy at any age, which might be attributed to an increased incidence of tuboperitoneal fistula at the distal end of the proximal tubal segment. For all methods combined, only about 20% of pregnancies occurring within 3 years after tubal sterilization are ectopic, but more than 60% of those occurring after 4 or more years are ectopic pregnancies.<sup>58,59,60,61</sup>

Ectopic pregnancies have been reported following emergency oral contraception. The best available evidence indicates that emergency contraception acts primarily by preventing or delaying ovulation or by preventing fertilization, rather than by inhibiting implantation. In theory, progestational agents may inhibit tubal motility and predispose to ectopic implantation, but none of the emergency oral contraceptive regimens in use appears to increase the risk.<sup>62,63,64,65</sup>

Although the assumption is that women without a uterus cannot conceive, a recent systematic review identified 57 reported cases of tubal ectopic pregnancies in hysterectomized women.<sup>66</sup> Thus, in the setting of a typical presentation concerning for ectopic pregnancy, a pregnancy test should be obtained in all women regardless of hysterectomy status.<sup>66</sup>

**Risk for ectopic pregnancy is increased approximately twofold for infertile women.**<sup>21,67,68,69,70,71</sup> The association between infertility and previous pelvic infection and tubal pathology offers one obvious explanation. Ovulation-inducing drugs also are associated with increased risk, but whether unrecognized coexisting tubal factors or altered tubal function in stimulated cycles may be responsible is unclear.<sup>32,68,72</sup>

**The risk of ectopic pregnancy may be increased as much as twofold in women who conceive with the use of ART.**<sup>73,74</sup> Indeed, it is interesting to remember that the first pregnancy achieved with in vitro fertilization (IVF) and embryo transfer was ectopic.<sup>75</sup> Although the mechanisms responsible have not been defined, spontaneous retrograde migration of the embryo(s) transferred within the uterine cavity into the tube and inadvertent direct tubal embryo transfer are logical considerations to explain occurrence of tubal ectopic pregnancy following intrauterine embryo transfer. Women with tubal factor infertility or those with a history of a previous ectopic pregnancy are at the highest risk for such an event following IVF-embryo transfer. However, risk is increased even among women without obvious tubal damage.<sup>12</sup> It is possible that the nonphysiologic hormone milieu of IVF cycles that is characterized by elevated estradiol and progesterone hormone levels may adversely affect tubal transport function.<sup>72,76</sup> This latter impression is strengthened by recent data identifying that unlike fresh IVF-embryo transfer cycles, the incidence of ectopic pregnancy is no higher in thawed embryo transfer IVF cycles.<sup>77</sup> Higher volumes of transfer media or deep catheter insertion into the uterine cavity may predispose to accidental tubal transfer.<sup>73,78,79</sup> Technically difficult transfers have been identified as another independent risk factor.<sup>80</sup> Heterotopic pregnancies, in which one or more embryos implant both in the uterus and elsewhere, are rare in naturally conceived pregnancies (approximately 1 in 4,000–10,000 pregnancies), but far more common in infertile women who conceive after ovulation induction or IVF.<sup>74,81,82,83</sup> A meta-analysis from 2017 demonstrated that day 5 embryo transfer was associated with lower risk of ectopic pregnancy than day 3 (relative risk 0.67; 95% confidence interval, 0.54–0.85; 143,643 pregnancies in 23 studies).<sup>84</sup> Data from the U.S. ART registry suggest that the risk of ectopic pregnancy associated with ART has decreased in recent years and now is no greater than in naturally conceived pregnancies; in 2007, only 0.7% of pregnancies resulting from ART using fresh nondonor oocytes or embryos were ectopic pregnancies.<sup>85</sup>

Tubal anastomosis surgery has been offered to women with history of tubal sterilization as an alternative to IVF. With a pooled pregnancy rate of 42–69%, tubal reversal procedures are associated with increased risk of ectopic pregnancy (4–8% of all conceptions).<sup>86</sup>

**Overall, the risk for ectopic pregnancy is increased approximately twofold**

**among women who smoke.** Compared to never-smokers, the risk is increased by approximately 50% for past and light smokers (one to nine cigarettes daily) and rises progressively with heavier daily consumption.<sup>22,87</sup> Studies in animals suggest that the mechanism responsible may involve a lower efficiency of oocyte-cumulus complex capture or a decreased tubal ciliary beat frequency induced by chemical components of cigarette smoke.<sup>88,89</sup> Relationship between alcohol consumption and ectopic pregnancy has also been suggested. There is no evidence to indicate any relationship between ectopic pregnancy and exposure to other chemical or physical agents.<sup>90</sup>

**Early age at first intercourse, number of lifelong sexual partners, and early initiation of hormonal contraceptives are described to associate with a mildly increased risk of ectopic pregnancy, presumably because of the higher probability of exposure to sexually transmitted infections.**<sup>21,22,91</sup> Numerous studies have found an association between vaginal douching and ectopic pregnancy.<sup>92,93,94,95,96,97</sup> Understandably, most have attributed the observation to an associated increased risk of ascending infection, but others have suggested that women with symptoms of genital infection are simply more likely to douche<sup>98</sup>; a causal relationship between douching and ectopic pregnancy has not been established.

An increased risk of ectopic pregnancy is described in patients with female genital tuberculosis, and this relationship merits consideration in at-risk populations.<sup>99</sup> Crohn disease (but not ulcerative colitis) has also been associated with increased risk of ectopic pregnancy.<sup>100</sup>

Salpingitis isthmica nodosa (SIN), first described by an Austrian pathologist Hans Chiari in 1887, is a recognized risk factor for recurrent ectopic pregnancy.<sup>101</sup> Gross appearance of the involved specimen is classic with one or more areas of nodular thickening involving the isthmic portion of the tube. Etiology for SIN remains unclear.

# PATHOGENESIS OF ECTOPIC IMPLANTATION

The fallopian tube is by far the most common site of ectopic implantation, accounting for more than 98% of all ectopic pregnancies. Overall, 70% of ectopic pregnancies are located in the tubal ampulla, 12% in the isthmus, 11% in the fimbria, and 2% in the interstitial (cornual) segment (Figure 33.1).<sup>102,103</sup> Ectopic pregnancies in sites other than the fallopian tubes are relatively rare and can involve the ovary, cervix, and cesarean scar and abdominal sites.<sup>102,103</sup>

**FIGURE 33.1**

Anything that interferes with normal tubal transport mechanisms may predispose to ectopic pregnancy. It is possible, but unproven, that endocrine factors predisposing to premature implantation also may contribute to the pathogenesis of ectopic pregnancy.<sup>104</sup> In histopathologic studies, postinflammatory changes (chronic salpingitis and SIN) have been observed in up to 90% of fallopian tubes excised for ectopic pregnancy.<sup>105,106,107</sup> Other abnormalities have included diverticula and foci of persistent decidual transformation. Any such underlying tubal pathology remains after conservative

treatments, medical or surgical, and may predispose to recurrence. The ectopic implantation itself may further damage the tube, depending on the extent of trophoblastic invasion. The endometrium in women with ectopic pregnancies usually exhibits decidual change, but also can have secretory or even proliferative histologic characteristics.<sup>108</sup>

The histopathology of ectopic pregnancies varies with the site of implantation. In approximately half of ampullary ectopic pregnancies, trophoblastic proliferation occurs entirely within the tubal lumen and the muscularis remains intact.<sup>109</sup> In the remainder, the trophoblast penetrates the tubal wall and proliferates in the loose connective tissue between the muscularis and the serosa.<sup>109,110,111</sup> In most cases, the characteristic segmental dilation of the tubal ampulla is composed mostly of coagulated blood rather than trophoblastic tissue. In contrast, ectopic implantations in the tubal isthmus typically penetrate the tubal wall relatively early,<sup>109</sup> probably because the more muscular segment is less distensible. All ectopic pregnancies are not destined to rupture. In fact, many will resolve without intervention, presumably by spontaneous regression in situ or tubal abortion (expulsion via the fimbria).<sup>112</sup>

A number of studies have suggested that the prevalence of chromosomal abnormalities is increased in ectopic pregnancies and that intrinsic genetic abnormalities might in some way predispose to extrauterine implantation. However, more careful studies have failed to corroborate this phenomenon.<sup>113</sup> In fact, the prevalence of chromosomal aberrations among ectopic pregnancies appears almost identical to that expected (approximately 5%) when maternal and gestational age are considered.<sup>103,113,114,115</sup>

# DIAGNOSIS OF ECTOPIC PREGNANCY

---

Ectopic pregnancy is associated with a classic triad of symptoms—delayed menses, vaginal bleeding, and lower abdominal pain—observed in women with both ruptured and unruptured ectopic pregnancies. In a series of 147 patients with ectopic pregnancy, the clinical presentation included abdominal pain in 99%, amenorrhea in 74%, and vaginal bleeding in 56%.<sup>116</sup> Unfortunately, there are no physical findings unique to ectopic pregnancy; similar symptoms are observed commonly in women with failing intrauterine pregnancies.<sup>117,118</sup> Symptoms that should alert clinicians to the possibility of a ruptured ectopic pregnancy include shoulder pain (from irritation of the diaphragm by blood in the peritoneal cavity), light-headedness, and features of shock (from severe intra-abdominal hemorrhage). Thankfully, the symptoms associated with advanced or ruptured ectopic pregnancy now are seldom seen, because most women present with mild pain or vaginal spotting well before tubal rupture and are identified promptly using methods that are more sensitive and specific than in the past.

Clinical suspicion, based on an awareness of risk factors and the early symptoms of ectopic pregnancy, is the key to identifying women who merit prompt and careful evaluation. **The ready availability of highly sensitive and specific assays for the  $\beta$ -subunit of human chorionic gonadotropin (hCG) has narrowed the differential diagnosis of ectopic pregnancy to include only pregnancy-related problems, including threatened, missed, complete, and incomplete abortions.** In almost all women, one or more serum  $\beta$ -hCG determinations and transvaginal ultrasonography can establish or exclude the diagnosis of ectopic pregnancy within a short time, if not immediately. Serum progesterone measurements and uterine curettage (only when an early viable intrauterine pregnancy can be confidently excluded) also can be informative. Laparoscopy remains an important management option but rarely is any longer necessary for diagnosis alone in clinically stable patients.

Numerous diagnostic algorithms have been proposed for women suspected of having an ectopic pregnancy. All are based on the same basic concepts. Outpatient evaluation has been shown to be safe and effective for establishing a diagnosis of viable or nonviable intrauterine pregnancy or ectopic pregnancy. Accurate diagnosis is important because management of the three conditions is distinctly different.

# The Serum $\beta$ -hCG Concentration

hCG is secreted by the syncytiotrophoblast and becomes detectable in maternal serum as early as 8–10 days after ovulation in normal conception cycles. At or near the time of the first missed menses, serum levels between 50 and 100 IU/L are typical. Modern assays for the  $\beta$ -subunit of hCG are highly specific and sensitive, with detection limits below 5 IU/L. Consequently, virtually all women with suspected ectopic pregnancy who are not truly pregnant will have a negative test (no detectable hormone). False-negative tests are quite rare but, in the past, have been described in women with documented ectopic pregnancies.<sup>119,120,121</sup> False-positive tests are equally rare and most often result from endogenous heterophilic antibodies, which bind to the animal antibodies (mouse, rabbit, goat) used in commercial immunometric assay systems and thereby mimic hCG immunoreactivity.<sup>122,123,124,125</sup>

**Although rare, heterophilic antibodies are important to understand and to recognize because persistent false-positive tests may be misinterpreted as evidence of ectopic pregnancy or gestational trophoblastic disease and lead to inappropriate evaluation and treatments having potential for serious consequences.**<sup>122</sup> A false-positive serum hCG usually remains at the same level over time, neither increasing or decreasing. When the clinical presentation is uncertain or inconsistent with the test result, a true-positive hCG can be confirmed by (1) obtaining a similar result with a different assay method, (2) demonstrating hCG in the urine, and (3) obtaining parallel results with serial dilutions of the hCG standard and the patient's serum.

**Serum  $\beta$ -hCG concentrations rise predictably, at an exponential pace, during the early weeks of normal intrauterine pregnancy. In general, levels double every 1.4–2.1 days in early pregnancy and peak between 50,000 and 100,000 IU/L at 8–10 weeks of gestation.**<sup>126,127,128</sup> The rate of rise slows gradually as gestational age advances and  $\beta$ -hCG concentrations increase,<sup>128</sup> but during the brief interval when diagnosis of ectopic pregnancy is most important (from 2 to 5 weeks after ovulation), the pattern is close to linear. Evidence from studies performed before 1990 indicated that  $\beta$ -hCG levels should increase at least 66% every 2 days at concentrations below 10,000 IU/L in viable early intrauterine pregnancies, that few normal pregnancies (3–10%) ever exhibit an abnormal pattern, and that most of those do so only transiently.<sup>126,127,129,130</sup> However, in a more recent and careful analysis of data derived from evaluation of 287 women presenting with pain or bleeding and nondiagnostic ultrasonography who ultimately proved to have viable intrauterine pregnancies, the slowest or minimal rise observed was 24% after 1 day and 53% after 2 days.<sup>131</sup> The median rise in  $\beta$ -hCG levels was 50% after 1 day, 124% after 2 days, and 400% after 4

days. A recent retrospective cohort study demonstrated that hCG rise was faster when initial hCG level was lower and slower when presenting hCG was high. The study included 285 women initially diagnosed with pregnancy of unknown location who subsequently had a confirmed viable intrauterine pregnancy. For initial hCG values of less than 1,500, 1,500–3,000 and greater than 3,000 mIU/mL, the predicted 2-day minimal rise was found to be 49%, 40%, and 33%, respectively. Notably, African American women had a faster hCG rise compared to non–African American women.<sup>132</sup>

**Overall, existing data indicate that compared to the pattern observed in viable intrauterine pregnancies,  $\beta$ -hCG levels increase at a slower rate in most, but not all, ectopic and nonviable intrauterine pregnancies.<sup>126,133</sup> Thus, when encountering a suboptimal rise in serum hCG levels, high level of suspicion for an ectopic pregnancy must be maintained. Also notable is that the minimal normal increase in  $\beta$ -hCG concentrations for women with a viable intrauterine pregnancy (50% over 2 days) is “slower” than previously reported. Therefore, when following suspected ectopic pregnancy, a level of vigilance regarding possibility of a normal intrauterine gestation is needed and should be considered in decision-making to diagnose and treat abnormal pregnancies.<sup>131</sup>**

In an analysis of data derived from evaluation of 200 women presenting to an emergency department who ultimately proved to have ectopic pregnancies, the median rise in serum  $\beta$ -hCG levels was 25% over 2 days, with 60% of patients having an increase and 40% exhibiting a decrease in  $\beta$ -hCG concentrations over that interval.<sup>133</sup> Among those with rising levels, the mean increase (75% over 2 days) was smaller than the average for women with viable intrauterine pregnancies, and among those with declining concentrations, the decrease (27% over 2 days) was smaller than the average for women with completed spontaneous abortions. However, in 21% of women with ectopic pregnancies, the rise in  $\beta$ -hCG levels was greater than or equal to the minimal rise defined for women with viable intrauterine pregnancies, and in 8% of women with declining levels, the decrease was similar to that in women with completed spontaneous abortions.<sup>133</sup> When levels do not rise normally, or fall, the pregnancy is almost certainly not viable, but may be ectopic or intrauterine. Serum hCG concentrations generally fall more rapidly in spontaneous abortions than in ectopic pregnancies, but the rate of decrease varies with the initial  $\beta$ -hCG concentration and is slower when levels are lower<sup>134</sup>; overall, a decrease of less than 21% after 2 days or 60% after 7 days suggests retained products of conception or an ectopic pregnancy. **Normally rising (>50% over 2 days) or rapidly falling (>20% over 2 days)  $\beta$ -hCG concentrations generally are reassuring, but do not exclude the possibility of ectopic pregnancy.**<sup>133,135,136</sup>

In a woman with a pregnancy of unknown location whose hCG level is more than 2,000 mIU/mL, the most likely diagnosis is a nonviable intrauterine pregnancy,

occurring approximately twice as often as ectopic pregnancy. Ectopic pregnancy, in turn, occurs approximately 19 times as often as a viable intrauterine pregnancy when the hCG level is 2,000–3,000 mIU/mL in the absence of evidence of an intrauterine gestation on transvaginal ultrasound and 70 times as often as a viable intrauterine pregnancy when the hCG level is more than 3,000 mIU/mL in the absence of sonographic evidence of an intrauterine gestation.<sup>137</sup>

**When the risk of multiple gestation is relatively high, as in pregnancies resulting from ovarian stimulation or IVF, serial serum  $\beta$ -hCG determinations are more difficult to interpret confidently because the usual standards established for naturally conceived singleton pregnancies may not apply.**<sup>138</sup> In most multiple pregnancies,  $\beta$ -hCG levels are higher than in singleton gestations of the same age, reflecting the combined contributions of all gestations; the rate of hCG rise, however, should remain within the described norms.<sup>139</sup> However, spontaneous pregnancy reductions are common in multiple gestations,<sup>140</sup> and heterotopic pregnancies are not altogether rare in women conceiving following ART.<sup>74,82</sup> One or more normally progressing intrauterine gestations may produce normal or increased levels of hCG, but a coexisting failing intrauterine or ectopic gestation likely will not. The  $\beta$ -hCG level at any one point in time will reflect the sum contributions from all gestations, normal and abnormal, intrauterine and ectopic. The normal hCG production from a viable intrauterine pregnancy easily can obscure the abnormally small contribution from another abnormal gestation. Alternatively, falling levels of hCG production from an ill-fated intrauterine or ectopic gestation may yield a slower than expected increase in serum concentrations even though a coexisting viable intrauterine gestation is progressing normally.

It also is important to note that interassay variation in  $\beta$ -hCG measurements ranges between 10% and 15% in most laboratories. Consequently, for most confident interpretation, serial concentrations should be performed in the same laboratory whenever possible. Alert to all possible scenarios, serum  $\beta$ -hCG concentrations must be interpreted cautiously. **In sum, paired serum hCG concentrations alone cannot reliably distinguish ectopic pregnancies from abnormal or even normal intrauterine pregnancies. Consequently, the diagnostic evaluation of women with suspected ectopic pregnancy also must include transvaginal ultrasonography.**

# Transvaginal Ultrasonography

Numerous studies have helped to define the ultrasonographic characteristics of normal and abnormal early pregnancies.<sup>141,142,143,144,145,146,147,148,149,150</sup> An intrauterine gestational sac is the first ultrasonographic landmark in an early intrauterine pregnancy. The sac consists of a sonolucent center with a thick echogenic ring, formed by the surrounding decidual reaction. Modern high-frequency transducers (>5 MHz) can detect a gestational sac earlier than older, lower-frequency probes.<sup>151,152</sup> **Today, in pregnancies at gestation of 5.5 weeks or greater, transvaginal ultrasonography should identify a viable intrauterine pregnancy with almost 100% accuracy.**<sup>153,154,155</sup> The absence of an intrauterine gestational sac 38 days or more after onset of menses or 24 days after conception is strong presumptive evidence for a nonviable pregnancy (ectopic or intrauterine).<sup>156</sup> The criterion is useful when the menstrual history is well documented or conception occurs under close observation, but has little practical value when broadly applied, because irregular bleeding so often confounds attempts to define gestational age.<sup>157</sup>

When ultrasonography reveals no obvious intrauterine pregnancy, careful examination of the adnexal regions and cul-de-sac can provide additional useful information. **Observation of a gestational sac with a yolk sac, embryo, or cardiac activity outside of the uterus establishes the diagnosis of ectopic pregnancy and justifies immediate treatment.** Evidence of an extrauterine gestation can be identified in up to 80–90% of ectopic pregnancies.<sup>150,154,158,159,160</sup> A complex adnexal mass (not a simple cyst) or fluid in the cul-de-sac increases the probability of ectopic pregnancy but does not, by itself, make the diagnosis or justify immediate treatment.<sup>161,162</sup> Any other result is simply inconclusive. Some have suggested that measurements of endometrial thickness have predictive value because the endometrium is thinner in women with ectopic pregnancy than in those with viable or nonviable intrauterine pregnancies.<sup>163</sup> However, others have observed wide variations in endometrial thickness among women with suspected ectopic pregnancy or differences are too small to have clinical utility.<sup>157,164</sup> In a study involving 576 women presenting to an emergency department with complaints of pain and/or bleeding, the mean endometrial thickness was  $9.56 \pm 4.87$  mm for women with ectopic pregnancies,  $12.12 \pm 6.0$  mm for those with intrauterine pregnancies, and  $10.19 \pm 6.10$  mm for women with spontaneous abortions.<sup>165</sup> Although the extent of overlap among groups makes endometrial thickness a poor diagnostic test, a thickness greater than 21 mm with no evidence of an intrauterine gestational sac excludes ectopic pregnancy with 96% specificity.<sup>165</sup>

In many cases, transvaginal ultrasonography alone can establish the diagnosis in women with suspected ectopic pregnancies by revealing either an intrauterine or an

extrauterine gestational sac. In the emergency room or other acute setting, ultrasonography is diagnostic in 70–90% of women with suspected ectopic pregnancy.<sup>15,148,149,153,155,166,167</sup> While transvaginal sonography is an excellent method for diagnosis of ectopic pregnancy, tubal rupture, a well-known life-threatening complication of tubal pregnancy, cannot be reliably predicted with ultrasound. In a retrospective cohort study, the researchers reviewed 231 sonograms of women with sonographic diagnosis of ectopic pregnancies. Surgery was performed in 143 cases, and tubal rupture was diagnosed in 36 patients. They concluded that neither sonographic findings nor hCG levels correlated with tubal rupture.<sup>168</sup>

The diagnosis of ectopic pregnancy can be challenging. **When neither an intrauterine nor an extrauterine gestational sac is observed, defining a “pregnancy of unknown location,” the possibilities include an early intrauterine pregnancy in which the gestational sac has not yet developed or is collapsed, an intrauterine pregnancy that has completely aborted, or an ectopic pregnancy that is too small to be detected or one that has aborted.** In some cases, uterine anomalies, fibroids, or a hydrosalpinx can obscure an intrauterine or extrauterine pregnancy; obesity also can prevent confident sonographic interpretation. **Overall, at least 25% of women with an ectopic pregnancy present first with a pregnancy of unknown location,<sup>15,149,167</sup> and in 7–20% of women with that initial diagnosis, the location of pregnancy is eventually proven to be ectopic.<sup>149</sup>**

When available, color and pulsed Doppler ultrasonography can improve diagnostic accuracy. A small intrauterine gestational sac sometimes can be difficult to distinguish from the “pseudosac” (blood in the uterine cavity) observed in approximately 10% of women with ectopic pregnancy.<sup>169</sup> The local vascular changes associated with a true gestational sac can help to differentiate the two.<sup>170,171</sup> Vascular pulses and arterial flow velocity increase in early intrauterine pregnancy. The extent of peritrophoblastic arterial flow correlates with gestational sac size and serum  $\beta$ -hCG concentrations. Blood flow in the arteries of the fallopian tube containing an ectopic pregnancy is 20–40% greater than that in the contralateral tube.<sup>171,172</sup> Similarly, adnexal masses may be distinguished by the characteristics of blood flow surrounding them. For example, the resistive index of ectopic pregnancies also is higher than for corpus luteum cysts.<sup>173</sup> However, the method has numerous diagnostic pitfalls and requires substantial technical expertise, and use of standard transvaginal ultrasonography and serum  $\beta$ -hCG concentrations usually is sufficient.<sup>174</sup>

When ultrasonography is inconclusive, serum  $\beta$ -hCG concentrations can serve as a surrogate marker for gestational age and help determine whether an intrauterine gestational sac should or should not be present. The concept of a “discriminatory zone,”

the minimum serum  $\beta$ -hCG concentration above which a gestational sac always should be detected in a viable intrauterine pregnancy, revolutionized the diagnostic approach to suspected ectopic pregnancy. When the concept was first introduced in 1981, transabdominal ultrasonography was the standard and the discriminatory zone for  $\beta$ -hCG was at 6,000–6,500 IU/L.<sup>175</sup> **With the development of endovaginal transducers of higher frequency, the discriminatory zone decreased progressively and now generally ranges between 1,500 and 3,000 IU/L but may be as high as 3,500 IU/L in some institutions.**<sup>28,162,176,177,178</sup> In one study, 185 of 188 intrauterine pregnancies (98%) among women with a  $\beta$ -hCG concentration greater than 1,500 IU/L were imaged.<sup>15</sup> **In any given center, the discriminatory zone or value will depend on the experience of the examiner and on the type of equipment in use.**<sup>162,176,177</sup> **Using a higher, more conservative threshold value (e.g., 2,500 or even 3,500 IU/L) helps to minimize the risk of diagnostic error but also may delay diagnosis of an ectopic pregnancy.** A threshold value of 2,000 IU/L is suggested in the algorithm appearing in this chapter. Identification of an intrauterine gestational sac excludes the diagnosis of ectopic pregnancy, except in circumstances wherein a heterotopic pregnancy or a pregnancy in a rudimentary uterine horn must be considered.

When the  $\beta$ -hCG concentration is clearly above the discriminatory value in the absence of ultrasound evidence of an intrauterine gestation, attention should focus on establishing the location of the pregnancy that is now deemed as nonviable.<sup>28,148,179</sup> **The absence of an intrauterine gestational sac is a strong, but not conclusive, evidence for an ectopic pregnancy.**<sup>15</sup> Other possibilities must be considered before treatment begins. In incomplete abortions, an intrauterine gestational sac may be absent or difficult to recognize. In very recent complete abortions, serum  $\beta$ -hCG levels may be declining rapidly, but still elevated above the threshold. Even a viable intrauterine pregnancy cannot be excluded entirely when there is good reason to suspect a multiple gestation. **Consequently, even when the  $\beta$ -hCG concentration is above the discriminatory value, a repeated  $\beta$ -hCG measurement in 1–2 days merits consideration in women at low risk for ectopic pregnancy with few or no symptoms, to identify those who might otherwise receive unnecessary treatment, or worse, harmful treatment.** A rapidly falling  $\beta$ -hCG level indicates a resolving nonviable pregnancy and can be followed until undetectable. A normally rising  $\beta$ -hCG concentration indicates the need for repeated ultrasonography to exclude the possibility of a viable intrauterine pregnancy not detected previously and that otherwise might result in inadvertent termination of a desired pregnancy or in severe embryopathy due to exposure to methotrexate (intrauterine growth restriction, microcephaly, and facial, cranial, and skeletal abnormalities).<sup>180,181,182,183,184,185</sup>

In patients with initial  $\beta$ -hCG values below the discriminatory zone, the absence of

an intrauterine gestational sac is inconclusive; clinical signs (hemodynamic instability), symptoms (pain), and other sonographic findings (extrauterine gestational sac, complex adnexal mass, cul-de-sac fluid) must guide clinical management.<sup>186</sup> In some women, clinical circumstances will demand an immediate and definitive surgical diagnosis. Women with no or few symptoms require close follow-up and serial evaluations until the possibility of ectopic pregnancy can be excluded.<sup>153,162,187,188</sup> Repeated measurements of serum  $\beta$ -hCG at 2-day intervals help to distinguish nonviable pregnancies from early viable intrauterine gestations not yet large enough to be detected at initial ultrasound evaluation.

**In women with normally increasing  $\beta$ -hCG levels below the discriminatory value, ultrasonography should be performed or repeated when levels have risen above the discriminatory value.** After 2–7 days, ultrasonography can be expected to demonstrate the location of the pregnancy in the large majority of cases.<sup>149</sup> Occasionally, a new adnexal abnormality (complex mass) or increasing clinical symptoms may demand a definitive surgical diagnosis.<sup>162,187,188</sup> **Women with rapidly decreasing  $\beta$ -hCG concentrations and absence of symptoms warrant only continued observation because the likelihood of an underlying ectopic pregnancy progressing to rupture is low.**<sup>189</sup> Nonetheless, serial measurements should be obtained until levels are no longer detectable, which can take up to as much as 6 weeks.<sup>12</sup> Those in whom an intrauterine pregnancy has not been documented remain at risk for rupture of an ectopic pregnancy until  $\beta$ -hCG is no longer detectable.<sup>153</sup> **Slowly declining or abnormally rising  $\beta$ -hCG levels indicate a nonviable pregnancy that still may be ectopic or intrauterine, but virtually exclude the possibility of a viable intrauterine pregnancy. The same is true when  $\beta$ -hCG levels rise to a concentration clearly above the discriminatory value and ultrasonography is again inconclusive (no intrauterine or extrauterine gestational sac). In either case, medical treatment could be offered safely, but a presumed diagnosis of ectopic pregnancy will be inaccurate, and treatment unnecessary, in up to 40% of women.**<sup>190</sup> Therefore, many prefer to perform uterine curettage to distinguish the remaining two possibilities (discussed below).

**A conservative approach to pregnancies of unknown location prevents inappropriate intervention in the setting of a viable intrauterine pregnancy.** Although it risks a modest delay in diagnosis of ectopic pregnancy and a small possibility of rupture, evidence from several studies indicates that a conservative diagnostic approach rarely compromises the care of women with pregnancies of unknown location.<sup>155,167,187,191,192,193,194,195</sup> Consequently, every reasonable effort should be made to establish a definite diagnosis.

# Serum Progesterone Concentration

Serum progesterone concentrations generally are lower in ectopic pregnancies than in viable intrauterine pregnancies.<sup>196,197,198,199</sup> The most logical explanation is that ectopic pregnancies are almost always accompanied by abnormally low levels of  $\beta$ -hCG production. Whereas the  $\beta$ -hCG secreted by ectopic gestations is chemically and biologically indistinct from that in intrauterine pregnancies,<sup>200,201</sup> production rates are lower, primarily because ectopic trophoblast proliferates more slowly and is less biologically active.<sup>202,203</sup> Corpus luteum progesterone production in early pregnancy is regulated primarily by the rate of change in serum hCG concentrations.<sup>201</sup> Under normal circumstances, the exponential increase in hCG levels ensures that LH/hCG receptors are occupied to the extent corresponding with maximal stimulation as the corpus luteum matures and the number of available receptors increases. In contrast, few ectopic pregnancies exhibit normal hCG production rates for very long. Consequently, progesterone secretion may increase normally at first but inevitably slows, resulting in lower serum concentrations.<sup>204,205</sup> There is no evidence to support the alternative hypothesis that poor luteal function in ectopic pregnancy results from reduced or absent production of other trophic fetoplacental factors distinct from hCG.<sup>201</sup>

**Serum progesterone levels associated with early normal and abnormal intrauterine pregnancies and ectopic pregnancies vary widely and overlap to a large extent.** Consequently, whereas a grossly low serum progesterone concentration is unlikely to be associated with a viable intrauterine pregnancy, it cannot distinguish an ectopic pregnancy from a failed intrauterine gestation.<sup>9,14,206,207,208,209,210</sup> **The probability of a viable intrauterine pregnancy increases with higher serum progesterone concentration.** Levels greater than 20 ng/mL almost always indicate a normal intrauterine pregnancy. Conversely, concentrations less than 5 ng/mL almost always indicate a nonviable pregnancy, which may be either ectopic or intrauterine.<sup>9,14</sup> Unfortunately, 50% of ectopic pregnancies, nearly 20% of spontaneous abortions, and almost 70% of viable intrauterine pregnancies are associated with serum progesterone levels **between** 5 and 20 ng/mL.<sup>211,212</sup> Moreover, because exceptions to the norm can and do occur, neither threshold value is entirely reliable in an individual woman. Only about 0.3% of women with viable intrauterine pregnancies have a serum progesterone level under 5 ng/mL, but approximately 3% of those with ectopic pregnancies have progesterone concentrations above 20 ng/mL.<sup>207,212</sup> The utility of serum progesterone measurements in the evaluation of women with suspected ectopic pregnancy is further limited when conception results from treatments involving ovarian stimulation strategies. Higher than usual progesterone levels logically may be expected because treatment often yields more than a single corpus luteum.<sup>213</sup>

Some have suggested that progesterone levels less than 5 ng/mL identify women in whom uterine curettage can be performed safely in search of chorionic villi to distinguish ectopic pregnancies from spontaneous abortions.<sup>9,214</sup> Using that approach, the probability of inappropriate intervention in a viable intrauterine pregnancy is indeed very low, but even that small risk may be unacceptably high. **In sum, serum progesterone measurements generally add very little to the diagnostic evaluation of women suspected of having an ectopic pregnancy.**

# Uterine Curettage

When ultrasonography is inconclusive and  $\beta$ -hCG concentrations are above the discriminatory zone, or below the threshold value, and rise abnormally, plateau, or fall, the possibility of a viable intrauterine pregnancy is all but excluded; an early multiple pregnancy and an error in performing or interpreting ultrasonography are the only exceptions. **Uterine curettage or office vacuum aspiration can help to distinguish ectopic from nonviable intrauterine pregnancies, but still should be applied selectively.** Uterine sampling clearly is inappropriate when there is any possibility of interrupting a viable intrauterine pregnancy and is unnecessary in women with rapidly falling  $\beta$ -hCG levels. **Recovery of chorionic villi from curetted or aspirated tissue excludes ectopic but not heterotopic pregnancy.** The absence of villi makes the diagnosis of ectopic pregnancy likely, although a very recent complete abortion or a technical failure to obtain or to recognize villi is possible; chorionic villi are not detected by histopathology in 20% of elective terminations of pregnancy.<sup>215</sup> **If uterine sampling is not performed and ectopic pregnancy is presumed, misdiagnosis leading to unnecessary treatment will occur in approximately 40% of women.**<sup>190</sup> **Therefore, uterine curettage or vacuum aspiration is recommended for women with nonviable pregnancies of unknown location, to distinguish an ectopic pregnancy that requires additional treatment from a nonviable intrauterine pregnancy that does not.**

If chorionic villi are present in the curetted or aspirated tissue, gross inspection of the sample in saline will reveal obvious villi about half of the time. If chorionic villi are found, the failed intrauterine pregnancy is confirmed and no further evaluation is necessary. Frozen section and histologic examination will demonstrate villi in 80–90% of specimens obtained from women with spontaneous abortion, and is recommended when available, to help avoid delays in establishing a definite diagnosis. Otherwise, a postprocedure serum  $\beta$ -hCG may be obtained. A 20% or greater decrease in the  $\beta$ -hCG level within 12–24 hours suggests strongly that the patient had a nonviable intrauterine gestation that was removed.<sup>215,216</sup> Conversely, a slower rate of decrease, or an increase, strongly suggests an ectopic pregnancy.<sup>12</sup> Women with declining levels can be monitored with serial  $\beta$ -hCG concentrations until no longer detectable or until the pathology report confirms the presence of chorionic villi. In a series of 111 women with nonviable pregnancies of unknown location that had curettage, villi were detected in 37% overall and in 51% of those whose initial  $\beta$ -hCG level was greater than 1,500 IU/L.<sup>190</sup>

Uterine curettage is costly, requires an operating room and anesthesia in some institutions, and is associated with a small risk of a complication. By comparison, uterine aspiration using a pipelle is simple to perform in the outpatient setting and

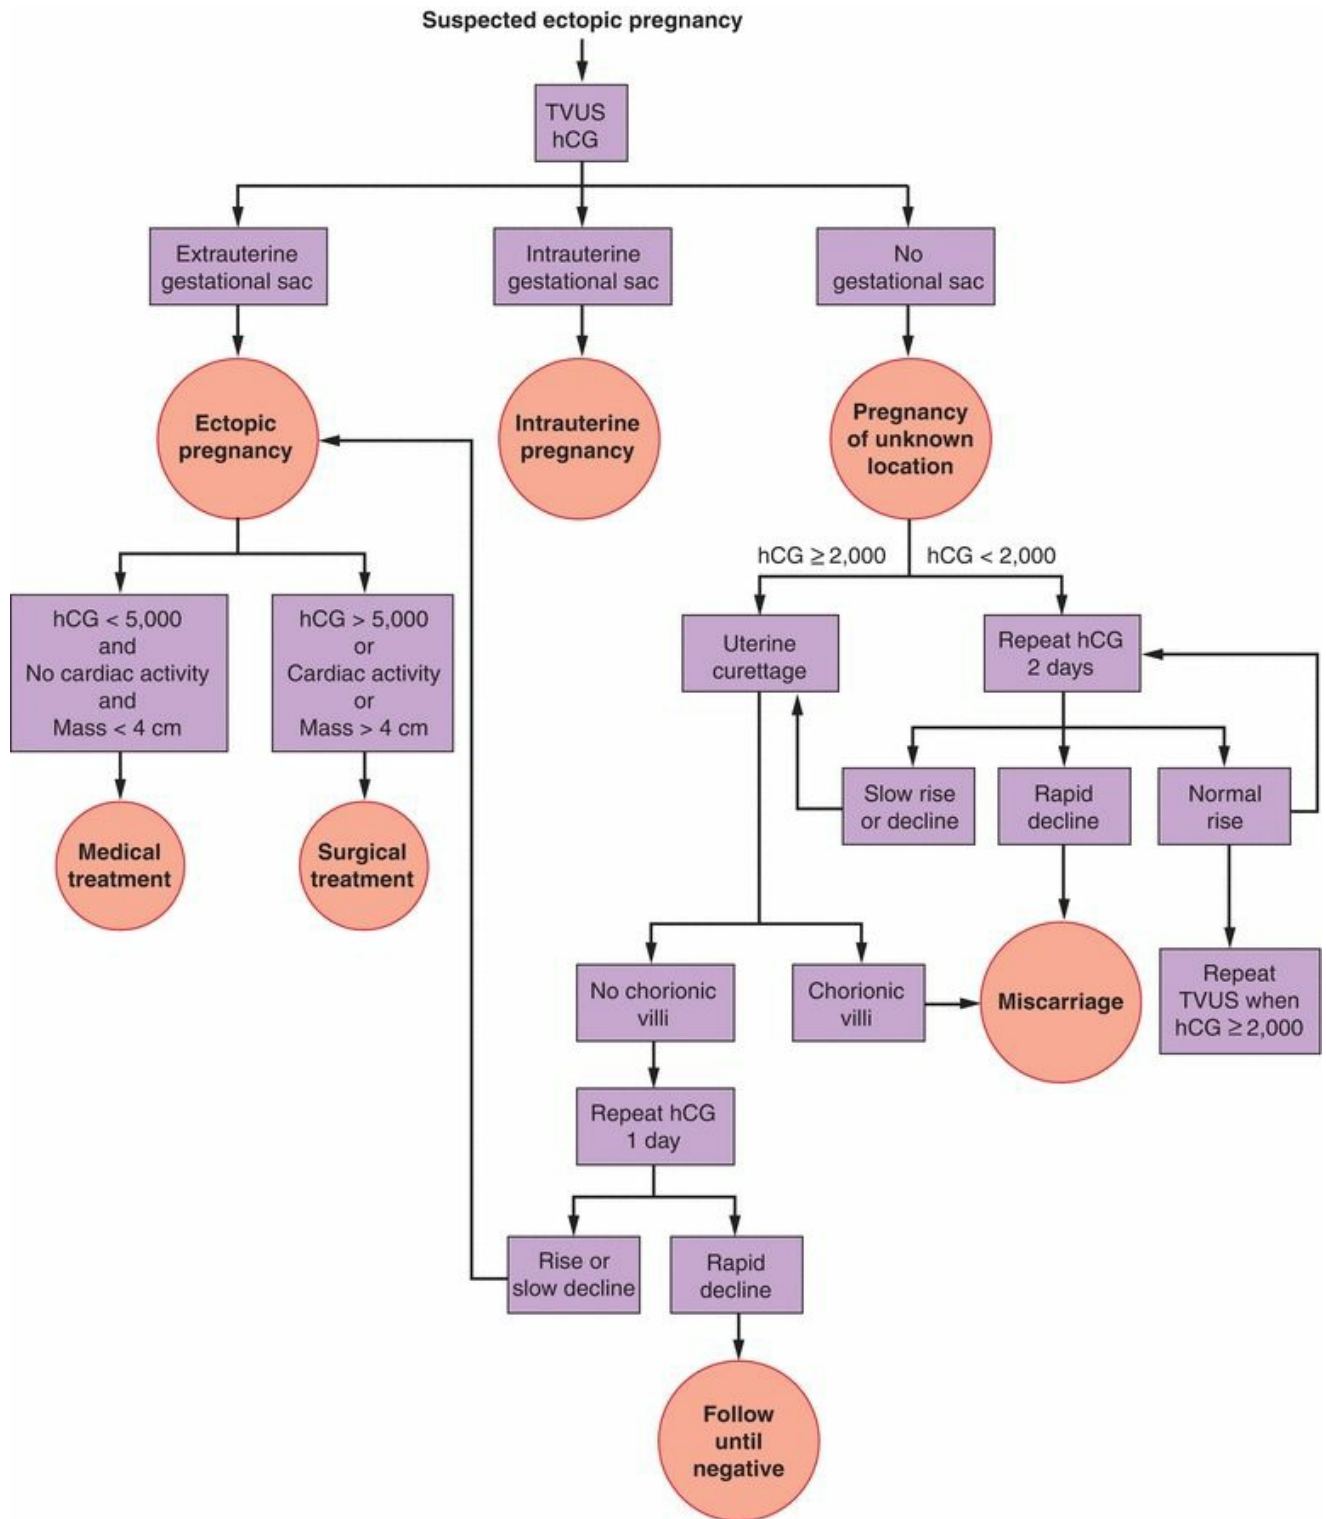

minimally invasive. The results obtained with pipelle aspiration and curettage generally correlate extremely well when they are performed for suspected endometrial pathology (hyperplasia or carcinoma). **Unfortunately, pipelle biopsy is not an effective substitute for curettage in the evaluation of women with suspected ectopic pregnancy. The sensitivity of pipelle biopsy for detecting chorionic villi is unacceptably poor, ranging between 30% and 60%.**<sup>217,218</sup> If treatment is based on results obtained with a pipelle biopsy, up to one in three women with a miscarriage may receive unnecessary and inappropriate medical or surgical treatment. The higher sensitivity of curettage (80–90%) yields a misdiagnosis of ectopic pregnancy in no more than approximately 2 in 10 women with a spontaneous abortion.<sup>218,219,220</sup> Manual vacuum aspiration has emerged as a safe and effective method for surgical abortion in early pregnancy (up to 12–14 weeks),<sup>221,222</sup> and it is now recommended as a preferred method for uterine sampling to diagnose the presence of chorionic villi in cases when abnormal intrauterine pregnancy cannot be distinguished from ectopic pregnancy by sonographic features.<sup>223,224</sup> Although rare, it is useful to remember that chorionic villi sometimes may be found in curettings from women with an ectopic pregnancy.<sup>225</sup>

Some advocate empiric medical treatment for all women with nonviable pregnancies of unknown location, viewing treatment as more practical and less invasive than curettage.<sup>193,226</sup> **A decision analysis found neither approach superior, but also observed that empiric treatment yields little savings, does not reduce complications, and clouds the prognosis for future fertility and the risk of repeat ectopic pregnancy.**<sup>227</sup> We favor uterine aspiration over empiric medical treatment, preferring to avoid unnecessary treatment and the uncertainties that result from a presumptive diagnosis of ectopic pregnancy.

# SCREENING FOR ECTOPIC PREGNANCY

---

Transvaginal ultrasonography and serum  $\beta$ -hCG determinations have proven diagnostic value in the evaluation of symptomatic women with suspected ectopic pregnancy (**Figure 33.2**). Not surprisingly, some have advocated applying the same diagnostic tools to screen asymptomatic women at increased risk for ectopic pregnancy. In practice, women at risk might be instructed to contact their clinician as soon as pregnancy is suspected and, if confirmed, receive careful monitoring with serial  $\beta$ -hCG determinations and timely ultrasonography. The alternative is to evaluate only those in whom clinical symptoms of pain or vaginal bleeding emerge. The rationale for screening at-risk women is that early diagnosis of ectopic pregnancy allows early intervention and noninvasive treatment that may help to minimize tubal damage and to reduce costs.<sup>228,229</sup> However, widespread screening of symptom-free women is costly and increases the likelihood of false-positive diagnoses of ectopic pregnancy that may result in unnecessary or inappropriate medical or surgical treatment.<sup>229,230</sup>

**FIGURE 33.2**

From both a clinical and economic perspective, the cost-effectiveness of screening depends on the prevalence or risk of ectopic pregnancy in the population chosen for screening. If the risk is low, very few ruptured ectopic pregnancies will be prevented, and the costs of screening far exceed the benefits and savings resulting from early

diagnosis and medical instead of surgical treatment. If uterine curettage is performed for all nonviable pregnancies identified through screening, the costs are even greater because the large majority will be spontaneous abortions that otherwise might be managed expectantly.<sup>230,231,232,233</sup> If the risk is high, the benefits and savings realized through prevention of ruptured ectopic pregnancies are proportionately greater and better justify the costs associated with screening.

**Results of a decision analysis suggest that screening probably is justified when the risk of ectopic pregnancy is approximately 8% or higher.** At that risk level, screening may be expected to prevent one to two ruptured ectopic pregnancies and to yield less than one false-positive diagnosis for every 100 women screened.<sup>230</sup> **Accepting a 2% background rate of ectopic pregnancy and considering the increased incidence associated with certain risk factors, screening seems justified for women with previous tubal surgery or prior ectopic pregnancy and those with known tubal pathology or who conceive with an IUD in situ or after a sterilization procedure or in those with a history of pelvic inflammatory disease.**

# EXPECTANT MANAGEMENT OF ECTOPIC PREGNANCY

---

If untreated, an ectopic pregnancy may end in tubal abortion, regress spontaneously, or progress to result in tubal rupture. Unfortunately, the outcome cannot be predicted reliably. Because the risk of tubal rupture and potential associated morbidity and mortality are significant, almost all women with a diagnosis of ectopic pregnancy receive medical or surgical treatment. However, in selected women, expectant management of a presumed ectopic pregnancy is an option with a reasonably high probability for success.<sup>234,235</sup>

Expectant management in the setting of a presumed ectopic pregnancy includes careful surveillance of clinical symptoms, serial monitoring, repeat assessments of serum  $\beta$ -hCG concentrations, and transvaginal ultrasonography. In essence, expectant management is identical to the diagnostic approach recommended for women with suspected ectopic pregnancy in whom ultrasonography is inconclusive and  $\beta$ -hCG levels are below the discriminatory zone.

**In the absence of any significant change in clinical status, women with known or presumed ectopic pregnancies can be observed as long as  $\beta$ -hCG levels are steadily decreasing.** Overall, approximately 25% of ectopic pregnancies are associated with declining  $\beta$ -hCG concentrations, and almost 70% of these (about 18% of all ectopic pregnancies) will resolve spontaneously without medical or surgical treatment.<sup>195,235,236</sup> The likelihood of success with expectant management is high when there is no demonstrable extrauterine gestational sac and  $\beta$ -hCG levels are relatively low.<sup>235,236</sup> When the baseline  $\beta$ -hCG concentration is less than 1,000 IU/L and falling, almost 90% of ectopic pregnancies regress without treatment.<sup>237</sup> Expectant management succeeds in 60% of women with decreasing  $\beta$ -hCG concentrations under 2,000 IU/L, but fails in over 90% with higher baseline  $\beta$ -hCG levels.<sup>236</sup>

A randomized clinical trial involving expectant management of women with known or suspected ectopic pregnancy involved 60 women who received either oral methotrexate (2.5 mg daily for 5 days) or placebo.<sup>238</sup> The mean  $\beta$ -hCG concentrations in the two groups were comparable. In both groups, 77% of patients were managed successfully without surgery, over an interval of less than 4 weeks. Given the absence of evidence that oral methotrexate treatment is effective, it is perhaps not surprising that outcomes in the two groups were similar. Another placebo-controlled randomized trial enrolled 80 women with conclusive diagnosis of tubal pregnancy and  $\beta$ -hCG level less than 1,500 IU/L; 42 received methotrexate and 38 women were assigned to placebo group. The success rates were 83% and 76% in methotrexate and placebo groups,

respectively. There was no statistically significant difference between the groups suggesting that in clinically stable women with confirmed ectopic pregnancy and with  $\beta$ -hCG levels less than 1,500 IU/mL expectant management is a safe and effective method.<sup>239</sup>

**Considering the potentially serious risks of tubal rupture and hemorrhage and the established safety and effectiveness of both medical and surgical treatments of ectopic pregnancy, it seems prudent that expectant management should be reserved only for asymptomatic patients with very low and falling  $\beta$ -hCG levels.** The acceptable upper limit of  $\beta$ -hCG has not been established, but a threshold value of 200 IU/L has been suggested.<sup>19</sup> It is important to remember that tubal rupture has been reported even in women with low and declining  $\beta$ -hCG concentrations.<sup>240</sup> If expectant management is elected, close follow-up is essential and  $\beta$ -hCG levels should be followed until undetectable. Any plateau or rise in the  $\beta$ -hCG concentration should prompt medical or surgical treatment.

Limited evidence indicates that long-term outcomes (subsequent intrauterine and ectopic pregnancies) after successful expectant management are comparable to those achieved with medical and surgical treatment.<sup>241</sup>

# MEDICAL TREATMENT OF ECTOPIC PREGNANCY

---

Methotrexate, potassium chloride, hyperosmolar glucose, actinomycin D, and prostaglandins all have been used successfully as medical treatments for ectopic pregnancy.<sup>242,243,244,245,246,247</sup> Direct local injections into the ectopic gestational sac under ultrasonographic or laparoscopic guidance have been described but generally are reserved for the treatment of ectopic pregnancies in unusual sites (abdominal, cervical, interstitial) or conditions (heterotopic pregnancy), as discussed below. Systemic methotrexate therapy is simpler and less invasive. **Methotrexate has been studied extensively and now is established as a safe and effective alternative to surgical treatment for ectopic pregnancy.**<sup>7,12,248</sup> Medical management avoids the inherent morbidity of anesthesia and surgery and reduces costs.<sup>249</sup> Success rates and future reproductive performance also are comparable to those observed with surgical management.<sup>9,249,250</sup>

**Methotrexate is a folic acid antagonist that inactivates the enzyme dihydrofolate reductase, thereby depleting available stores of tetrahydrofolate, an essential cofactor in DNA and RNA synthesis during cell multiplication. Rapidly proliferating tissues like trophoblasts are particularly vulnerable to its actions.** Considering that methotrexate has long been used successfully for the treatment of gestational trophoblastic disease, the drug was a logical choice for the treatment of ectopic pregnancy. Even in women with undesired viable early intrauterine pregnancies, methotrexate treatment decreases the rate of increase in serum  $\beta$ -hCG levels; as a direct result, progesterone and 17-hydroxyprogesterone concentrations also fall.<sup>251</sup> Methotrexate is cleared rapidly, via the kidneys; 90% of an intravenous bolus dose is excreted unchanged within 24 hours.<sup>252</sup>

# Prognostic Indicators

Numerous studies have sought to define ultrasonographic and biochemical characteristics that might reliably predict success or failure with medical treatment for ectopic pregnancy.<sup>253,254,255,256,257,258</sup> The size of any demonstrable extrauterine gestational mass, the presence or absence of embryonic heart activity or cul-de-sac fluid, and baseline serum  $\beta$ -hCG and progesterone concentrations all have been examined as potential prognostic indicators.

## Ultrasonographic Characteristics

**An ectopic gestational mass greater than 3–4 cm is widely considered as a relative contraindication to medical treatment with methotrexate, and surgical management is deemed as the preferred first-line approach in this setting.**<sup>19,259,260,261,262</sup> There are few data to justify the recommendation, primarily because virtually all studies have limited treatment to women with ectopic pregnancies measuring less than 3.5–4 cm. In one study of 44 women treated with intratubal injection of methotrexate, ectopic pregnancies measuring 2 cm or less regressed more often (76%) than larger masses (52%).<sup>263</sup> However, larger studies involving systemic methotrexate therapy have observed no correlation between size and treatment success,<sup>160,258,264</sup> possibly because the ectopic pregnancy cannot always be distinguished from surrounding blood clot or because size does not accurately predict viability. **In reality, the distinction has limited importance because relatively few ectopic pregnancies imaged with ultrasonography exceed 4 cm in size.**<sup>258,263,264,265</sup>

**Ultrasound evidence of embryonic heart activity and free peritoneal fluid are also considered relative contraindications to medical treatment.**<sup>19,254,260,261,262,263,265</sup> Medical treatment can succeed, but fails significantly more often when heart activity is present (odds ratio [OR] = 9.09; CI = 3.8–22).<sup>264,266</sup> Free peritoneal fluid, presumably blood, has been viewed as evidence suggesting tubal rupture and intra-abdominal hemorrhage. In older studies, 70–80% of ectopic pregnancies were associated with a positive culdocentesis (recovery of nonclotting blood), even though only 40–50% were ruptured.<sup>267,268</sup> Peritoneal blood also can result from tubal abortion. **More contemporary studies involving ultrasonography indicate that free peritoneal fluid may be observed in almost 40% of women with early unruptured ectopic pregnancies and that the presence or absence of cul-de-sac fluid does not accurately predict the success or failure of medical treatment.**<sup>258</sup> Thus, cul-de-sac fluid, by itself, in the absence of symptoms, has relatively little value in guiding choice of treatment or offering prognosis on likelihood of success of medical treatment.

## Serum $\beta$ -hCG Concentrations

Whereas ultrasonographic observations have limited prognostic value, serum  $\beta$ -hCG concentrations are quite useful. **The likelihood of failed medical treatment correlates directly with the initial serum  $\beta$ -hCG concentration; as the level rises, the probability of success decreases.**<sup>258,269</sup> A systematic review and analysis of data derived from five observational studies involving 503 women found a substantial and significant increase in failure rate for patients with initial  $\beta$ -hCG concentrations greater than 5,000 IU/L, compared with that for women with levels less than 5,000 IU/L (OR = 5.45; CI = 3.04–9.78)<sup>269</sup> (Table 33.2).

### TABLE 33.2

Serum $\beta$ -hCG (IU/L)	Women Treated Successfully (%) <sup>269</sup>
<1,000	98.5
1,000–1,999	94.4
2,000–4,999	96.2
5,000–9,999	85.7
10,000–150,000	81.2

The correlation between serum  $\beta$ -hCG concentrations and treatment success is understandable. High or normally increasing serum  $\beta$ -hCG levels suggest an advanced and progressing ectopic pregnancy.<sup>12</sup> Conversely, low serum  $\beta$ -hCG concentrations and absent embryonic heart activity are more likely to be associated with a very early or failing ectopic pregnancy having greater sensitivity to methotrexate therapy. Not surprisingly, the prevalence of embryonic heart activity increases with higher  $\beta$ -hCG concentrations. Heart activity is present in only 5% of ectopic pregnancies associated with a  $\beta$ -hCG level less than 5,000 IU/L, but observed in 27% with  $\beta$ -hCG levels between 5,000 and 10,000 IU/L, in 41% with levels between 10,000 and 15,000 IU/L, and in 50% of ectopic pregnancies associated with a serum  $\beta$ -hCG level over 15,000 IU/L.<sup>258</sup> **The correlation between  $\beta$ -hCG concentrations and embryonic heart activity explains why medical treatment fails more often when heart activity is observed.**

In general, as one might logically expect, serum progesterone concentrations correlate closely with the  $\beta$ -hCG level. The serum progesterone level, however, has no significant added predictive value to that offered by  $\beta$ -hCG alone.

# Indications and Contraindications to Medical Management of Ectopic Pregnancy

Logically, the best candidates for medical treatment of ectopic pregnancy are those in whom treatment is most likely to succeed, although there are other important practical considerations. The ideal candidate has the following characteristics.

## Absolute Requirements

- Hemodynamic stability
- No evidence of tubal rupture or acute intra-abdominal bleeding
- Reliable commitment to comply with required follow-up care
- No contraindications to methotrexate treatment (see below)

## Preferred Characteristics

- Absent or minimal symptoms (pain)
- Serum  $\beta$ -hCG concentration less than 5,000 IU/L
- Absent embryonic heart activity
- Ectopic mass measuring less than 4 cm in diameter
- Willing to accept blood products in case of emergency
- Easy access to health care system

The first four criteria are the most important, for obvious reasons. Among the second four criteria, the first is a practical consideration; it is difficult to justify medical treatment in women with severe or unrelenting pain, which can be signs of impending or ongoing rupture. The next two predict a high probability for success. **Medical treatment is not contraindicated for ectopic pregnancies associated with serum  $\beta$ -hCG concentrations greater than 5,000 IU/L or presence of embryonic heart activity, but the likelihood of treatment failure and the risk of tubal rupture are increased substantially.**<sup>248,253,258</sup> The second to last criterion conforms to convention in the absence of any data to indicate the safety of medical treatment in women with larger ectopic pregnancies.

Women who do not meet the absolute requirements listed above and those having a specific contraindication to methotrexate are not candidates for medical treatment.<sup>19,270</sup>

## Contraindications to Methotrexate Treatment

- Viable and desired intrauterine pregnancy
- Breastfeeding

- Immunodeficiency states
- Hematologic abnormalities (severe anemia, leukopenia, thrombocytopenia)
- Known sensitivity to methotrexate
- Active pulmonary disease
- Active peptic ulcer disease
- Alcoholism
- Clinically important hepatic or renal dysfunction

# Systemic Methotrexate Treatment

Early trials of methotrexate treatment for ectopic pregnancy were modeled after regimens already in wide use for the treatment of gestational trophoblastic disease. Consequently, the first suggested treatment regimen involved multiple alternating daily doses of methotrexate and folinic acid (also known as leucovorin or citrovorum).<sup>259,271</sup> As experience with medical treatment expanded, a single-dose regimen was introduced in efforts to simplify treatment, improve compliance, and reduce side effects and costs.<sup>248,254,261</sup> A two-dose treatment regimen also has been described, aimed at maximizing success rates while minimizing the number of injections and visits required (Table 33.3).<sup>272</sup>

## TABLE 33.3

Treatment Day	Single-Dose Regimen	Two-Dose Regimen	Multidose Regimen
1	$\beta$ -hCG MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG MTX 1 mg/kg IM
2			LEU 0.1 mg/kg IM
3			$\beta$ -hCG If $\geq 15\%$ decrease (day 1–3), repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 1 mg/kg IM
4	$\beta$ -hCG	$\beta$ -hCG MTX 50 mg/m <sup>2</sup> IM	LEU 0.1 mg/kg IM (if MTX on day 3)
5			$\beta$ -hCG If $\geq 15\%$ decrease (day 3–5), repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 1 mg/kg IM
6			LEU 0.1 mg/kg IM (if MTX on day 5)
7	$\beta$ -hCG If $\geq 15\%$ decrease (day 4–7), repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG If $\geq 15\%$ decrease (day 4–7), repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG If $\geq 15\%$ decrease (day 5–7), repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 1 mg/kg IM
8			LEU 0.1 mg/kg IM (if MTX on day 7)
11	$\beta$ -hCG If $\geq 15\%$ decrease, repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG If $\geq 15\%$ decrease, repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, MTX 50 mg/m <sup>2</sup> IM	$\beta$ -hCG If $\geq 15\%$ decrease, repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, surgical treatment
14	$\beta$ -hCG If $\geq 15\%$ decrease, repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, surgical treatment	$\beta$ -hCG If $\geq 15\%$ decrease, repeat $\beta$ -hCG weekly until undetectable If $< 15\%$ decrease, surgical treatment	

Regardless which treatment regimen is selected, pretreatment evaluation should include the following:

- **Complete blood count**
- **Blood type and Rh(D)**
- **Serum creatinine**
- **Liver function tests**
- **Transvaginal ultrasonography**

In addition, patients should be advised to discontinue any folic acid supplements, including prenatal vitamins, that they may be taking, as well as avoid direct sun exposure (to decrease risk of methotrexate dermatitis), use of nonsteroidal anti-inflammatory drugs (interaction with methotrexate may cause bone marrow suppression or gastrointestinal toxicity), and intercourse or strenuous physical activity (to decrease the risk of tubal rupture).

Although Rh(D) immunoglobulin treatment is recommended commonly for all women with Rh-negative blood type who have an ectopic pregnancy or early spontaneous abortion,<sup>273,274</sup> evidence to support the recommendation is weak. Overall, the likelihood of Rh sensitization after ectopic pregnancy is extremely small because ectopic pregnancies are rarely sufficiently advanced to have a fetal blood volume that is large enough to pose a significant risk of maternal sensitization. It is entirely possible that treatment may be necessary only for ectopic pregnancies that reach at least 8 weeks of gestation.<sup>275</sup> Nevertheless, current recommendations are to administer at least 50  $\mu\text{g}$  of Rh immunoglobulin to all nonsensitized Rh-negative women diagnosed with an ectopic pregnancy or experiencing early spontaneous abortion (protection against a fetomaternal hemorrhage of up to 2.5 mL).<sup>273</sup> Because side effects and complications of treatment are rare, the overall balance of risks and benefits favors treatment.

It is important to note that the single-dose, two-dose, and multidose methotrexate treatment regimens are named for the number of doses **intended**, rather than the number actually administered. Moreover, the first day of treatment has not been consistently defined, designated in some studies as day 0, and in others as day 1. In the absence of evidence that it matters, and for clarity, the different treatment regimens are described here as beginning on day 1.

In the “single-dose” treatment regimen, methotrexate is administered in a single dose (intramuscular 50 mg/m<sup>2</sup>, day 1), and serum  $\beta$ -hCG is measured on days 4 and 7; a decline in serum  $\beta$ -hCG by 15% or more between days 4 and 7 is taken to reflect treatment success, and  $\beta$ -hCG concentrations are monitored weekly thereafter until undetectable. In the majority of women (85%), serum  $\beta$ -hCG concentrations rise somewhat between days 1 and 4.<sup>248,276</sup> This observation is deemed as predictable and does not necessarily indicate failed treatment. However, any subsequent further increase in  $\beta$ -hCG levels, or a decrease in  $\beta$ -hCG of less than 15% between days 4 and 7, is indication for a second dose of methotrexate (to be administered on day 7); thenceforth, the same criteria are followed and adequacy of treatment response is assessed on day 11. If required, a third dose of methotrexate can be administered on day 11 and response evaluated by measuring  $\beta$ -hCG again on day 14. Although a fourth dose of methotrexate can be administered on day 14 if decline in  $\beta$ -hCG is suboptimal, surgical treatment should be given serious consideration after 2 weeks of failed medical treatment.

In the two-dose treatment regimen, methotrexate is administered on days 1 and 4 (intramuscular 50 mg/m<sup>2</sup>). Similar to the single-dose regimen, if the serum  $\beta$ -hCG declines 15% or more between days 4 and 7,  $\beta$ -hCG is monitored weekly until levels become undetectable. If the  $\beta$ -hCG concentrations decrease by less than 15% between days 4 and 7, a third dose of methotrexate is administered (on day 7), and the same criterion is applied in judging the response to treatment on day 11.<sup>272</sup> If necessary, a fourth dose is administered (on day 11) and the serum  $\beta$ -hCG concentration is assessed again on day 14. Similar to the single-dose regimen, surgical treatment should be given serious consideration after 2 weeks of failed medical treatment.

In the multidose treatment regimen, methotrexate (intramuscular 1 mg/kg) and leucovorin (intramuscular 0.1 mg/kg) are administered on alternate days, up to a maximum of four doses, until the serum  $\beta$ -hCG level declines by 15% from the previous value. Thereafter,  $\beta$ -hCG concentrations are monitored on a weekly basis until levels become undetectable.

Routine serial sonography during medical treatment is not useful. After methotrexate treatment, half or more of ectopic masses actually enlarge, probably due to formation of hematomas, but such observations do not predict treatment failure and most patients remain asymptomatic.<sup>160,277</sup> **In women with complaints of increasingly severe abdominal pain, repeat ultrasonography should be performed to detect an obvious increase in peritoneal fluid, suggesting rupture of a tubal pregnancy.** Moderate to severe pain, fluid level extending above the uterine fundus or surrounding the ovary, and a hemoglobin concentration less than 10 g/dL suggest a significant hemoperitoneum; one study found that the probability of a hemoperitoneum amounting to 300 mL or more was 93% when two or more of the criteria were met.<sup>278</sup>

It is important to note that symptoms of pain commonly emerge or increase over the days following methotrexate treatment.<sup>248</sup> The cause is uncertain but most likely reflects tubal abortion (expulsion via the fimbria) or peritoneal tension resulting from a hematoma.<sup>216,279</sup> **A complaint of increasingly severe pain should prompt a thorough reevaluation to determine whether observation and medical treatment can be continued safely, but is not, by itself, an indication for immediate surgery.** Although “separation pain” may be the most likely cause, tubal rupture also is a possibility. Most patients can be reassured and outpatient management can be continued. Some may require hospitalization for more careful observation. Even those with severe or unrelenting pain after methotrexate treatment often can be managed with analgesics and serial hematocrit assessments as long as they remain hemodynamically stable.<sup>279</sup> In a review of 56 women with abdominal pain severe enough to require reevaluation or hospitalization, only 8 ultimately required surgical treatment.<sup>279</sup> However, stubborn adherence to medical management can be difficult to justify in those with severe pain.

**Surgical treatment is indicated when a ruptured ectopic pregnancy is suspected or diagnosed or when the patient elects not to continue medical treatment.**

## **Outcomes of Medical Treatment**

In numerous independent case series, both the single-dose and multidose methotrexate treatment regimens have achieved excellent success rates (75–95%).<sup>216,266</sup> A meta-analysis including 26 nonrandomized studies involving 1,327 cases of ectopic pregnancy treated with systemic methotrexate found that both single-dose treatment (1,067 women; 88% successful) and multidose therapy (260 women; 93% successful) were highly effective.<sup>266</sup> **However, when viewed from the opposite perspective, the failure rate of single-dose treatment (127/1,067; 12%) was significantly higher (OR = 1.7; CI = 1.04–2.82) than for multidose therapy (19/260; 7%). After adjustment for other known prognostic indicators ( $\beta$ -hCG concentration, embryonic heart activity), the higher risk of failure with single-dose treatment was even more striking (OR = 4.8; CI = 1.8–12.6).**<sup>266</sup> The gross difference in success rates between the two treatment regimens (approximately 5%) is comparable to that observed by other investigators<sup>264,280,281</sup> and suggests that for every 20 women treated with multidose rather than single-dose therapy, at least one surgical procedure can be avoided. The results of a small randomized trial are consistent with those of the meta-analysis; treatment was successful in 48/54 women (89%) receiving single-dose therapy and in 50/54 (93%) in those who received multidose therapy.<sup>282</sup>

The meta-analysis observed that single-dose treatment often involves more than one dose of methotrexate (15%) and multidose therapy frequently requires less than four doses (50%).<sup>266</sup> Success rates also were higher in women who received a second “single-dose” (50 mg/m<sup>2</sup>) treatment and lower in those who required more than four doses during multidose (1 mg/kg) therapy. These observations suggested the optimal treatment regimen likely would involve at least two doses of methotrexate.

The efficacy of a planned two-dose regimen was evaluated in a study involving 104 women with a diagnosis of ectopic pregnancy (ultrasonographic imaging of an extrauterine gestational sac containing a yolk sac and/or fetal pole, no products of conception observed in frozen section performed on uterine curettings, or an increase in  $\beta$ -hCG 12–24 hours after curettage).<sup>272</sup> Ultimately, three patients were diagnosed with a failed intrauterine pregnancy after products of conception were identified on final pathologic examination of uterine curettings. Among the remaining 101 women, 88 were treated successfully (87%); 3 required only a single dose of methotrexate, 73 received the planned two doses of treatment, 7 required a third dose, and 5 required four doses. Medical treatment failed in 13/101 patients (13%) and all received surgical treatment;

three were diagnosed with a ruptured ectopic pregnancy, four elected surgical treatment after medical therapy began, four had a plateau in  $\beta$ -hCG levels after an initial decline and chose surgery over additional medical treatment, and two received surgical treatment because of increasing  $\beta$ -hCG or liver transaminase levels.<sup>272</sup> Whereas the results achieved with the two-dose treatment regimen are comparable to those reported for single-dose and multidose treatment regimens, the success rate may be a conservative estimate, primarily because all patients met fairly strict criteria for diagnosis of ectopic pregnancy. **Patients included in previous series and trials often did not receive uterine curettage, making it likely that many did not, in fact, have an ectopic pregnancy, resulting in falsely inflated estimates of the success of medical treatment.**

A recent systematic review and meta-analysis examined six clinical trials comparing single to multidose regimens of methotrexate.<sup>283</sup> Three randomized controlled trials involving a total of 325 clinically stable patients demonstrated similar rates of successful resolution for the two-dose and single-dose protocols (RR = 1.09; 95% CI = 0.98–1.20) and comparable risk of adverse effects (RR = 1.33; 95% CI = 0.92–1.94).<sup>283</sup> However, in two of the three trials included in the review, the two-dose regimen was associated with greater success among women with high initial  $\beta$ -hCG levels. In the first trial, there was a nonstatistically significant trend toward greater success for the two-dose regimen in the subgroup with an initial  $\beta$ -hCG level greater than 5,000 mIU/mL (80.0% vs. 58.8%; P = 0.279; RR = 0.74; 95% CI = 0.47–1.16).<sup>284</sup> The second trial reported a statistically significant higher success rate for the two-dose regimen versus the single-dose regimen in patients with initial serum hCG levels between 3,600 and 5,500 mIU/mL (88.9% vs. 57.9%; P = 0.03; OR = 5.80; 95% CI = 1.29–26.2).<sup>285</sup>

A more recent systematic review and meta-analysis, which included 11 trials and 1,121 patients treated with single-dose and non-single-dose protocols, demonstrated similar success rates (RR = 1.00; 95% CI = 0.96–1.04) with non-single-dose regimens associated with higher adverse effect rates.<sup>286</sup>

**Ipsilateral tubal patency rates after successful medical treatment of ectopic pregnancy are generally comparable to those observed after conservative laparoscopic surgical treatment (linear salpingostomy) and range between 60% and 85%.<sup>30,248,280,287,288,289</sup> Among those who seek another pregnancy, subsequent reproductive performance and pregnancy outcomes also are similar. In general, 50–80% of women treated with methotrexate later achieve an intrauterine pregnancy, whereas 10–20% experience a recurrent ectopic pregnancy.<sup>29,30,290</sup> Women with ectopic pregnancies associated with an IUD typically have a better prognosis, probably**

because their ectopic pregnancy was less likely related to tubal pathology.<sup>290</sup> As might be expected, older women,<sup>22,291,292,293</sup> previously infertile women,<sup>294,295,296</sup> and those with past history of ectopic pregnancy or tubal damage<sup>22,291,294</sup> have a poorer prognosis. **In essence, fertility after ectopic pregnancy depends more on already established patient characteristics than on the method of treatment.**<sup>297,298</sup>

Occasionally, the ectopic gestational mass may persist for weeks after successful medical treatment. Whereas it seems prudent to postpone new attempts to conceive again until the mass resolves completely, whether the delay is necessary or may reduce risk for another ectopic pregnancy is unknown.

Evidence from studies of pregnancy outcomes in women treated with methotrexate for ovarian germ cell tumors,<sup>299</sup> gestational trophoblastic disease,<sup>300</sup> or ectopic pregnancy<sup>301,302</sup> do not suggest that treatment has any adverse effect on the outcomes of future pregnancies or on ovarian reserve.<sup>303</sup>

## Side Effects and Complications

Although medical treatment is a viable option for many women with unruptured ectopic pregnancies and, on average, costs significantly less than surgical treatment,<sup>304</sup> it is not necessarily the best option for all women. Medical treatment avoids anesthesia and invasive surgery, but also has its drawbacks. If thoroughly counseled and given the choice, some women prefer surgical to medical treatment.<sup>305</sup>

Whereas surgery usually is definitive and followed by a prompt return to normal function, medical treatment can become tedious and inconvenient. The results of both medical and conservative surgical treatments must be monitored with serial serum  $\beta$ -hCG determinations to ensure that treatment has been successful, but levels typically fall about twice as fast after surgery.<sup>306</sup> **When medical treatment is successful, the time to resolution (undetectable serum  $\beta$ -hCG) generally correlates with the initial serum  $\beta$ -hCG concentration; the average time to resolution is approximately 5 weeks.**<sup>248,306</sup> Unfortunately, some women may require weekly monitoring for up to 3 months or more before  $\beta$ -hCG is no longer detectable.<sup>248,264</sup>

**Side effects of methotrexate are relatively common, but also usually minor and transient; their prevalence is somewhat higher with multidose therapy than with single-dose treatment.**<sup>266</sup> Elevated hepatic transaminases are the most common. Nausea, vomiting, and diarrhea may result from a drug-induced gastritis or enteritis. Methotrexate-induced stomatitis, reversible alopecia, and pneumonitis are uncommon. Serious side effects are rare and include severe bone marrow suppression and hepatotoxicity. When necessary, treatment with leucovorin can help to reduce their

severity and speed resolution.

Compared to women who receive surgical treatment, medically treated women more often experience prolonged vaginal bleeding and perceive more depression and limitations in physical and social function.<sup>288,307</sup> **Tubal rupture requiring emergent surgery during medical treatment can and does occur, even when serum  $\beta$ -hCG levels are falling; tubal rupture has been observed as long as 6 weeks after initiation of medical treatment.**<sup>216</sup> Evidence from randomized trials comparing systemic methotrexate and conservative surgical treatment indicates that approximately 15% of women first treated medically ultimately require surgery, about half because of tubal rupture.<sup>287,288</sup> Isthmic tubal ectopic pregnancies are at higher risk for rupture, but cannot be accurately differentiated from more common ampullary implantations without laparoscopy. **Fortunately, tubal rupture does not appear to have any independent adverse effect on subsequent fertility or pregnancy outcomes.**<sup>32</sup>

# Local Medical Treatment by Direct Injection

Methotrexate also can be administered by direct local injection (1 mg/kg) into an ectopic gestational sac under laparoscopic or ultrasonographic guidance.<sup>265,306,308</sup> The method delivers a high concentration of the drug to the site of implantation and achieves circulating concentrations comparable to those seen with systemic therapy.<sup>309</sup> A large experience with direct local injection of methotrexate has accumulated, mostly in Europe. Overall, results have been somewhat inconsistent but generally comparable to those achieved with systemic therapy.<sup>30</sup> This approach of medical intervention is more invasive, is more costly, and requires greater technical skill. With those disadvantages, and no clear advantages, systemic methotrexate treatment is the more logical choice.

The efficacy and safety of direct local injection of other medications (potassium chloride, hyperosmolar glucose) and their long-term impact on fertility are not well established because experience is limited.<sup>30</sup> However, intratubal injection of potassium chloride or hyperosmolar glucose does have one important and specific niche application. In heterotopic pregnancies, the method can ablate the ectopic implantation without compromising a coexisting viable intrauterine pregnancy while also avoiding surgery and its attendant potential complications.<sup>310</sup>

# **SURGICAL TREATMENT FOR ECTOPIC PREGNANCY**

---

Traditionally, ectopic pregnancies were treated surgically and salpingectomy was the most common operation performed. However, the contemporary management of ectopic pregnancy in asymptomatic patients has moved away from surgical treatment. Nonetheless, many women still receive surgical treatment, by choice, or because they are poor candidates for medical treatment. As modern methods for early diagnosis of unruptured ectopic pregnancies emerged, conservative procedures like linear salpingostomy and segmental resection are preferred approaches for those electing surgical treatment, as well as needing emergent surgery. At first, most operations still were performed via laparotomy, but soon thereafter, laparoscopic surgery became standard treatment for unruptured ectopic pregnancies. With the instrumentation available today, even most ruptured ectopic pregnancies can be successfully managed laparoscopically.

# Indications for Surgical Management

The following generally are accepted as indications for choosing surgical treatment over medical therapy:

- Hemodynamic instability
- Rupture of an ectopic mass
- Coexisting viable intrauterine pregnancy
- Unwillingness or inability to comply with required follow-up after medical treatment
- Lack of ready access to a hospital for management of tubal rupture
- Desire for permanent sterilization
- Contraindications to medical treatment
- Failed medical treatment

Surgical treatment also merits serious consideration for women having clinical characteristics known to be associated with an increased risk for failed medical therapy, such as a serum  $\beta$ -hCG concentration over 5,000 IU/L or demonstrable embryonic heart activity. In women who are stable hemodynamically, surgical treatment should be reserved for those having a demonstrable extrauterine gestational sac or an adnexal mass consistent with the diagnosis of ectopic pregnancy. Otherwise, there is a high probability that no ectopic pregnancy will be identified at surgery. Such women are best managed expectantly until the diagnosis is more firmly established, by serial  $\beta$ -hCG measurements and timely ultrasonography or by performing curettage (provided a viable intrauterine pregnancy can be confidently excluded). Alternatively, they can be treated empirically with medical therapy, realizing that many will receive unnecessary methotrexate treatment and thereafter carry a presumptive diagnosis that clouds their prognosis and decisions regarding future treatment.

Surgery does have some distinct advantages over medical therapy, primarily including a shorter time to resolution of the ectopic pregnancy, with no need for prolonged monitoring. Surgery also allows for an accurate assessment of the pelvic anatomy, which helps in subsequent counseling and treatment planning.

# Surgical Techniques

For the treatment of ectopic pregnancy, laparoscopy has several advantages over laparotomy—less blood loss, fewer adhesions, less operating time, a shorter hospital stay (usually <24 hours), reduced postoperative analgesic requirements, and a more rapid convalescence—all of which also help to reduce costs.<sup>30,311,312,313,314,315,316,317,318</sup>

There are two operative techniques used for surgical management of tubal pregnancy: salpingectomy and salpingostomy. Salpingostomy technique involved is straightforward. A longitudinal incision is made on the antimesenteric surface of the fallopian tube directly over the bulging mass using an electrosurgical needle or scissors, or a laser, and the products of conception are gently removed with forceps or irrigation. Preliminary injection of a dilute solution of aqueous vasopressin (1 unit/mL)<sup>319</sup> or oxytocin (20 units)<sup>320</sup> into the subjacent mesosalpinx can help to minimize the amount of electrocautery needed to achieve hemostasis. The incision may be sutured closed, but usually is left open to heal by itself; long-term reproductive outcomes are the same with either technique.<sup>321</sup> Because the bulk of the ectopic mass usually resides just beneath the serosa, the endosalpingeal mucosa most often can be left relatively undisturbed. Attempts at linear salpingostomy are successful in approximately 80% of women; in the remainder, persistent bleeding may require salpingectomy. Unsuccessful salpingostomy procedures are associated with higher serum  $\beta$ -hCG concentrations,<sup>322</sup> possibly because the ectopic gestation in these situations is more advanced and possesses a more highly developed neovasculature.

The decision to perform salpingostomy or salpingectomy should be based on the patient's clinical status, on the desire for future fertility, and on the observed extent of damage and potential for salvage of the affected fallopian tube. Two randomized controlled trials did not reveal any statistical difference in the subsequent intrauterine pregnancy rate (RR = 1.04; 95% CI = 0.89–1.21; P = 0.61) or the repeat ectopic pregnancy rate (RR = 1.30; 95% CI = 0.72–2.38; P = 0.39) between salpingostomy and salpingectomy groups. Meta-analysis of cohort studies, however, showed that salpingostomy was associated with both higher intrauterine pregnancy rate compared with salpingectomy rate (RR = 1.24; 95% CI = 1.08–1.42; P = 0.002) and higher tubal ectopic pregnancy recurrence rate (RR = 2.27; 95% CI = 1.12–4.58; P = 0.02).<sup>323</sup>

In general, salpingectomy is preferred when the affected fallopian tube is severely damaged or when significant bleeding is encountered despite attempts at achieving hemostasis. Unilateral salpingectomy may be a method of choice in patients desiring future fertility with a distorted affected tube when the contralateral tube appears normal or when the patient desires permanent sterilization. In the latter case, bilateral salpingectomy is performed. Salpingostomy is preferred when the remainder of the tube

appears normal and particularly so when fertility is desired but contralateral tube is damaged. If salpingostomy is performed, serial  $\beta$ -hCG monitoring is required to confirm resolution of ectopic trophoblastic tissue.

**Attempts at fimbrial evacuation of the ectopic pregnancy, such as by “milking the affected segment,” are likely to cause greater damage to the tube than linear salpingostomy and are best reserved for those where the ectopic products of conception are already protruding through the fimbria.**<sup>324</sup> The typical subserosal propagation of ampullary ectopic pregnancies explains why “milking” a more proximal ectopic is not recommended. **Isthmic ectopic pregnancies probably are best managed by segmental excision, with the option of later microsurgical tubotubal anastomosis.** The lumen of the isthmic segment of the fallopian tube is much narrower than that of the ampulla and is more likely to be damaged by salpingostomy and more prone to postoperative obstruction. The involved segment is simply excised, taking care to ensure that hemostasis is achieved.

In all cases, every effort should be made to preserve the adjacent ovary. The only indication for salpingo-oophorectomy (which rarely arises) is bleeding that cannot be controlled by more conservative measures.

# Outcomes of Surgical Treatment

Observational studies indicate that cumulative intrauterine pregnancy rates are significantly higher after salpingostomy than after salpingectomy (73% vs. 57%), but the incidence of recurrent ectopic pregnancy also is higher (15% vs. 10%).<sup>28,30,31</sup> Parous women are more likely to conceive again than nulliparous women.<sup>296,325</sup> Women with a normal contralateral tube have a higher probability of achieving an intrauterine pregnancy and a lower risk for recurrent ectopic pregnancy than those with contralateral tubal pathology.<sup>318,325,326</sup>

**Conservative surgical treatment is successful (requires no additional treatment) in approximately 90% of women with unruptured ectopic pregnancies.** The combined results of two randomized trials<sup>313,314,316</sup> indicate that salpingostomy is less often successful when performed laparoscopically than via the open surgical approach (OR = 0.28; CI = 0.09–0.86), because the incidence of persistent trophoblast is higher following conservative management (OR = 3.5; CI = 1.1–11).<sup>30</sup> **Among women who desire future fertility, tubal patency rates (80–90%) and intrauterine (55–75%) and recurrent ectopic pregnancy rates (10–15%) after laparoscopy or laparotomy are similar.**<sup>30</sup>

## Persistent Ectopic Pregnancy

**Persistent ectopic pregnancy is the most common and potentially serious complication of conservative surgical treatment for ectopic pregnancy.**<sup>327</sup> The phenomenon was first described in 1979.<sup>328</sup> The reported incidence of persistent ectopic pregnancy has ranged widely from 3% to almost 30%,<sup>329,330,331,332</sup> in part because of differences in definition (postoperative increase in serum  $\beta$ -hCG vs. continued growth requiring additional treatment).<sup>331,333</sup> The risk for persistent ectopic pregnancy may be increased when surgery is performed early (before 6 weeks of gestation) and for small ectopic pregnancies (<2 cm in diameter), which may be more difficult to identify and excise completely,<sup>329,330,334</sup> is more common following laparoscopic procedures compared to when ectopic pregnancy is managed via laparotomy.<sup>335</sup> **Clinicians must remain alert to the possibility because unrecognized persistent ectopic pregnancies frequently rupture during the postoperative period.**<sup>336</sup>

**The most effective way to identify persistent ectopic pregnancies is to monitor serum  $\beta$ -hCG levels during the postoperative period, until resolution.** Recommendations have varied from every 3 days to 2 weeks. The postoperative day 1

serum  $\beta$ -hCG concentration has significant predictive value; the greater the fall from preoperative levels, the lower the incidence of persistent ectopic pregnancy.<sup>337</sup> A 50% decline is the threshold value offering the best blend of sensitivity (42%) and specificity (88%). Women in whom the serum  $\beta$ -hCG concentration falls less than 50% are more than three times as likely to have a persistent ectopic pregnancy (RR = 3.51; CI = 1.25–6.68), but the risk is quite low when levels fall by 80% or more.<sup>337</sup> **In light of these observations, it seems logical to recommend measuring serum  $\beta$ -hCG on postoperative day 1 and every 3–7 days thereafter, depending on the rate of decline, until levels are undetectable.** For those who exhibit evidence of persistent ectopic pregnancy (rising or slowly falling postoperative  $\beta$ -hCG concentrations), the single-dose methotrexate treatment regimen (intramuscular 50 mg/m<sup>2</sup>) is highly effective.<sup>338</sup>

A decision analysis comparing observation and prophylactic postoperative methotrexate, involving 1,000 hypothetical women treated with linear salpingostomy, concluded that prophylactic treatment results in fewer cases of tubal rupture, fewer procedures, and lower costs, but also invites complications relating to medical treatment.<sup>339</sup> Treatment can be offered routinely or reserved for those in whom the postoperative day 1 serum  $\beta$ -hCG does not fall by more than 50%. Regardless whether prophylactic treatment is or is not used, serum  $\beta$ -hCG levels should be monitored until no longer detectable. Intrauterine pregnancy rates after treatment of persistent ectopic pregnancy are similar to those after primary treatment.<sup>340</sup>

## **Recurrence Risk of Ectopic Pregnancy**

The chance of a repeat ectopic pregnancy in a woman with a history of one ectopic pregnancy is approximately 10% (OR = 3.0; 95% CI = 2.1–4.4). In a woman with two or more prior ectopic pregnancies, the risk of recurrence increases to more than 25% (OR = 11.17; 95% CI = 4.0–29.5).<sup>18</sup>

# UNUSUAL TYPES OF ECTOPIC PREGNANCY

---

Heterotopic pregnancies and abdominal, ovarian, interstitial, cervical, and cesarean scar ectopic pregnancies are rare and unusual variants that present unique challenges; management strategies must be individualized, prioritizing patient safety while keeping in perspective each woman's reproductive plans and wishes.

# Heterotopic Pregnancy

A heterotopic pregnancy involves coexisting pregnancies at distinctly different implantation sites. The most common combination is an intrauterine and an extrauterine gestation, most of the latter being in the tube (90%), although implantations in the cervix, ovary, interstitial segment, abdomen, and previous cesarean scar have all been reported.<sup>335,341,342,343,344,345,346</sup> The often quoted approximate incidence of 1/30,000 spontaneously conceived pregnancies was derived from calculations over 50 years ago, based on the observed incidence of ectopic pregnancy (0.37%) and dizygotic twinning (0.8%) at the time.<sup>81</sup> The incidence of heterotopic pregnancy has risen substantially due to increasing use of exogenous gonadotropins and ART. Today, the best overall current estimate is approximately 1/3,900 pregnancies,<sup>28,347,348</sup> but the incidence is about 1.5/1,000 pregnancies resulting from ART.<sup>349</sup>

**Heterotopic pregnancies often escape early recognition because both serum  $\beta$ -hCG concentrations and ultrasonography can be misleading.** Normally rising levels of  $\beta$ -hCG derived from a normally developing intrauterine pregnancy usually obscure the abnormal pattern typically observed in ectopic pregnancies, and when ultrasonography reveals an intrauterine pregnancy, the possibility of a coexisting ectopic pregnancy in an asymptomatic patient is seldom considered. Consequently, diagnosis is delayed and over half of all heterotopic pregnancies are recognized only after tubal rupture occurs.<sup>342</sup> The signs and symptoms of heterotopic pregnancy are similar to those of ectopic pregnancy but, unfortunately, are often dismissed due to the false reassurance offered by the coexisting intrauterine gestation.

**Treatment of a heterotopic pregnancy in the setting of a viable concomitant intrauterine pregnancy gets complicated.** Expectant management is inappropriate because neither serum  $\beta$ -hCG levels nor ultrasonography can accurately determine the fate of the ectopic pregnancy nor quantify the risk of rupture. Systemic methotrexate treatment is contraindicated when the intrauterine pregnancy is viable and desired. Even direct local injection of methotrexate<sup>350</sup> may be unwise because of the potential for systemic absorption and thereby exposure of the intrauterine gestation to a documented teratogen.<sup>309</sup> Surgical treatment by salpingostomy or salpingectomy while leaving the intrauterine gestation undisturbed is effective and generally is considered the treatment of choice.<sup>335,342</sup> Selective embryo reduction by direct local injection of potassium chloride<sup>310,351</sup> or hyperosmolar glucose<sup>352,353</sup> into the ectopic gestational sac is another viable treatment option. However, in a review of 11 cases of heterotopic pregnancy treated with potassium chloride injection, 6 patients failed medical therapy and required surgical treatment.<sup>335</sup>

Bilateral ectopic pregnancies as a form of heterotopic pregnancy have been described.<sup>354,355,356</sup>

# Abdominal Pregnancy

Abdominal ectopic pregnancies, involving implantation in the peritoneal cavity, are rare, with an estimated incidence of approximately 1/10,000 pregnancies and 1/100 ectopic pregnancies.<sup>357,358</sup> Implantation sites include the omentum, pelvic sidewall, broad ligament, cul-de-sac, spleen, bowel, liver, diaphragm, and serosa of the uterus. Whether abdominal pregnancies result from primary peritoneal implantation or secondary implantation following a tubal abortion is unknown. One reported case after IVF in a patient without tubes may have resulted from uterine perforation at the time of embryo transfer.<sup>358</sup>

The symptoms most frequently encountered are abdominal pain, nausea and vomiting, general malaise, and painful fetal movements, and the most frequent physical findings are abdominal tenderness, abnormal fetal lie, and a displaced uterine cervix.<sup>359</sup> In rare cases, diagnosis may follow a failed induction of labor.<sup>360</sup> Ultrasonography is the most accurate method for diagnosis, but fewer than half of all abdominal pregnancies are recognized before intra-abdominal hemorrhage occurs. The classic ultrasonographic sign is the absence of any myometrium between the maternal bladder and the pregnancy.<sup>361</sup>

Immediate surgery is the treatment of choice, except perhaps in rare cases of advanced abdominal pregnancy involving a fetus nearing viability when judicious delay to allow fetal lung maturation may be considered under stringent surveillance. If recognized early, an abdominal pregnancy may be amenable to laparoscopic surgery<sup>341,362,363</sup>; in one reported attempt, medical treatment with methotrexate was unsuccessful.<sup>364</sup> Although delivery of viable infants has been reported,<sup>361,365</sup> the likelihood is very low and the risk of maternal complications is very high. **The maternal mortality associated with abdominal pregnancy (at least 5/1,000 cases) is the highest of all types of ectopic pregnancy.**

Whereas delivery of the fetus is accomplished easily, management of the placenta is complicated. When technically feasible, the placenta should be removed because complications (hemorrhage, abscess, sepsis, intestinal obstruction, amniotic fluid cysts, hypofibrinogenemia) are otherwise common.<sup>366</sup> However, given the absence of cleavage planes, removal of the placenta can be challenging and hemorrhage is common and can be difficult to control.<sup>367</sup> When the placenta is left in situ, arterial embolization and systemic methotrexate treatment may help to speed its involution.<sup>361,368,369</sup>

# Ovarian Pregnancy

Ovarian pregnancy accounts for less than 3% of all ectopic pregnancies. The clinical signs and symptoms are the same as for more common tubal ectopic pregnancies.<sup>370,371</sup> Although ultrasonography may suggest the possibility, diagnosis usually is made only at surgery, or by the pathologist, because an ovarian ectopic pregnancy frequently is confused with a hemorrhagic corpus luteum at the time of surgery.<sup>370,372</sup> Diagnosis of ovarian pregnancy has specific criteria, but they are largely of academic relevance: (1) an intact ipsilateral tube, separate from the ovary, (2) a gestational sac occupying the position of the ovary, (3) a gestational sac connected to the uterus by the ovarian ligament, and (4) ovarian tissue in the wall of the gestational sac.<sup>373</sup> Treatment of almost all known ovarian ectopic pregnancies has been surgical. Case reports have described successful methotrexate therapy,<sup>374,375,376</sup> and it seems likely that many of the innumerable ectopic pregnancies that are treated medically may actually be ovarian implantations.

# Interstitial Pregnancy

No more than approximately 2% of tubal ectopic pregnancies implant in the interstitial tubal segment, which lies within the uterine wall and measures 1–2 cm in length. In the largest single series of 32 interstitial pregnancies collected by the Society for Reproductive Surgeons, 13 were recurrent ectopic pregnancies, 12 were in women with a previous ipsilateral salpingectomy, and 11 were in women who conceived after IVF.<sup>377</sup>

Conventional gynecologic wisdom has held that interstitial pregnancies rarely rupture before approximately 12 weeks of gestation because the myometrium surrounding the interstitial tubal segment is more distensible than the muscularis of the more distal portions of the fallopian tube. However, in the case series alluded to above, 14/32 (44%) interstitial pregnancies ruptured before diagnosis and all before 12 weeks (mean 6.9 weeks; range 5–12 weeks) of gestation.<sup>377</sup>

Most cases of interstitial pregnancy are diagnosed after the typical symptoms of ectopic pregnancies appear. The unusual location of interstitial pregnancies makes diagnosis difficult, but their ultrasonographic characteristics also are somewhat unique. A careful and experienced examiner may observe an eccentric gestational sac or heterogeneous mass, abnormal thinning of the myometrial mantle, or an abnormally prominent interstitial tubal segment (“the interstitial line”), the last criteria having the greatest diagnostic sensitivity (80%) and specificity (98%).<sup>378</sup> Other proposed criteria include the combination of an empty uterine cavity, a gestational sac separate and at least 1 cm from the lateral edge of the cavity, and a thin (<5 mm) myometrial layer surrounding the sac.<sup>379</sup> When doubt persists, laparoscopy can help to accurately differentiate true interstitial pregnancies from normal but eccentric or “angular” intrauterine pregnancies.<sup>380</sup>

Historically, the traditional treatment for interstitial pregnancy has been hysterectomy or cornual resection by laparotomy, primarily because most interstitial pregnancies were not recognized before rupture and often were associated with massive hemorrhage.<sup>343,381,382,383</sup> Now, earlier diagnosis of interstitial pregnancy offers the opportunity for more conservative surgical or medical treatment. Some advocate laparoscopic “cornuostomy” with excision of the interstitial portion of the tube, if necessary.<sup>377,381</sup> Others prefer primary medical therapy, typically using a multidose methotrexate treatment regimen, reserving surgery for those who fail medical management; in one series, 16/17 (94%) were treated successfully, including four cases in which embryonic heart activity was present.<sup>384</sup> Successful hysteroscopic resection of interstitial pregnancies and selective arterial embolization (alone or in combination with medical treatment) have also been described.<sup>385,386,387,388</sup> Direct local injection of

potassium chloride is another option that may have particular value for the treatment of heterotopic interstitial pregnancies.<sup>381,389</sup> A recently proposed “best practice” recommends systemic methotrexate therapy for hemodynamically stable women with interstitial ectopic pregnancies and laparoscopic surgical resection for those who are hemodynamically unstable or prefer surgery over medical treatment.<sup>383</sup>

The risk of uterine rupture in a subsequent pregnancy after successful treatment for an interstitial pregnancy is uncertain, but cases of uterine rupture have been reported.<sup>390,391</sup> Consequently, careful monitoring of any later pregnancy is essential, and cesarean delivery is recommended.

# Cervical Pregnancy

Cervical pregnancy is a rare type of ectopic pregnancy in which implantation occurs in the endocervical canal. The reported incidence ranges between 1/2,500 and 1/10,000 pregnancies.<sup>392,393</sup> Cervical pregnancy is somewhat more common among pregnancies conceived through ART, with an incidence of approximately 1/1,000 pregnancies resulting from IVF.<sup>394</sup> The cause is unknown, but over two-thirds of women with cervical pregnancies have had a previous uterine curettage or cesarean delivery, suggesting some association with prior surgical trauma to the uterus or cervix.<sup>392,393</sup>

Painless vaginal bleeding is the classical symptom of cervical pregnancy. On clinical examination, the cervix is usually distended, appearing hyperemic or cyanotic, soft, and enlarged out of proportion to the uterus (“hourglass” cervix).<sup>392</sup> Most often, the diagnosis has been incidental to routine ultrasonography or curettage for an assumed incomplete abortion. Early diagnosis is based on ultrasonographic observations of an endocervical gestational sac with associated trophoblastic invasion below a closed internal cervical os, with a normal endometrial thickness<sup>392,395,396</sup>; focally increased blood flow detected by color and pulsed Doppler ultrasonography or cardiac activity confirms the diagnosis.<sup>395,397,398</sup>

In hemodynamically stable women with cervical pregnancies, conservative treatment is aimed at preserving the uterus and reducing the substantial risks of catastrophic hemorrhage. A wide variety of management strategies have been employed successfully. Local and/or systemic treatment with methotrexate has been successful in over 80% of treated women with cervical pregnancies,<sup>392,399</sup> but experience is limited to case reports and small series.<sup>400,401,402</sup> Other medical treatment strategies include direct local injection of potassium chloride when embryonic heart activity is present.<sup>403,404,405</sup>

Traditional treatment for cervical pregnancy was curettage and hysterectomy, when necessary for control of hemorrhage. Methods aimed at minimizing that risk have included cervical cerclage, intracervical injection of vasopressin, and transvaginal ligation of the cervical branches of the uterine arteries. Similar measures as well as intracervical balloon tamponade and bilateral uterine or internal iliac artery ligation have been used to control postoperative bleeding. More recently, uterine artery embolization (UAE) has been used both preoperatively and postoperatively to prevent or control hemorrhage,<sup>392,403,404</sup> but experience to date is insufficient to warrant its routine recommendation.

# Cesarean Scar Pregnancy

Ectopic pregnancies in a cesarean scar account for approximately 6% of all ectopic pregnancies among women with a previous cesarean delivery (**Figure 33.1**).<sup>406,407,408</sup> The number of reports has increased dramatically in the last 20 years. In 2002, a review paper on cesarean scar pregnancies reported 19 cases described in the literature.<sup>409</sup> Since then, an increasing number of case reports and case series on this topic have been published, and by 2012, the numbers had escalated to 44, 483, and 107 cases, respectively, reported in the United States, China, and the United Kingdom.<sup>410</sup> This uptrend in the number of reported cases may be related to the true increase in the incidence of cesarean scar pregnancies or reflect increasing awareness of the condition among obstetricians and gynecologists.

The exact mechanism for abnormal implantation is unknown, but is thought to be due to the migration of a blastocyst through either a wedge-shaped myometrial scar defect, a scar dehiscence, or through a microscopic tract within the scar.<sup>411,412</sup>

Since scar and fistula formation can develop following other uterine surgeries, scar pregnancies have also been reported after previous dilation and curettage, myomectomy, metroplasty, hysteroscopy, and manual removal of the placenta.<sup>411,412</sup> In addition to prior uterine surgery, other risk factors include history of placental pathology, ectopic pregnancy, adenomyosis, and IVF.<sup>413,414</sup>

It has been suggested that the risk of CSP increases with the number of previous cesarean sections, possibly due to increased scar surface area or risk of scar defect.<sup>413</sup> However, other studies have found no such correlation. A recent systematic review found that over half (52%) of reported cases occur in women with only one prior cesarean delivery, 36% after two, and 12% after three or more prior cesarean sections.<sup>407</sup> Limited data are available on the association between cesarean scar ectopic and indication for cesarean delivery; however, cesarean section for breech presentation is most frequently identified as a possible risk factor.<sup>407,413</sup> No data are available in the literature regarding surgical technique (i.e., single- vs. double-layered closure) or interpregnancy interval as possible risk factors for cesarean scar pregnancy.

The clinical presentation of women with cesarean scar ectopic pregnancies varies widely, from vaginal bleeding, with or without pain, to uterine rupture and hemorrhagic shock.<sup>415</sup> Diagnosis usually is made by ultrasonography in the first trimester, revealing an enlarged hysterotomy scar with an associated mass that extends beyond the external contour of the uterus.<sup>416,417</sup> Other findings include an empty uterine cavity and cervical canal, without contact with the gestational sac; presence of a trophoblast in the anterior part of the uterine isthmus or between the bladder and the anterior uterine wall; and

absence of, thinning, or visible defect in the myometrium between the bladder and the sac.<sup>411,412</sup>

Due to the risk of life-threatening complications, including uterine rupture and hemorrhage, pregnancy termination is generally recommended in the first trimester. Treatment goals include ending the pregnancy prior to rupture, removing the sac, and preserving future fertility if desired by the patient. **The best management for cesarean scar ectopic pregnancies has not yet been defined.**

A vast variety of treatment modalities have been proposed over the last few years. A systematic review from 2012 mentioned 31 different treatment modalities for managing cesarean scar ectopic pregnancy.<sup>410,418</sup> Identification of treatment of choice should reflect a balance between minimal necessary intervention and maximal efforts to reduce the risk of complications. It should account for clinical presentation and level of suspicion for ongoing or risk of uterine rupture, gestational age, trend of laboratory values, imaging characteristics, patients' preference and plans for future fertility, as well as availability of the appropriate equipment and qualified staff. A more recent systematic review recommended five treatment modalities as being most effective and associated with the least number of complications and need for additional therapy<sup>419</sup>; these approaches were resection through a transvaginal approach, laparoscopy, UAE in combination with dilation and curettage, and hysteroscopy. Notably, use of systemic methotrexate alone or in combination with local injection was associated with severe complications in 13% of the cases and need for additional treatment in 15% (systemic and local) and 25% (systemic only).<sup>419</sup>

Use of UAE has been effectively employed to decrease the risk of hemorrhage.<sup>420,421,422,423</sup> In a randomized trial involving 72 women with cesarean scar pregnancy treated with UAE or methotrexate before dilation and curettage, UAE was associated with significantly less blood loss and a shorter hospital stay.<sup>424</sup> Intrauterine placement of a cervical ripening double-balloon catheter is a novel approach that has been effective in achieving compression of the gestational sac and its blood supply and has shown promising results in managing cesarean scar pregnancies.<sup>425</sup> Expectant management of cesarean scar pregnancies has been reported.<sup>418,426</sup> A recent meta-analysis and systematic review examined outcomes in 69 cases of cesarean scar pregnancy that were managed expectantly across 17 studies; fetal cardiac activity was evident in 75% (52/69) of the cases. This review established that in the presence of fetal cardiac activity, expectant management approach to cesarean scar pregnancy is fraught with a high likelihood of a variety of maternal complications that include severe hemorrhage, abnormally adherent placenta, uterine rupture, and a need for hysterectomy. In contrast, when there is absent fetal cardiac activity, a cesarean scar early pregnancy is likely to result in an uncomplicated miscarriage, as was observed in a majority

(69.1%; 95% CI = 47.4–87.1%) of cases; an intervention (surgical or medical) was required in almost 31% (95% CI = 12.9–52.6%). Uterine rupture was uncommon in the absence of fetal cardiac activity (in only 13.4% of cases, 95% CI = 2.7–30.3%).

High incidence of abnormal placental invasion is described in cesarean scar pregnancies. In two separate studies, each reporting on 10 patients managed expectantly, a diagnosis of morbidly adherent placenta was confirmed at the time of delivery by cesarean section.<sup>427,428</sup> These data identify cesarean scar site as a precursor for abnormal placental invasion.

After successful treatment of a cesarean scar pregnancy, recurrent cesarean scar implantation, successful intrauterine pregnancies, placenta accreta, and uterine rupture (resulting in maternal death) all have been reported.<sup>429,430,431</sup> The exact risk of recurrence of CSP is unknown; however, some studies quote the rate of recurrence 4–15.6%.<sup>413,432,433</sup> Consequently, early ultrasonography to establish the site of implantation is indicated in subsequent pregnancies.<sup>434</sup>

# Appendix: Selected Laboratory Values Expressed in Conventional Units and the International System of Units (SI Units)

## Laboratory Values for Selected Measurements in Urine

Substance	Conventional Units	Conversion Factor	SI Units
Cortisol, free	10–90 µg/24 h	2.759	28–250 nmol/24 h
Estrogens, total	5–25 µg/24 h	3.67	18–92 nmol/24 h
17-Hydroxycorticosteroids	2–6 mg/24 h	2.759	5.5–15.5 mmol/24 h
17-Ketosteroids	6.0–15 mEq/24 h	3.467	21–52.5 mmol/24 h

## SI Prefixes and Their Symbols

$10^9$	giga	G
$10^6$	mega	M
$10^3$	kilo	k
$10^2$	hecto	h
$10^1$	deka	da
$10^{-1}$	deci	d
$10^{-2}$	centi	c
$10^{-3}$	milli	m
$10^{-6}$	micro	$\mu$
$10^{-9}$	nano	n
$10^{-12}$	pico	p
$10^{-15}$	femto	f
$10^{-18}$	atto	a

**Laboratory Values for Selected Measurements in Blood, Plasma, and Serum**

Substance	Conventional Units	Conversion Factor	SI Units
ACTH, adrenocorticotropin hormone 6:00 A.M. 6:00 P.M.	10–80 pg/mL <50 pg/mL	0.2202 0.2202	2.2–17.6 pmol/L <11 pmol/L
Alkaline phosphatase, bone specific Premenopausal Postmenopausal	µg/L 5.0–19 5.6–29	1.0	µg/L 5–19 5.6–29
Antimüllerian hormone (AMH) <3 mo 3 mo to 2 y 2–12 y 13–45 y >45 y Postmenopausal	ng/mL Undetectable <5 <10 1–10 <1 Undetectable	7.1429	pmol/L Undetectable <35 <70 7–70 <10 Undetectable
Androstenedione	60–300 ng/dL	0.0349	2.1–10.5 nmol/L
Calcium, total	8.5–10.5 mg/dL	0.25	2.1–2.6 mmol/L
Cholesterol LDL cholesterol HDL cholesterol Total cholesterol	<200 mg/dL 60–130 mg/dL >50 mg/dL	0.0259 0.0259 0.0259	<5.2 mmol/L 1.6–3.4 mmol/L >1.3 mmol/L
Collagen type I C-telopeptide (CTX) Premenarchal 18–29 y 30–39 y 40–49 y ≥50 y	pg/mL Not established 64–640 60–650 40–465 Not established	1.0	ng/L Not established 64–640 60–650 40–465 Not established
Cortisol 8:00 A.M. 4:00 P.M. 10:00 P.M.	5–25 µg/dL 3–12 µg/dL <50% of A.M. value	27.6 27.6 27.6	140–690 nmol/L 80–330 nmol/L <50% of A.M. value
DHEA-S, dehydroepiandrosterone sulfate	80–350 µg/dL	0.0027	2.2–9.5 µmol/L
11-Deoxycortisol	0.05–0.25 µg/dL	28.86	1.5–7.3 nmol/L
11-Deoxycorticosterone	2–10 ng/dL	30.3	60–300 pmol/L
Estradiol	20–400 pg/mL	3.67	70–1,500 pmol/L
Estrone	30–200 pg/mL	3.7	110–740 pmol/L
FSH, reproductive years	5–20 mIU/mL	1.0	5–20 IU/L
Glucose, fasting	70–110 mg/dL	0.0556	4.0–6.0 mmol/L
Growth hormone	<10 ng/mL	1.0	<10 µg/L
17-Hydroxyprogesterone	100–300 ng/dL	0.03	3–9 nmol/L
Inhibin B Premenopausal Follicular Luteal Postmenopausal	pg/mL <139 <92 pg/mL <10	1.0	ng/L <139 <92 pg/mL <10
Insulin, fasting	5–20 µU/mL	7.175	35–145 pmol/L
Insulin-like growth factor-I	0.3–2.2 U/mL	1,000	300–2,200 U/L
LH, reproductive years	5–20 mIU/mL	1.0	5–20 IU/L

Substance	Conventional Units	Conversion Factor	SI Units
Procollagen type I intact N-terminal propeptide Premenopausal Postmenopausal	µg/L 19–83 16–96	0.0286	nmol/L 0.54–2.4 0.45–2.7
Progesterone Follicular phase Secretory phase	<3 ng/mL 5–30 ng/mL	3.18 3.18	<9.5 nmol/L 16–95 nmol/L
Prolactin	1–20 ng/mL	44.4	44.4–888 pmol/L
Testosterone, total	20–80 ng/dL	0.0347	0.7–2.8 nmol/L
Testosterone, free	100–200 pg/dL	0.0347	35–700 pmol/L
TSH, thyroid-stimulating hormone	0.4–4.5 µU/mL	1.0	0.4–4.5 mU/L
Thyroxine, free T <sub>4</sub>	0.8–2.3 ng/dL	1.29	10–30 nmol/L
Triglycerides	<150 mg/dL	0.0113	<1.7 mmol/L
Triiodothyronine, T <sub>3</sub> , total	80–220 ng/dL	0.0154	1.2–3.4 nmol/L
Triiodothyronine, T <sub>3</sub> , free	0.13–0.55 ng/dL	15.4	2.0–8.5 pmol/L
Triiodothyronine, reverse	8–35 ng/dL	15.4	120–540 pmol/L
Vitamin D, 25 hydroxy	ng/mL ≥30 <sup>a</sup> ≥20 <sup>b</sup>	2.496	nmol/L ≥75 ≥50

<sup>a</sup>Endocrine Society threshold for normal.

<sup>b</sup>Institute of Medicine (IOM) threshold for normal.
